The effect of pneumococcal vaccination on respiratory tract antibody concentrations is not clearly defined. Most studies assessing the immune response to the pneumococcal vaccine focus on serum and salivary antibody titers. Only a few studies have tried to analyze the pulmonary response after vaccination. One study found no difference in the opsonic function of BAL IgG against pneumococcus 1 and 6 months after systemic immunization with the conjugate pneumococcal vaccine.[190] In another study the effect of intramuscular administration of the 23-valent vaccine was compared with inhalation of the same preparation.[191] Bronchoalveolar lavage was performed on month after vaccination. Intramuscular administration resulted in significant increases in serum and BAL pneumococcal-specific IgG titers. Pneumococcal-specific IgA1 titers increased in serum, but not in BAL. This observation supports the concept that mucosal exposure is needed to generate local IgA responses. No change was seen in any serum or BAL measurement in subjects who inhaled the vaccine. Similarly, nasal inoculation with two live pneumococcus serotypes induced local pneumococcal specific IgG and IgA in nasal washes and bronchoalveolar lavage, but did not affect serum anti-pneumococcal titers.[192] This contrasts with two other studies that found a mild systemic IgG response to inhaled pneumococcal vaccine.[193,194] Lung-specific measurements were not assessed in these latter two studies. Thus, studies to date suggest that while mucosal vaccination against pneumococcus may offer advantages in preventing pneumonia, effective immunization against pneumococcus still requires systemic (intramuscular) immunization, especially with regard to preventing severe invasive disease.

■ Vaccination Against Influenza

Vaccination against influenza is generally effective in preventing morbidity and mortality.[195,196] Effectiveness varies from year to year due to the constantly changing genetic makeup of circulating viruses. For example, a recent analysis from the CDC showed that from years 2004 to 2020 influenza vaccine effectiveness ranged from 10% in the 2004–2005 season to 60% during the 2011–2012 season. Each year world experts meet to determine the upcoming vaccine composition.[176] There are two currently available routes for influenza vaccination in humans. The most common are intramuscularly administered trivalent (made up of three strains) or quadrivalent (made up of four strains) killed (inactivated) vaccines. Depending on the manufacturer, vaccines may contain either whole killed viruses or further purified viruses to isolate the immunodominant neuraminidase and haemagglutinin antigens, which give rise to the classic “H” and “N” nomenclature used for influenza virus. A second formulation consists of a live attenuated influenza vaccine and is given intranasally. Because it is a live vaccine it is not used in individuals with underdeveloped or impaired immunity. Thus candidates for the nasal vaccine are individuals between the age of 2 and 49 with no existing potentially immunosuppressive condition, including pregnancy.[176]

Because there are systemic and mucosal vaccination options for influenza, more is known about the pulmonary immune response to these vaccines.[197] In one study, comparison of inactivated intramuscular and live intranasal influenza vaccines in young children undergoing primary immunization demonstrated that the intranasal preparation induced longer-lasting protective antibody concentrations.[198] Nasal secretory IgA developed almost exclusively in nasally vaccinated individuals, whereas nasal IgG was detected in both nasal and intramuscular vaccine recipients. In general, studies show that influenza intramuscular vaccinations result in a strong IgG response but minimal mucosal influenza-specific IgA. In contrast, the nasal live attenuated vaccine gives a stronger mucosal IgA response. Furthermore, because it results in low-level infection, the intranasal formulation also induces a specific cellular (cytotoxic T cell) response.[199] Studies that have directly compared the clinical efficacy of the two vaccine strategies have generally found that intramuscular injection of inactivated influenza virus is generally slightly superior to use of the live attenuated intranasal virus in adults,[200,201] whereas the intranasal approach may be more effective in children.[202]

Newer vaccine strategies are being developed to enhance population vaccination strategies and improve immunogenicity in individuals with poor antibody responses. Studies comparing high-dose versus standard-dose influenza vaccination in subjects over 65, a population known to have a poorer vaccine response, demonstrate that high-dose vaccination is more effective.[203] Novel adjuvants are also being developed to augment the immune response to influenza vaccines.[204] Another innovative approach is to target more conserved influenza antigens, which would obviate the need for yearly vaccination.[205,206] However, many conserved epitopes are poorly immunogenic, indicating that novel delivery methods will be necessary to elicit broad immune responses. Nanoparticles are being studied in vaccine formulations because of their ability to enhance antigen stability and immunogenicity and provide a mechanism for targeted delivery and slow release.[207] Newer animal models are exploring the use of adenovirus vectors to immunize with conserved influenza vaccines.[208] Thus, recent advances in vaccine strategies offer hope that newer influenza vaccines will generate broader antigenic coverage, induce both humoral and cellular immunity, and provide longer-lasting and better protection against this worldwide pathogen.

CONCLUSION

The humoral immune response is essential for host defense against pathogens. After exposure to infectious microbes, antibody responses in the respiratory tract can occur either quickly through activation of resident memory B cells if there has been prior pathogen exposure, or more slowly through the induction of both systemic and local mucosal immunity if the host is naïve to the organism. The resulting production of antigen-specific IgG and IgA acts to help clear the invading pathogen and reduce subsequent colonization of respiratory epithelium. The type and concentration of antibody produced is dependent on the site of exposure. Upper airway exposure results in primarily an IgA response. Organisms that reach the lung after passing through the upper airway induce a more systemic response, including increased production of pathogen-specific IgG. The importance of an effective pulmonary antibody response is highlighted by the significant morbidity associated with diseases characterized by deficient or defective antibody production. Increasing evidence is also pointing toward a key role of autoantibodies in many common lung diseases. Finally, vaccination against respiratory pathogens is dependent on an intact humoral immune system. Systemic vaccination against respiratory pathogens, while effective in generating systemic IgG responses and some mucosal IgA responses, may be less effective than vaccination through mucosal surfaces, which induce a brisk IgA and IgG response both locally and systemically depending on the site of vaccine deposition. Future studies should provide further insight on the pulmonary humoral host response to microbial challenge and optimal vaccine regimens to minimize the burden of respiratory disease caused by these organisms.

CHAPTER 23

T Cell Responses in the Lung

Lauren Cohn

INTRODUCTION

The lung is a major site of exposure to the outside world in air-breathing species. Lung immunity has developed to recognize pathogens and activate appropriate responses, to temper inflammation in response to nonpathogenic exposures, and to turn off immune responses when danger signals have been shut down. T lymphocytes play a major role in lung immunity predominantly as CD4+ and CD8+ T cells involved in adaptive immunity. A number of smaller subsets of T lymphocytes also play critical roles in early immune responses to pathogens and to stimulate adaptive immune responses. Long-lived memory CD4+ and CD8+ T cells are crucial for host protection from pathogens, but they also may drive chronic disease states such as asthma. This chapter reviews the basic biology of T lymphocytes and their relevance in the lung in health and disease.

T LYMPHOCYTE SUBSETS

Lymphocytes make up approximately 10% of leukocytes in the blood and nearly 70% of leukocytes in the normal human lung.[1] In both sites, a majority of lymphocytes are T lymphocytes. Lymphocytes include T and B cells and are small, mononuclear cells with a characteristic large nucleus-to-cytoplasm ratio in the resting state. T lymphocytes have their origin in the thymus. T lymphocytes are essential for adaptive immune responses, the type of immunity that develops over a period of days to weeks and fine-tunes an immune response to limit a specific pathogen or insult. The majority of T lymphocytes express alpha-beta (α/β) T cell antigen receptors (TCRs) on the cell surface. The α/β TCR consists of two polypeptide chains with a variable region that binds to antigen, a constant region, and an anchor to the cell membrane. During development in the thymus, T cells undergo TCR gene rearrangement to generate a receptor that has an antigen-binding structure. Each mature T cell bears only this TCR with its unique specificity for antigen binding. Approximately 10^6 different TCRs develop and allows an individual to respond to an extraordinary range of antigens throughout life. After exposure to a new antigen, TCRs expressed on conventional CD4- and CD8-expressing T lymphocytes develop even finer antigen-binding capabilities through a process called affinity maturation.

There are also unconventional subsets of T lymphocytes that express T cell receptors with restricted diversity and include NKT and MAIT cells that express an α/β TCR, and gamma-delta (γ/δ) TCR-expressing cells. These populations of T lymphocytes are typically fewer in number and more prominent at sites of pathogen exposure, such as the mucosal surfaces. They express preformed receptors that bind to common pathogen components. This preset ability to bind and react to pathogens allows them to respond quickly, leading to early release of cytokines. NKT, MAIT, and γ/δ T cells are part of the early immune response to pathogens and other insults and provide signals to initiate and direct CD4 and CD8 T cell activation in the adaptive immune response.

T lymphocytes that express α/β TCR most commonly also express a co-receptor CD4 or CD8. CD4-expressing T cells are called T helper (Th) cells because of their ability, through production of cytokines, to instruct and activate other cells. Another subset, CD4 regulatory T cells (Treg), downregulate immune responses. CD8-expressing T cells, traditionally called cytotoxic T cells (Tc), release preformed effector molecules that destroy infected cells. They also produce cytokines that aid in local immunity. TCRs on CD4+ T cells recognize peptide antigens that bind to domains on MHC class II molecules that are present on the surface of antigen-presenting cells (APCs). CD8+ T cells recognize endogenously derived antigens bound to MHC class I molecules. MHC class I molecules are present on the surface of all nucleated cells, whereas MHC class II molecules are only present on APCs, including dendritic cells, B cells, and macrophages. Exogenous protein antigens, such as extracellular pathogens and environmental substances, are taken up by APCs and processed into peptides in endocytic vesicles, which are presented on the cell surface bound to MHC II molecules. Endogenous antigens, such as those of intracellular pathogens, including viruses, are processed and presented by class I MHC molecules.

CD4+ T CELLS

Below are selected aspects of CD4+ T cell activation and differentiation, as well as elements of CD4+ effector/memory and regulatory cells.

CD4+ T Cell Activation

Mature, naïve CD4+ T cells are released from the thymus into the circulation and enter the lymph node through specialized blood vessels, the high endothelial venules (HEVs). Expression of L-selectin (CD62L) on the naïve CD4 T cell along with chemokine signals produced by stromal cells within lymphoid tissues permits attachment and transit through the HEVs into the lymph node.[2,3] In the lung, this occurs in the lymph nodes that drain the trachea, bronchi, and lung parenchyma.

Antigens or pathogens that enter the lung are taken up by APCs in the airways and alveoli. DC are the major APC of the mucosal surfaces. DC in the airway walls and alveoli form a dense network just beneath the epithelium with processes that extend to the air-spaces, designed to catch foreign antigens.[4] Macrophages in the airways and lungs also engulf large particles and pathogens through phagocytosis, but they are typically poor stimulators of adaptive immune responses, and likely eliminate antigens or induce regulatory responses, rather than activate immunity. After antigen uptake, APCs break down antigens into peptide fragments in endocytic vesicles, where the peptides are loaded onto class II MHC proteins and transported to the cell surface. Concurrent with antigen presentation, the APC increases expression of co-stimulatory molecules and migrates to the lung-draining lymph nodes.

In the T cell area of the lymph node, naïve CD4+ T cells move past antigen-expressing APCs, permitting the interaction of TCR and MHC class II-peptide. When the TCR on a CD4+ T cell interacts with its specific antigen on an APC, it ceases to migrate further. T cell activation is initiated upon (1) TCR recognition of MHC class II peptide and (2) co-stimulatory signaling from the APC (Fig. 23-1). The principal co-stimulatory molecules expressed on the surface of APCs are CD80 (B7-1) and CD86 (B7-2), which both interact with

AL GRAWANY

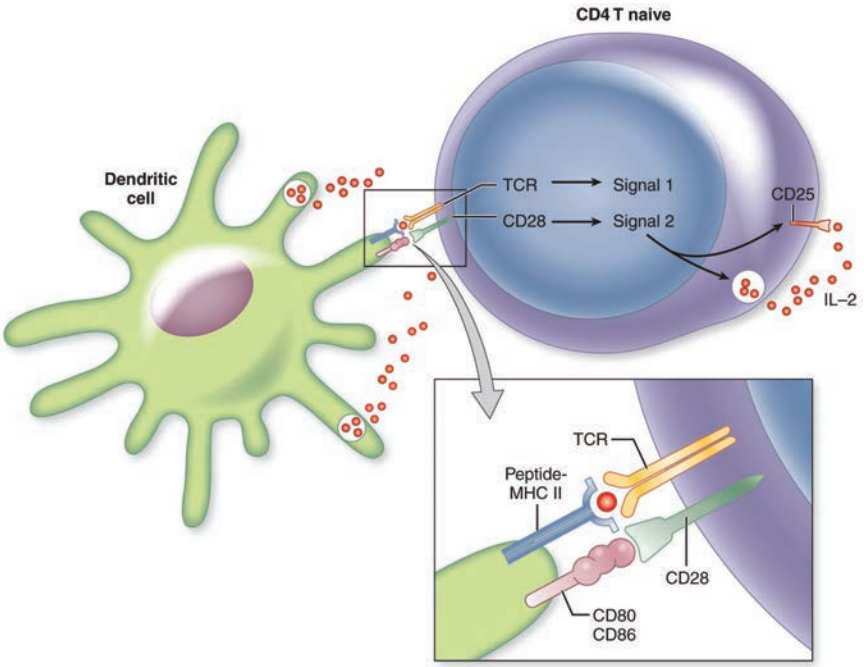

Figure 23-1 Two-signal mechanism of CD4 T cell activation. An antigen-presenting cell (APC) takes up a protein antigen and processes it into peptide fragments that are presented by class II major histocompatibility complex (MHC) molecules. A naïve CD4 T cell and APC interact with **Signal 1**, which is engagement of the T cell antigen receptor (TCR) and class II MHC-peptide complex, and **Signal 2**, the interaction of CD28 on the T cell with CD80 or CD86 on the APC, termed co-stimulation. These signals stimulate interleukin-2 (IL-2) production and IL-2 receptor (IL-2R) expression, and they induce CD4 T cell proliferation.

CD28 on the T cell.[5] If both signal 1 and signal 2 are received, the T cell goes into G1 phase of the cell cycle, begins to produce interleukin-2 (IL-2), and undergoes clonal expansion. This gives rise to a population of effector cells with the identical TCR specificity to the parental cell.

■ CD4+ Helper T Cell Differentiation

The primary immune response and molecular mechanisms of CD4+ Th cell differentiation are considered below.

Primary Immune Response

Antigen-activated CD4+ T cells differentiate into effector cells of different subsets defined by the cytokines they produce and expression of lineage-defining molecules (Table 23-1).[6] *T helper type 1* (Th1) cells are a subset of CD4+ T cells that secrete the macrophage activating factor interferon gamma (IFN-γ), as well as lymphotoxin (LT or TNF-β), and express the molecule t-bet. Th1 cells stimulate strong cell-mediated immune responses, particularly against intracellular pathogens.

TABLE 23-1 T Lymphocyte Subsets, Signals and Functions

		Signals to Activate/Differentiate			
T Lymphocyte		Cytokine	Transcription Factor	Cytokines and Mediators Produced	Major Functions
CD4 Activated by peptide- MHC class II	Th1	IFN-γ, IL-12	T-bet	IFN-γ, lymphotoxin	Antiviral and -mycobacterial effects, activation of macrophages to kill intracellular pathogens
	Th2	IL-4	GATA-3	IL-4, IL-5, IL-13	Antiparasitic responses Stimulation of IgE and other antibody production, increased mucus production, promotion of eosinophilia
	Th17	IL-6, TGF-β1, IL-1β (human)	RORγt	IL-17A, IL-17F, IL-22	Antibacterial and -fungal effects, recruitment and activation of PMNs
	Treg	TGF-β1, IL-10	FoxP3	TGF-β1, IL-10	Suppression of T cell activation, inhibition of APC function
	Tfh	IL-6	BCL6	IL-21, IL-4 (and crucial signaling molecules incl. CD40-ligand)	Promote antibody production by B cells in germinal center
CD8		Peptide-MHC class I		IFN-γ, TNF-α Granzyme, perforin	Cytotoxicity of cells infected with virus or bacteria
iNKT		Glycolipids		Extensive range of pre-formed cytokines that are rapidly released	Shaping adaptive immunity against pathogens
MAIT		Vitamin B metabolites		IFN-γ, TNF-α, IL-17, granzyme	Antimicrobial responses
γ/δ		Mycobacterial lipids, heat-shock proteins, lipid antigens		Extensive range of pre-formed cytokines that are rapidly released	Antimicrobial responses, immunosurveillance

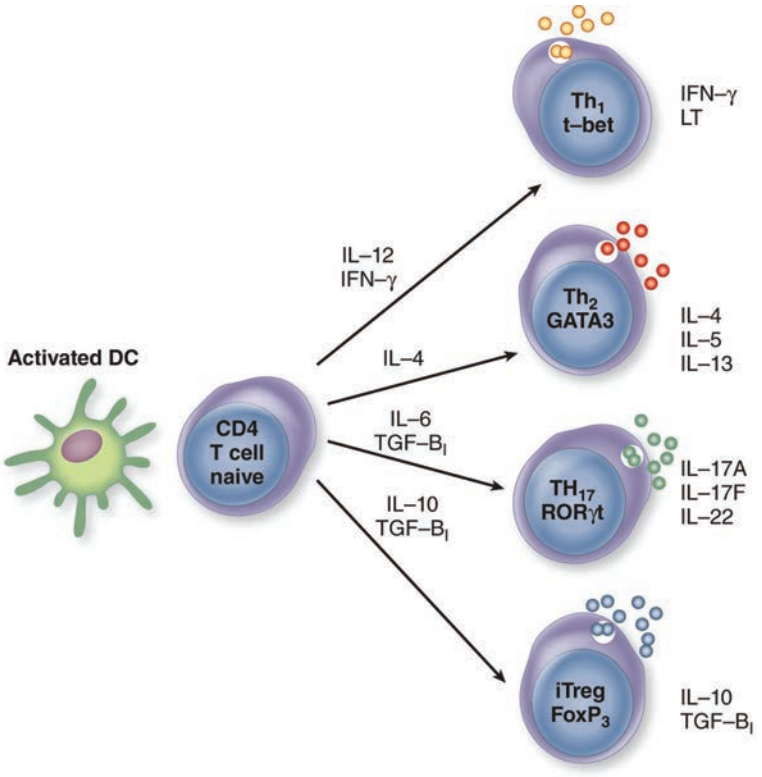

Figure 23-2 Generation of T helper types 1, 2, and 17 (Th1, Th2, Th17) and regulatory T (Treg) cells from a naïve CD4+ T cell. A naïve CD4+ T cell secretes very low levels of cytokines. Differentiation along the Th1, Th2, Th17, and Treg pathways is triggered when antigen is presented to the T cell receptor in the context of the major histocompatibility complex (MHC) by the appropriate antigen-presenting cell (APC) and a second signal imparted by ligation of co-stimulatory molecules CD80/CD86 and CD28. Dendritic cells (DCs) represent the key APCs for naïve T cells. Cytokines produced in innate immune responses activate DC to produce cytokines that direct differentiation of Th subsets leading to induction of critical lineage-determining molecules, T-bet for Th1 cells, GATA-3 for Th2 cells, RORγt for Th17 cells, and FoxP3 for inducible (i)Treg. Naïve CD4 T cells can also differentiate into Tfh cells that promote B cell antibody production.

T helper type 2 (Th2) cells produce IL-4, IL-5, and IL-13 and express the transcription factor GATA-3. Th2 cells, through the production of IL-4 and IL-13, are potent activators of B cell antibody production, particularly immunoglobulin E (IgE). IL-5 secretion by Th2 cells is critical for eosinophil differentiation and maturation. Th2 cells are elicited in immune responses that require a strong humoral component and in antiparasitic responses.

T helper type 17 (Th17) cells produce IL-17A, IL-17F, and IL-22 and express the transcription factor RORγt. Th17 cells stimulate neutrophil mobilization and recruitment, promote release of antimicrobial peptides, and serve critical host defense functions at mucosal surfaces. IL-10, an anti-inflammatory cytokine, was originally defined as a Th2 cytokine, but it is now recognized that it can be synthesized by all Th cell subsets upon appropriate activation.[7]

Regulatory CD4+ T cells (Treg) produce IL-10 and/or TGF- β1 and express the transcription factor FoxP3.

CD4+T follicular helper cells (Tfh) provide help to B cells within the germinal centers of the secondary lymphoid tissues to facilitate antibody production. Tfh produce IL-21 and express the transcription factor BCL6.[8] An effective immune response to a pathogen commonly results in the induction of a balance of Th1, Th2, Th17, and Tfh cells to provide strong cellular and humoral immunity.

CD4+ Treg cells comprise subsets of cells generated in the thymus (natural Treg) or induced in the secondary lymphoid tissues (inducible Treg) that produce IL-10 and/or TGF-β1 and express the transcription factor FoxP3. They are often identified by their high expression of CD25 and Foxp3.[9] CD4+ Treg inhibit the development of Th1, Th2, and Th17 subsets through actions on APCs, naïve T, cells and effector T cells.[10] Treg exert their suppressive effects by secreting cytokines, including TGF-β1 and/or IL-10, by cell contact leading to cytotoxicity or metabolic disruption or by suppression of APCs.[11]

Molecular Mechanisms of CD4+ Th Differentiation

Differentiation of a naïve CD4+ T cell into Th1, Th2, Th17, or Treg requires the coordinate action of multiple molecular signals induced by stimulation of the TCR, co-stimulatory molecules, and cytokine receptors (Fig. 23-2). These actions lead to expression of lineage-determining molecules that promote T cell differentiation, simultaneous inhibition of the opposing Th cell phenotypes, T cell proliferation, epigenetic remodeling to modify the chromatin structure and cytosine methylation, and expression of key transcription factors.

T-bet is one of the lineage-determining molecules required for Th1 differentiation. It belongs to the T-box family of transcription factors that regulate multiple developmental processes. T-bet is upregulated in Th1 cells, through effects of IL-12 and activation of STAT4, and IFN-γ and activation of STAT1.[12] Induced expression of t-bet in vitro and in vivo leads to IFN-γ production;[13] thus t-bet drives Th1 development. T-bet also promotes Th1 induction through negative regulation of GATA-3.[14]

The transcription factor GATA-3 is an essential regulator of Th2 differentiation.[15,16] Whereas GATA-3 is expressed at low levels in naïve CD4+ T cells,[15] it is markedly upregulated in cells differentiating along the Th2 lineage and is downregulated in cells differentiating along the Th1 pathway.[15] The differentiation of a naïve CD4+ T cell along the Th1 or Th2 pathway is accompanied by extensive reorganization of chromatin structure around the IFN-γ or IL-4/IL-5/IL-13 locus, respectively.[17] GATA-3 appears to be the critical downstream regulator of chromatin remodeling around the IL-4 locus.

The orphan nuclear receptor RORγt induces differentiation of naïve CD4+ T cells into Th17 cells.[18] RORγt is required for the expression of IL-17 and the related gene IL-17F in response to IL-6 and TGF-β1 in mice or IL-1β in humans.

Cytokines, by stimulating production of critical lineage-determining molecules, are the primary factors that affect CD4+ Th generation.[19,20] Cytokines produced in innate immune responses modulate how the adaptive immune response will develop. IFN-γ and IL-12 promote Th1 cell development. IL-4 and IL-13 drive Th2 cell generation. IL-10 enhances Th2 cell development by inhibiting Th1 cell induction. IL-6, IL-1β, IL-23, and TGF-β1 promote Th17 development.

Other factors that influence CD4+ T cell differentiation into Th subsets affect the quality of the signal through the TCR. The dose and structure of the antigen affect the APC-TCR interaction and have been shown to drive Th differentiation along distinct pathways.[21] If peptide-MHC class II complex on the APC has a high-affinity interaction with the TCR, then a Th1-predominant response results, whereas a weaker-affinity interaction leads to a Th2-like response. Very low doses of soluble protein antigen tend to stimulate Th2-predominant responses, and at higher antigen doses, Th1 responses, suggesting that the antigen dose affects the APC–T cell interaction. This may have important implications in allergy, since it has been estimated that exposure to common allergens is so small that it does not exceed 1 μg per year. Another line of investigation suggests that high-affinity interactions lead to preferential generation of Th2 cells.[22] Other studies show that the fate of Th differentiation is an effect of both antigen dose and TCR-MHC class II binding.[23] Ultimately, the integration of signals—including TCR binding, costimulatory signals, and cytokines in the environment—activates transcriptional networks that lead to expansion and differentiation of a naïve CD4 T cell.

■ Effector/Memory CD4 T /Cells

It takes 4 to 5 days of proliferation in the lymph node for a naïve CD4+ T cell to differentiate into an effector cell. Associated with differentiation is a change in expression of cell surface selectins, integrins, and chemoattractant receptors that permit exit from the lymph node and recruitment to sites of inflammation. With differentiation there is loss of expression of the lymph node homing receptor CD62L and gain of function of tissue homing receptors. Trafficking to different tissues is controlled by expression of a combination of selectins, chemokine receptors, and integrins on the lymphocyte surface, akin to area codes, and ensures that T cells accumulate where they are needed, at sites of inflammation.[24,25] Skin and gut effector CD4+ T cells each have ligands that confer their localization to that tissue through binding to vascular endothelial cells (skin, cutaneous lymphocyte-associated antigen [CLA]; small intestine, integrin α4β7), but such a lung-specific surface marker has not been identified. Human lung effector CD4+ T cells are enriched for expression of CCR5, CCR6, chemokine (C-X-C motif) receptor 3 (CXCR3), and the integrins VLA1 (α1β1), CD103 (αEβ7), and VLA4 (α4β1).[26]

In addition to expression of receptors that respond to specific signals to direct them to the tissue, subsets of effector CD4+ Th cells express different panels of chemokine receptors so they can be recruited to perform necessary duties. In response to a specific injury or invading pathogen, mediators are released to recruit appropriate populations of CD4+ Th cells to manage the problem. Th1 cells typically express CCR5 and CXCR3, Th17 cells express CCR6, and Th2 cells express CCR4, CCR8, and the prostaglandin D2 chemoattractant receptor DP_2 (CRTH2) in humans.[26]

CD4+ effector Th cells arrive at an inflammatory site in the lung where they proliferate and produce cytokines. The major function of CD4+ T cells is to produce cytokines to recruit other inflammatory cells that modulate local host-protective responses. Following this robust immune response, most activated effector CD4+ T cells die, either by apoptosis or necrosis. A small population of CD4+ T cells persists as memory cells for the life of the host. CD4+ memory T cells, upon re-exposure to specific antigen, respond quicker with a stronger response of longer duration. Subsets of CD4+ memory T cells have been identified that have specific tissue localization and circulation patterns guided by cell surface markers. Together these memory T cell subsets function to provide long-lasting immunity against pathogens in the peripheral tissues and blood, as well as a mechanism to replace dying cells.[27–29]

■ CD4+ Regulatory T Cells

CD4+ regulatory T cells (Treg) cells comprise subsets of cells generated in the thymus (natural Treg) or induced in the secondary lymphoid tissues (inducible Treg) that produce IL-10 and/or TGFβ1 and exhibit high expression of CD25 and the transcription factor FoxP3.[30] They make up 5% to 10% of the peripheral CD4+ T cell population. Cytokines produced by CD4+ Treg inhibit the development of Th1, Th2, and Th17 subsets through actions on APCs and naïve and effector T cells.[10] CD4+ Treg are critical for suppressing primary immune responses to self, as indicated by mice and humans deficient in a functional FoxP3 protein who develop autoimmune diseases.[31,32] Tregs exhibit additional diverse mechanisms to achieve immune suppression in different inflammatory milieu.[33]

CD8+ T CELLS

Pathogens that enter the lung activate tissue-resident DCs and migrate to lymph nodes where they activate naïve CD8+ T cells. CD8+ T cells are activated to differentiate into effector cells through interactions with DCs and provision of two required activation signals, antigenic peptide presented by MHC class I molecules and co-stimulatory signals. Viruses and intracellular bacteria are classic activators of CD8+ T cells. Cytokines secreted by dendritic cells drive proliferation and differentiation of CD8+ T cells to acquire the ability to become effector CD8+ T cells that most commonly secrete IFN-γ and TNF-α and have cytotoxic capabilities through production of granzyme B and perforin.[34] Effector CD8+ T cells may also differentiate into subsets of Tc2 cells that secrete IL-4, IL-5, and IL-13 and Tc17 cells that produce IL-17.[35] After pathogen clearance, the majority of antigen-specific CD8+ T cells die by apoptosis and about 10% develop into CD8+ memory cells. Similar to CD4+ T cells, multiple signals through the TCR, co-stimulatory molecules, and the local inflammatory milieu including metabolic factors coordinate the fate of CD8+ T cells.[36,37]

CD4+ AND CD8+ MEMORY T LYMPHOCYTES

Memory CD4+ and CD8+ lymphocytes allow the host to respond more quickly and effectively to reencounter with pathogens. Memory cells are more abundant than their naïve counterparts in order to provide wide-ranging host surveillance, and they populate peripheral tissues where they are poised to immediately proliferate and execute their functions. To integrate the need for tissue surveillance and self-renewal, there are subsets of memory cells with distinct functions and circulation patterns based on expression of different combinations of surface homing molecules. Tissue-resident memory T cells (T_{RM}) are responsible for barrier protection, exhibit the activation marker CD69, and can be activated locally in the tissue, without trafficking to the lymph node, to provide expedient control of infection.[38] T_{RM} remain in the tissue compartment in which they were initially activated, and do not recirculate. Most CD4+ and CD8+ T cells in nonlymphoid tissues, such as the skin and mucosal tissues, including the lung, are T_{RM} lymphocytes. In the lung, a majority of CD4+ and CD8+ T lymph are T_{RM}. A subset of lung CD8+ T_{RM}, and a smaller proportion of CD4+ T_{RM}, express the integrin CD103 (αEβ7) that binds to E-cadherin on epithelial cells, thus positioning and retaining T_{RM} in the lung and airways.[29] TRM are affected by O_2, pH, and blood supply and serve other surveillance functions including the ability to sense changes in metabolism, inflammation, cancer, and wound repair.[28]

Two subsets of circulating memory cells participate in protective immune responses by acting as reinforcements to T_{RM} or protecting sites that were not challenged in the initial infection. Effector memory cells (T_{EM}) circulate in the blood and in nonlymphoid tissues, such as liver and lung, and unlike naïve T cells, they do not enter uninflamed lymph nodes. They arrive within hours to days at a site of infection to help restrict pathogen replication and spread.[39] Central memory T cells (T_{CM}) recirculate through secondary lymphoid organs, lymphatics, and blood.[38] T_{CM} have high proliferative capacity and produce IL-2, rather than effector cytokines, which allows them to expand and replenish other memory cell compartments. More detailed phenotyping of memory cell populations suggests there are additional T lymphocyte memory cell subpopulations and heterogeneity within the populations described above, and this highlights ongoing research to understand the complexities of T cell memory in immunosurveillance.[40]

"UNCONVENTIONAL" T LYMPHOCYTE POPULATIONS

iNKT, MAIT, and g/d T cells are subsets of T lymphocytes that accumulate in the lung and other sites and have less diverse TCRs compared with traditional α/β CD4+ and CD8+ T cells. They also respond to different antigens. Their numbers in tissues are low, but due to their reduced diversity, more of them will respond to a single antigen. As described below, some "unconventional" T lymphocyte populations may be activated by cytokines through an antigen-independent process. These lymphocytes are already primed to respond; therefore, they can be activated quickly. These three T cell populations participate in the early immune response and may expand and adapt to exposures. Thus, these T lymphocytes subsets bridge innate and adaptive immunity and have been termed "adaptate."[41] There are two small populations of α/β T cells, iNKT cells and mucosal-associated invariant T (MAIT) cells that have semi-invariant α-chains. Thus, they have undergone somatic mutation in the thymus to generate a TCR, but they have limited diversity due to fewer possible TCR combinations. Both iNKT and MAIT cells are found in high frequencies in mucosal tissues. γ/δ T cells are the better-known "unconventional" T cell population.

Natural Killer T Lymphocytes

Type I or invariant (i) NKT cells are a small subpopulation of α/β T cells that express a narrow repertoire of TCRs due to invariant expression of the TCR variable (V) α chain and limited TCR Vβ chains. In humans Vα24-Jα18 pairs almost exclusively with Vb11, whereas in mice Vα14-Jα18 pairs with a limited number of Vβ chains. iNKT cells respond to glycolipids presented on the MHC-like molecule CD-1d, which is a member of a family of nonpolymorphic proteins that bind to lipids, rather than peptide antigens. In the lung, CD-1d is expressed on populations of DCs and alveolar macrophages.[42]

iNKT cells leave the thymus upon maturation and are already antigen-experienced when they migrate into tissues. Mirroring CD4+ T cell subsets, iNKT1 secrete IFN-γ, iNKT2 secrete IL-4, and iNKT17 secrete IL-17. Each iNK T cell subset has distinct combinations of surface receptors including chemokine receptors and integrins that direct their localization to different tissue sites.[42] iNKT cells have important functions in various lymphoid and nonlymphoid tissues, but they are best characterized in lung, liver, adipose, and intestine. In the BAL of normal human subjects, iNKT cells constituted less than 1% of the lymphocyte population.[43] In mice, iNKT cells constituted 5% to 10% of the lung lymphocytes.[44] Murine studies show that iNKT cells are resident in the lung interstitium and, for the most part, do not recirculate to other organs.[45] iNKT cells reside in the lung microvasculature in the resting state and upon exposure to inhaled lipids, become activated, and extravasate into the lung parenchyma where they contribute to lung inflammation.

Upon activation by lipid-CD1d or by cytokines, iNKT cells rapidly elaborate cytokines to activate an immune response. In mice, iNKT cells contain disease in pulmonary infections with bacteria, parasites, viruses, and fungi by reducing pathogen burden and increasing inflammation, particularly neutrophilia.[42] Pathogens activate iNKT cells in tissues early in an immune response, and the elaboration of cytokines is important in shaping the appropriate adaptive immune response.

MAIT Cells

Mucosal-associated invariant T (MAIT) cells are another small subpopulation of α/β T lymphocytes that express TCRs with limited diversity. MAIT cells express a semi-invariant α/β chain, Vα7.2-Jα33, that pairs with a limited number of Vβ chains. MAIT cells are present in humans in the peripheral blood and in mucosal tissues and liver, and constitute about 4% of T lymphocytes in the lung in humans.[46] Signal 1 for MAIT cell activation is TCR interaction with APCs expressing the nonpolymorphic MHC I-like molecule MR-1 bound to vitamin B2 and B9 precursor metabolites. Only certain bacteria, fungi, and yeast synthesize these B vitamins; therefore a limited number of pathogens can activate MAIT cells.[46,47] MAIT cells can also be activated independent of the TCR by IL-12 and/or IL-18 in synergy with other cytokines.[46] Activation of MAIT cells leads to release of cytokines, including IFN-γ, TNF-α, and IL-17, as well as granule exocytosis leading to apoptosis and delivery of antimicrobial peptides.[48,49] MAIT cells have direct antimicrobicidal effects and stimulate antipathogen CD4+ and CD8+ adaptive immune responses through effects on DC activation.[46] In the lung, MAIT cells are enriched in infections, such as tuberculosis, where they were increased five-fold compared with the blood.[50] MAIT cells also provided protection in animal models of influenza A where they were triggered rapidly by the cytokines IL-18, IFN-a, and IL-12.[51] MAIT cells serve in mucosal tissues as intermediary cells that bridge innate and adaptive responses, and potentiate protective antimicrobial immunity.

Gamma/Delta T Cells

Gamma/delta (γ/δ) cells are a subset of T cells that have a TCR comprised of γ and δ chains. The γ/δ TCR is generated by VDJ recombination during thymic maturation, but unlike the α/β TCR, γ- and δ-chain recombination results in a less diverse repertoire of TCRs. γ/δ T cells are the first T lymphocytes released from the thymus during fetal life, and they migrate to and expand in epithelial and mucosal tissues, including lung, skin, intestine, and uterus.[52] There they are considered a first-line defense against pathogens. Most γ/δ T cells are activated in an MHC-independent manner by nonpeptide phosphorylated metabolites of microbes, markers of cellular stress like heat shock proteins, or lipid antigens presented on CD1 molecules.[53] γ/δ T cells have a broad range of functions including production of cytokines, particularly IFN-γ, IL-17, and TNF-α and production of chemokines, many of which are preformed and quickly produced, to recruit other inflammatory cells. γ/δ T cell are capable of cytolysis of infected or transformed cells in an MHC-unrestricted manner. This suggests that γ/δ T cells play a role in surveillance and protection from infection, and possibly a role in cancer immunosurveillance. Their narrow TCR diversity in a tissue compartment, and ability to respond quickly to stimulation, allows for rapid clonal activation without the need for expansion, highlighting their role as a bridge between innate and adaptive immune responses.

T LYMPHOCYTES IN THE LUNG

The distribution of lymphocytes in the normal lung and their role in infection and in a variety of disease states is considered below.

T Lymphocyte Distribution in the Lung

In the normal human lung, T lymphocytes are found in the airways and alveolar spaces, lung parenchyma, pulmonary intravascular spaces, and lymph nodes, and their numbers differ in each of these compartments. In adult humans, lymphocytes in the lung are not typically organized into lymphoid structures, such as bronchus-associated lymphoid tissue (BALT), whereas BALT is more common in healthy children, smokers, and those with chronic infections and inflammatory diseases, as well as normal animals such as rabbits and rats.[54,55] Lymphocytes are not randomly distributed in each lung compartment, but are organized at sites of pathogen entry.[56] T lymphocytes have a multidimensional organization in the lung, including close associations with dendritic, epithelial, and mast cells, but these structural interactions are not yet well defined.

Lymphocytes, including T and B cells, make up about 7% of leukocytes isolated from the nondiseased human lung. It has been estimated that $2–4 \times 10^8$ lymphocytes reside in the airways and alveolar spaces. Twenty-fold more are estimated to make up the pool of lymphocytes in the lung parenchyma in the normal human lung.[57,58]

Lymphocytes isolated from the lung parenchyma consist of large populations within the interstitium and the intravascular spaces.[59]

In the lung parenchyma, T lymphocytes are the predominant lymphocyte population, a majority of which are CD4+ T cells (T:B ratio 15:1, CD4:CD8 2:1).[60] Memory CD4+ T cells make up a majority of CD4+ T cells in the lung and at other mucosal sites. CD8+ memory cells make up half of the CD8+ T cell population in the lung. With age, the number of lymphocytes and the proportion of lymphocytes with a memory phenotype increase. In the BAL, CD4+ T cells constitute about 4% of leukocytes in young adults and 20% in older adults.[61–63] In lung parenchyma, memory CD4+ T cells constitute 65% of the CD4+ T cell population in young adults and almost 80% in older adults.[60] Thus, the proportion of antigen-experienced CD4+ T cells increases with age in the lung and likely reflects an individual's accumulated respiratory exposure over time.

■ T Lymphocytes in Lung Infection

T lymphocytes play critical roles in host defense against bacteria, viruses, and fungi that enter the host through the respiratory tract. This essential function of T lymphocytes is illustrated in HIV infection, in which individuals lack functional T cell subsets leading to susceptibility to pulmonary infection with bacteria, including *Staphylococcus aureus*, *Streptococcus pneumonia*, *Haemophilus influenzae*, and mycobacterial species, viruses such as influenza, and fungi such as *Pneumocystis jirovecii*, *Histoplasma capsulatum*, and *Cryptococcus neoformans*.[64]

The immunocompetent individual responds to pathogen invasion through activation of NKT, MAIT, and γ/δ T cells along with other first responders, including macrophages, neutrophils, and epithelial cells. These innate immune cells are rapidly activated to secrete cytokines and other mediators that help to contain the pathogen directly and indirectly by shaping the necessary adaptive immune response through stimulation of populations of CD4+ and CD8+ T cell subsets. In a primary response to a pathogen, antigen-specific CD4+ and CD8+ effector T cells begin to arrive from the secondary lymphoid organs in the lung within days after the initial infection.

In lung infection, the primary function of CD4+ T lymphocytes is to produce cytokines that ultimately lead to elimination of pathogens. CD8+ T cells produce cytokines and have the additional capacity to kill infected cells. A primary infection results in the development and recruitment of a range of pathogen-specific T cell subsets, including CD4+ Th1, Th2, and Th17 cells, and CD8+ T cells. Each subset serves a specific purpose in the complex antimicrobial immune response. Yet, in some infections, one subset is essential for antipathogen immunity. Th1 cells are absolutely required for elimination of a number of pathogens, and this reflects Th1 production of IFN-γ. IFN-γ is essential for immunity to respiratory infections because of its myriad antimicrobial functions including macrophage activation, stimulation of microbicidal effectors, and stimulation of antiviral enzymes.[65] Th1 cells are essential for host defense against all mycobacterial species, other intracellular pathogens such as *Chlamydia pneumonia* and *Francisella tularensis*, virus infections including influenza and RSV, gram-negative bacterial infections with *Klebsiella pneumoniae*, and fungal infections including *Coccidioides*, cryptococcosis, and *Histoplasma*.[66] Th2 cells are required for immunity to helminth parasites, and Th17 cells are essential to eliminate the gram-negative bacteria *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*, chlamydia, and *Mycoplasma pneumoniae* and for immunity to various fungal infections including *Candida*.

After a primary infection, pathogen-specific memory CD4+ and CD8+ T cells develop. Some are retained in the lung as T_{RM}, and the population is retained in the lung through the life of an individual. Animal studies show that maintenance of the memory CD4+ T cell population in the lung in the first year after primary infection requires recruitment of new cells from the circulating pool.[56,67] And it is likely that a dynamic process like this sustains a population of memory T cells in the lung long after infection.

The population of memory T_{RM} are retained in the lung by surface expression of tissue-specific homing molecules.[68,69] Animal studies show that in different species memory CD4+ and CD8+ T lymphocytes isolated from the lung returned to the lung when re-injected systemically into another animal. One such localization signal is CD103, which is expressed on antigen-specific T cells.[38,70] In both mice and humans, CD69 expression characterized CD4+ and CD8+ memory T cells that were retained in the lung, rather than those that recirculated.[56] Influenza-specific CD4+ and CD8+ T_{RM} were compartmentalized in bronchovascular bundles surrounding the airways.[56] Thus, CD4+ T_{RM} may be retained adjacent to the tight web of dendritic cells just below the epithelial surface, where they can be quickly activated by specific antigen.[71] Virus-specific memory CD8+ T cells were observed in or near capillaries in the lung in association with epithelial cells, and this process was chemokine-dependent.[67,72] This juxtaposition in the lung at sites of exposures ensures that CD4+ and CD8+ T_{RM} can be activated locally.[38,56] T_{RM} produce the type-1 cytokines IFN-γ and IL-2 upon activation,[60] thus safeguarding that both antimicrobial and proliferative cytokines are released at the site of pathogen entry. This ensures that T_{RM} in the lung are rapidly reactivated, undergo proliferation, and stimulate recruitment of an appropriate inflammatory response upon pathogen re-exposure.

■ T Lymphocytes in Lung Diseases

T lymphocytes serve essential functions in host defense as they respond to specific antigens and are retained in the lung as memory cells, but they may also drive chronic disease when immune responses are generated against nonpathogens such as allergens or self-antigens. The development of immunity against nonpathogenic aeroallergens in allergic asthma is an example of immune dysregulation. Long-lived memory T lymphocyte populations may drive chronic diseases. While asthma is the most extensively studied T lymphocyte–driven lung disease, many other chronic pulmonary diseases may be caused and/or perpetuated by T lymphocytes, including sarcoidosis, hypersensitivity pneumonitis, autoimmune lung diseases, idiopathic pulmonary fibrosis, pulmonary hypertension, and others. In lung cancer, T lymphocyte activation using checkpoint inhibitors can lead to tumor cell death and improved survival. T lymphocyte subsets and the factors that cause these diseases will be addressed in other chapters. Here, we will consider the many T cell subsets that have been implicated in asthma pathogenesis and persistence.

T Lymphocytes in Allergic Asthma

The roles of a variety of T lymphocytes in allergic asthma are discussed below.

CD4+ T Helper Type 2 Cells in Asthma In asthmatic patients, CD4+ T cells are the predominant lymphocyte population infiltrating the airways, and they express markers of activation. CD4+ T cells producing IL-4, IL-5, and IL-13 have been identified in bronchoalveolar lavage (BAL) and airway biopsies and are secreted in the airways of patients with mild or asymptomatic asthma.[73] GATA-3 expression was increased in airways of asthmatic patients compared with those in control subjects, indicating the presence of Th2 cells.[74] Inhaled allergen challenge in allergic asthmatic patients led to an increase in Th2 lymphocytes in the airways.[75] In asthmatic patients, airway hyperreactivity (AHR) and airway eosinophilia correlated with airway CD4+ T cells that produced IL-4 or IL-5 or expressed GATA-3.[74] In conjunction with known effects of IL-4, IL-5, and IL-13, these studies support the hypothesis that Th2 cells drive the characteristic inflammatory response that results in asthma.

Animal studies show that activation of CD4+ Th2 cells in the airways leads to pathophysiologic manifestations of asthma. Eosinophilic airway inflammation and AHR have both been shown to be dependent on CD4+ T cells.[76] Studies that employed adoptive transfer of CD4+ T cells from animals with antigen-induced AHR resulted in airway inflammation and hyperresponsiveness in recipient mice, indicating that CD4+ T cells can control many aspects of the disease. CD4+ Th2 cells induced airway eosinophilia, mucus hypersecretion, and AHR, whereas Th1 cells caused a neutrophil-predominant inflammatory response without any of these features of asthma.[76]

Gene association studies also support a role for Th2 cells in asthma. Strong linkages have been identified to flanking markers of the human cytokine gene cluster on chromosomes 5q31 and 16p12, which include genes for IL-4, IL-13, and IL-4Rα.[77] Variants in the IL-4 promoter region are associated with atopy, as are polymorphisms of IL-4Rα, a component of both the IL-4 and IL-13 receptors, and a variant IL-13R.[78] Thus, modifications of IL-4 and/or IL-13 or their signaling, increasing Th2 cell functions, are associated with atopy and asthma.

CD4+ T Helper Type-1 Cells in Asthma Th1 cells are also present in the airways of asthmatic patients. CD4+ Th1 cells may serve a protective or pathogenic function in asthma. IFN-γ was elevated in the airways of some severe asthmatics, and it was reduced in subsets of other asthmatics.[79,80] Some studies show that Th1 cell activation inhibits allergic airway inflammation, whereas other studies suggest that Th1 cells potentiate the inflammatory response in asthma due to the proinflammatory effects of Th1 cytokines.[76,81]

Human and animal studies suggest that enhancing Th1 cytokines in the lung before or early in the generation of a Th2 response may protect against the development of allergic asthma. IFN-γ-dominated immune responses to viral or mycobacterial infection in childhood are associated with a reduced incidence of asthma.[82] Attendance at day care and exposure to other siblings was protective against wheezing in childhood, which is hypothesized to be from beneficial exposures to respiratory infections. Also, mice immunized in the presence of a Th1-stimulating environment exhibited a reduction in antigen-induced eosinophilic airway inflammation and AHR.[83] Thus, reducing the generation of Th2 cells appears to decrease allergic inflammation. However it is also apparent that a high frequency of virally induced wheezing in early life is a strong predictor for the subsequent development of asthma in children,[84] thus suggesting that timing and nature of infections in early life may be crucial.

Th1 cells can also inhibit the effects of ongoing Th2 cell responses. Th1 cells, through the production of IFN-γ, have been shown to inhibit Th2 cell cytokine production and Th2 cell proliferation in vitro.[85] In mice the Th1 cytokine IFN-γ has inhibitory effects on Th2-induced airway eosinophilia and AHR. When administered before inhaled antigen challenge, IFN-γ reduced the number of CD4+ T cells in the respiratory tract or reduced Th2 cytokine secretion.[86] These effects may result from inhibition of Th2 cell recruitment by IFN-γ. Once Th2 cells are present in the respiratory tract, IFN-γ promotes the resolution of airway eosinophilia and suppresses Th2 cytokine production.[87] Th1 cells, through the production of IFN-γ, can inhibit airway eosinophilia, mucus production, and AHR without an increase in airway inflammation.[88] Although many studies support Th1 cells and IFN-γ as inhibitors of Th2-type responses, other studies show that Th1 cells enhance inflammation and do not ameliorate disease.[89] The proinflammatory effects of Th1 cells are supported by the association of viral respiratory infections, which tend to induce Th1 responses, and exacerbation of symptoms in asthmatic patients. Ultimately, the influence of Th1 cells on allergic airway inflammation may depend on the timing of Th1 relative to Th2 cell activation and the sub-phenotype of the asthmatic.

CD4+ T Helper Type 17 Cells in Asthma Th17 cells, IL-17A, and IL-17F are increased in the airways, sputum, and blood of subjects with asthma.[90] Given the heterogeneity of asthmatic airway inflammation and the effects of IL-17A and IL-17F on neutrophil recruitment, it was hypothesized that Th17 cells would be pathogenic in neutrophilic, non-atopic asthma. Yet, there was a positive association of IL-17 and IL-5, and IL-17 with atopic, but not non-atopic, asthma.[91] As expected, IL-17A levels were associated with sputum neutrophils and not eosinophils,[92] suggesting that Th17 cells may drive disease in a subset of neutrophilic asthmatics.[93]

Studies to determine the function of CD4+ Th17 cells have not established a definitive role of Th17 and IL-17A in animal models of asthma. A number of laboratories have shown that Th17 cells, IL-17A, and IL-17 receptors are critical for optimal Th2 cell function, AHR, and eosinophilic inflammation. Furthermore, IL-17A was a major determinant in the development of AHR in mice with susceptibility compared to mice with resistance to develop AHR.[94] Yet, other investigators showed neutralization of IL-17 leads to worse disease.[32,95] The complex interplay of Th17 and Th2 cells is highlighted by studies showing that IL-13 inhibits IL-17A production and IL-17A production inhibits IL-25 that drives Th2 function. These studies suggest that disease pathogenesis in asthma may result from a disruption in a critical balance of cytokines that includes IL-17.

Regulatory T Cells in Asthma Foxp3+ Treg likely determine early sensitization to allergen, as suggested by studies of the rare **i**mmune dysregulation, **p**olyendocrinopathy, **e**nteropathy, **X**-linked syndrome (IPEX), which is caused by mutations in the *Foxp3* gene on the X chromosome. This results in markedly reduced or absent Foxp3+ Treg cells. Young boys with this condition suffer from both severe autoimmune and allergic symptoms.[31] T cells from these patients show skewing toward a Th2 phenotype. Mice with a mutation in the Foxp3 gene also demonstrate intense multiorgan inflammation, including allergic airway disease, high levels of IgE, eosinophilia, and dysregulated Th1 and Th2 cytokine responses, but they do not exhibit Th2 skewing, as observed in humans with IPEX.[96] FoxP3+ Treg also exert immunosuppressive actions on cells involved in asthma and allergy, including limiting mast cell activation by limiting IgE signaling through Fcε receptor 1 and suppressing ILC2 cells.[97]

Studies to assess the numbers of CD4+CD25+ T cells in the peripheral blood of healthy, compared to allergic, subjects have not consistently shown differences.[10,98] However, the methodologies used to detect Treg improved over time, and newer data show impaired CD4+CD25^{high} Foxp3 Treg in allergic disease. In asthmatic children there were reduced numbers of CD4+CD25^{high} T cells in BAL, but not blood, compared to control children with chronic cough.[99] A lower level of Foxp3 mRNA was reported in asthmatic children. CD4+CD25^{high} T cells in the airways of the asthmatic children correlated with clinical parameters such as lung function and were restored following corticosteroid treatment. A similar increase in Foxp3 mRNA was reported in the peripheral blood of adult asthma patients following inhaled corticosteroid treatment.[100] Foxp3-expressing Tregs are also important negative regulators of asthma and allergic disease in animal models. Treg expressing either IL-10, TGF-β1, or both were required to limit airway inflammation in numerous models of tolerance induction.[101–104] Overall, it appears that impaired Treg responses may contribute to the development of asthma and allergic diseases.

CD8+ T Cells in Asthma In atopic asthmatics there were increased CD8+ T cells in airway biopsies when compared to biopsies in non-asthmatic, atopic, and normal subjects.[105] Furthermore, the number of CD8 T cells in airway biopsies of atopic asthmatics was associated with a decline in FEV1.[106] During asthma exacerbations and in death from status asthmaticus, there were increased CD8+ T cells in the respiratory tract.[107] These observations suggest that CD8+ T cells are detrimental in asthma. Animal studies both support these observations and show that CD8+ T cells inhibit allergic airway disease through the production of IFN-γ and induction of IL-12 production. Most likely, CD8+ T cells have varying effects in different individuals and under different circumstances.

CD8+ T cells recognize endogenous antigens, like viral peptides, rather than inhaled allergens. Asthma exacerbations are most commonly caused by viral respiratory infections and, in response, virus-specific CD8 T cells are recruited and retained in the lung. Tissue-resident CD8+ T memory cells are present near the airways and poised to respond to reinfection, and the numbers of CD8+ T cells rise in asthmatic lungs after infection. CD8+ T cells, like CD4+ T cells, can be polarized into subsets. Cytotoxic type 1 (Tc1) T cells are activated in viral infections and generally produce IFN-γ and lymphotoxin. These are classic CD8+ T cells. Smaller subsets of CD8+ T cells can make other panels of cytokines. For example, when activated in the presence of IL-4, CD8+ T cytotoxic type 2 (Tc2) cells can be induced to produce IL-4, IL-5, and IL-13. Animal studies show that Tc2 cells retain their cytotoxic function, stimulate recruitment of eosinophils, provide B cell help for IgE production, and promote airway hyperresponsiveness.[107] It has been theorized that some respiratory infections may stimulate CD8+ Tc2 responses, thus initiating or exacerbating local allergic responses. Furthermore, CD8+ T cell effects may be pronounced after exacerbations in asthmatics because they are more resistant to corticosteroids and may persist in the lung for longer than CD4+ T cells.[108]

CHAPTER 24

Chemokines, Adipokines, and Growth Factors in the Lung

Marcus W. Butler
Paul McLoughlin
Michael P. Keane

INTRODUCTION

The normal development of organ systems—including the lungs in utero, their subsequent maturation to adulthood, and maintenance of health throughout life—requires intricate signals to be exchanged among various tissues, capable of permitting diversity and adaptation in differing cellular and extracellular contexts, while being robust to onslaughts from ever-changing environmental stimuli. Among the mediators involved in such complex cellular signaling, and relevant in the setting of many pulmonary disorders, are chemokines and growth factors. There has been further complexity added with increasing recognition of adipose tissue as a source of systemic bioactive mediators, called adipokines, that impact on lung health. While some of these mediators are implicated in the development of disease states, they are more often than not also critical to tissue homeostasis and are challenging target systems for therapeutic manipulation. Nonetheless, we are now in an era of exciting developments in targeted biologic therapies that offer the potential for substantial progress in the fight against difficult-to-treat pulmonary disorders characterized by pathogenic processes including acute and chronic inflammation, fibrosis, vascular remodeling, and neoplasia.

CHEMOTACTIC CYTOKINES AND THE INFLAMMATORY RESPONSE

The salient feature of inflammation is leukocyte infiltration. These recruited leukocytes contribute to the pathogenesis of chronic inflammation and promote fibrosis via the elaboration of a variety of cytokines. Maintenance of leukocyte recruitment during inflammation requires the expression of cell-surface adhesion molecules, and the production of chemotactic molecules, such as chemokines.[1] The chemokines can be divided into four families—CXC, CC, C, and CXXXC—which behave as potent chemotactic factors for neutrophils, eosinophils, basophils, monocytes, mast cells, dendritic cells, NK cells, and T and B lymphocytes (Table 24-1). There is approximately 20% to 40% homology between the members of the four chemokine families.[2] Chemokines are produced by an array of cells, including monocytes, alveolar macrophages, neutrophils, platelets, eosinophils, mast cells, T- and B-lymphocytes, NK cells, and various structural cells, including keratinocytes, mesangial cells, epithelial cells, hepatocytes, fibroblasts, smooth muscle cells, mesothelial cells, and endothelial cells. Specific chemokines can form heterodimers that differentially dictate their functional activity, for example, obligate CC-type heterodimers can drive acute lung injury.[3] Production of chemokines by both immune and nonimmune cells supports the contention that these cytokines may play a pivotal role in orchestrating chronic inflammation.[4]

CXC Chemokines

CXC chemokines can be further divided into two groups on the basis of a structure and function domain consisting of the presence or absence of three amino acid residues (Glu-Leu-Arg; ELR motif) that precede the first cysteine amino acid residue in the primary structure of these cytokines. ELR+CXC chemokines are chemoattractants for neutrophils and act as potent angiogenic factors. In contrast, ELR–CXC chemokines are highly induced by interferons, are chemoattractants for mononuclear cells, and are potent inhibitors of angiogenesis[5] (Table 24-2).

CXC Chemokine Receptors

Chemokine activities are mediated through G protein–coupled receptors. Seven CXC chemokine receptors have been identified (Table 24-3). The ELR+ chemokines bind to CXCR1 and CXCR2 receptors, which are found on neutrophils, T lymphocytes, monocytes/macrophages, eosinophils, basophils, keratinocytes and mast cells, and endothelial cells.[6] CXCR3 is the receptor for CXCL9, CXCL10, and CXCL11, and is expressed on activated T lymphocytes. CXCR3 is also expressed on HUMVEC in a cell cycle–dependent fashion. CXCR4 is the specific receptor for CXCL12 and is the cofactor for lymphotropic HIV-1. In contrast to CXCR3, CXCR4 appears to be expressed on resting T lymphocytes.[6] Two other chemokine receptors have been identified that bind chemokines without a subsequent signal-coupling event. The DARC receptor is similar to other chemokine receptors, and it binds both CXC and CC chemokines without apparent signal coupling. This receptor was originally found on human erythrocytes and was thought to represent a "sink" for chemokines.[7] The second nonsignaling chemokine receptor is the D6 receptor, which binds several CC chemokines with high affinity, including CCL2, CCL4, CCL5, and CCL7.[8]

CXC Chemokines in Pulmonary Inflammation

CXC chemokines play a significant role in mediating neutrophil infiltration in the lung parenchyma and pleural space in response to endotoxin and bacterial challenge. CXCL8 is in the bronchoalveolar lavage of patients with community-acquired pneumonia and nosocomial pneumonia and a variety of animal models of pneumonia. In a model of *Aspergillus fumigatus* pneumonia, neutralization of TNF resulted in marked attenuation of the expression of CXCL1 and CXCL2/3 that was paralleled by a reduction in the infiltration of neutrophils and associated with increased mortality.[9] Administration of a TNF agonist peptide to animals that had been intratracheally inoculated with *Klebsiella pneumoniae* led to markedly elevated levels of CXCL2/3 associated with increased neutrophil infiltration.[10] Studies have shown that ventilator-induced lung injury is secondary to stretch-induced chemokine release with a subsequent inflammatory response and neutrophil recruitment.[11] CXCR2$^{-/-}$ mice are also protected from hyperoxia-induced lung injury. In other studies, the production of CXCL5 in the lung was correlated with the presence of neutrophil-dependent lung injury, and passive immunization with neutralizing CXCL5 antibodies resulted in significant attenuation of lung injury.[12] Lung neutrophils have been shown by single-cell RNA sequencing in mouse models of allergic asthma to transiently activate in the presence of a pro-allergic, low-dose lipopolysaccharide environment, with upregulated expression of CXCR4 on the neutrophil surface, necessary for subsequent release of neutrophil extracellular traps (NETs), potentiating the uptake of house dust mite by dendritic cells to promote early triggering of type 2 allergic airway inflammation.[13]

AL GRAWANY

TABLE 24-1 The Human C, CC, CXC, and CXXXC Chemokine Families of Chemotactic Cytokines

Systemic Name	Human Ligand Name
C Chemokines	
XCL1	Lymphotactin
XCL2	SCM-1β
CC Chemokines	
CCL1	I-309
CCL2	Monocyte chemotactic protein 1 (MCP-1)
CCL3	Macrophage inflammatory protein 1 alpha (MIP-1α)
CCL4	Macrophage inflammatory protein 1 beta (MIP-1β)
CCL5	Regulated on activation normal T cell expressed and secreted (RANTES)
CCL7	Monocyte chemotactic protein 3 (MCP-3)
CCL8	Monocyte chemotactic protein 2 (MCP-2)
CCL9	Macrophage inflammatory protein 1 delta (MIP-1δ)
CCL11	Eotaxin
CCL13	Monocyte chemotactic protein 4 (MCP-4)
CCL14	HCC-1
CCL15	HCC-2
CCL16	HCC-4
CCL17	Thymus and activation-regulated chemokine (TARC)
CCL18	DC-CK-1
CCL19	Macrophage inflammatory protein 3 beta (MIP-3β)
CCL20	Macrophage inflammatory protein 3 alpha (MIP-3α)
CCL21	6Ckine
CCL22	MDC
CCL23	MPIF-1
CCL24	MPIF-2
CCL25	TECK
CCL26	Eotaxin-3
CCL27	CTACK
CCL28	MEC
CXC Chemokines	
CXCL1	Growth-related oncogene alpha (GRO-α)
CXCL2	Growth-related oncogene beta (GRO-β)
CXCL3	Growth-related oncogene gamma (GRO-γ)
CXCL4	Platelet factor 4 (PF4)
CXCL5	Epithelial neutrophil–activating protein 78 (ENA-78)
CXCL6	Granulocyte chemotactic protein 2 (GCP-2)
CXCL7	Neutrophil-activating protein 2 (NAP-2)
CXCL8	Interleukin 8 (IL-8)
CXCL9	Monokine induced by interferon γ (MIG)
CXCL10	Interferon γ–inducible protein (IP-10)
CXCL11	Interferon-inducible T cell alpha chemoattractant (ITAC)
CXCL12	Stromal cell–derived factor 1 (SDF-1)
CXCL13	B cell–attracting chemokine 1 (BCA-1)
CXCL14	BRAK/Bolekine
CXCL16

TABLE 24-2 The CXC Chemokines That Display Disparate Angiogenic Activity

CXC chemokines that contain the ELR motif	
CXCL1	Growth-related oncogene alpha (GRO-α)
CXCL2	Growth-related oncogene beta (GRO-β)
CXCL3	Growth-related oncogene gamma (GRO-γ)
CXCL5	Epithelial neutrophil–activating protein 78 (ENA-78)
CXCL6	Granulocyte chemotactic protein 2 (GCP-2)
CXCL7	Neutrophil-activating protein 2 (NAP-2)
CXCL8	Interleukin 8 (IL-8)
CXC Chemokines that lack the ELR motif	
CXCL4	Platelet factor -4 (PF4)
CXCL9	Monokine induced by interferon γ (MIG)
CXCL10	Interferon γ–inducible protein (IP-10)
CXCL11	Interferon-inducible T cell alpha chemoattractant (ITAC)
CXCL12	Stromal cell–derived factor 1 (SDF-1)

The B lymphocyte chemokine CXCL13 is a key mediator in development of tertiary lymphoid follicles, a histologic hallmark of COPD progression.[14] CXCL13 expression within these structures in resected lungs of COPD patients and cigarette smoke–exposed mice is increased, and anti-CXCL13 antibodies prevented pulmonary lymphoid follicle formation in mice, attenuating alveolar wall destruction and BALF inflammation.[14]

CXCL8 is chemotactic for neutrophils via high-affinity binding to CXCR2, a receptor also activated by CXCL1 and CXCL5, ligands that rise from baseline expression in lung-derived tissues during COPD exacerbations.[14] This initially led to clinical development, since discontinued for lack of efficacy, of three different oral CXCR2 small molecule antagonists in neutrophilic airways diseases such as COPD and neutrophilic asthma.[15–17]

Several studies have demonstrated that CXCL8 levels correlate with the development and mortality of acute respiratory distress syndrome (ARDS). Early increases in CXCL8 in bronchoalveolar lavage fluid correlated with an increased risk of subsequent development of ARDS, and also demonstrated that alveolar macrophages were an important source of CXCL8 prior to neutrophil influx.[11] Furthermore, there is an imbalance in the expression of ELR+ (CXCL1, CXCL5, CXCL8) as compared with ELR-CXC (CXCL10, CXCL11) chemokines from BALF of patients with ARDS compared with controls. This imbalance correlated with angiogenic activity and both procollagen I and procollagen III levels in BALF.[18] These findings suggest that CXC chemokines have an important role in the fibroproliferative phase of ARDS via the regulation of angiogenesis. In sterile ARDS such as severe trauma or hemorrhagic shock, lung injury has been thought to be due to excessive recruitment of activated neutrophils into pulmonary vasculature. Many activated neutrophils may in fact physiologically arrive in the lung in a preprogrammed homeostatic pathway, having performed key repair functions at extrapulmonary injured tissue sites, then selectively migrate via CXCR4 to the bone marrow from the “pit-stop” in the lungs, a “reverse migration” process that may be dysregulated in ARDS.[19,20]

■ The Role of CXC Chemokines in Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (IPF) is characterized by the progressive deposition of collagen within the interstitium and subsequent destruction of lung tissue.[21,22] The mechanisms of cellular injury and the role of classic inflammatory cells remain unclear. Several CXC chemokines are elevated in the BAL of IPF patients, including CXCL5, CXCL8, and CXCL17.[23,24] CXCL8 is significantly elevated in IPF, as compared with either normal or sarcoidosis patients, and correlates with BALF presence of neutrophils. The alveolar macrophage is an important cellular source of CXCL8 in IPF.[25] In addition, BALF levels of CXCL8 in IPF may correlate with a worse prognosis.[26] CXCL4 may be a useful biomarker as the predominant circulating protein secreted by plasmacytoid dendritic cells in systemic sclerosis, and predicts risk and progression of the pulmonary fibrosis and pulmonary arterial hypertension as well as response to immunosuppressive therapy in systemic sclerosis–related interstitial lung disease.[27,28]

TABLE 24-3 The CXC Chemokine Receptors

Receptor	Ligand
CXCR1	CXCL6, CXCL7, CXCL8
CXCR2	CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, CXCL8
CXCR3A	CXCL9, CXCL10, CXCL11
CXCR3B	CXCL4, CXCL9, CXCL10, CXCL11
CXCR4	CXCL12
CXCR5	CXCL13
CXCR6	CXCL16
CXCR7	CXCL11, CXCL12

■ Vascular Remodeling in Pulmonary Fibrosis: The Role of CXC Chemokines

The existence of neovascularization in IPF was originally identified in 1963 by Turner-Warwick, who demonstrated that within areas of pulmonary fibrosis there was extensive neovascularization with anastomoses between the systemic and pulmonary microvasculature.[29] Further evidence of neovascularization during the pathogenesis of pulmonary fibrosis has been demonstrated in a rat model of bleomycin-induced pulmonary fibrosis.[30] An imbalance in the levels of angiogenic chemokines (CXCL5, CXCL8), as compared with angiostatic chemokines (CXCL9, CXCL10, CXCL11), favoring net angiogenesis has been demonstrated in both animal models and tissue specimens from patients with IPF (Fig. 24-1).[31] Renzoni have demonstrated vascular remodeling in both IPF and fibrosing alveolitis associated with systemic sclerosis.[32] Cosgrove et al. provided further support for the concept of vascular remodeling in IPF when they demonstrated a relative absence of vessels in the fibroblastic foci of IPF. This appeared to correlate with increased expression of pigment epithelium–derived factor in the fibroblastic foci. Interestingly, they also noted significant vascularity in the areas of fibrosis around the fibroblastic foci, with numerous abnormal vessels in the regions of severe architectural distortion.[33] These findings are similar to those of Renzoni and support the concept of regional heterogeneity of vascularity in IPF. This heterogeneity is not surprising, as usual interstitial pneumonia, which is the pathologic description of IPF, is defined by its regional and temporal heterogeneity.[34] CXCR7, expressed on pulmonary capillary endothelial cells (PCECs), appears to play a role in ameliorating lung fibrosis in a bleomycin or hydrochloric acid mouse model, but is downregulated by such repetitive lung injury when PCECs are activated, resulting in Jagged 1 (JAG1)-mediated Notch signaling activation in lung perivascular fibroblasts and recruitment of vascular endothelial growth factor receptor 1 (VEGFR1)-expressing perivascular macrophages. Agonism of CXCR7 reduces JAG1 expression in PCECs, reducing fibrosis and promoting alveolar repair, and such CXCR7 agonists are a potential therapeutic target.[35]

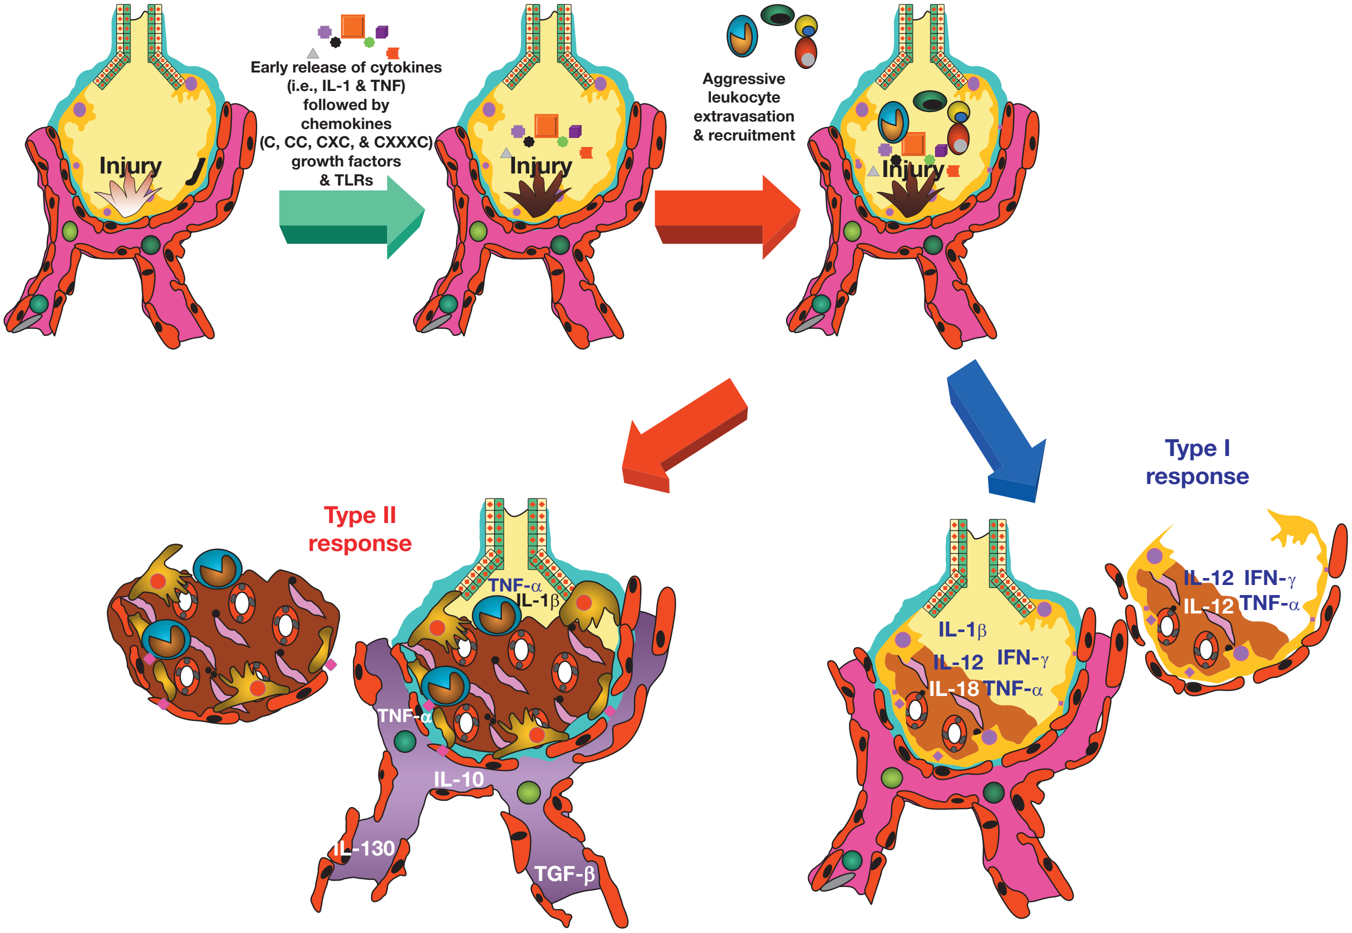

Figure 24-1 The inflammatory response to lung injury. The cytokine profile that is secreted by inflammatory cells during lung injury determines the ultimate outcome following injury. Polarization of the inflammatory response toward a type I response is associated with resolution of lung injury or infection. In contrast, chronic infections (e.g., tuberculosis) and chronic inflammatory diseases (e.g., idiopathic pulmonary fibrosis) are associated with a type II profile.

■ CXC Chemokines in Pulmonary Hypertension

The potential role of the CXCL12/CXCR4/CXCR7 axis in pulmonary hypertension was first suspected when it was reported that CXCR7 expression increased in the lungs of hypoxic hypertensive mice and in the lungs of patients with IPAH.[36] Subsequently, CXCL12 was found to be elevated in the peripheral plasma of patients with PAH, although in a separate study this increase was not observed.[37,38] Increased expression of CXCL12 in remodeled vessels and particularly in the plexiform lesions in explanted IPAH lungs also has been shown.[39]

CXR7 was most prominently expressed in the endothelium of the explanted lungs of hypertensive subjects and, in addition to its well-established role in leucocyte chemotaxis, was shown to play a central role in stimulating endothelial proliferation, whereas CXCR4 was required for endothelial cell chemotaxis.[37] Recruitment of progenitor cells to the remodeled pulmonary vessels is a prominent feature in PAH lungs.[39,40] In vivo blockade of CXCR4 in hypoxic mice reduced the recruitment of progenitor cells to the remodeled vasculature of hypertensive lungs, whereas blockade of CXCR7 did not affect this behavior.[38,40,41]

In rodents models inhibition of CXCL12 action using function blocking antibodies, or separate selective inhibition of CXCR4 signaling or CXCR7 signaling, attenuates the development of hypoxic pulmonary hypertension.[38,41,42] There is a greater attenuation of established pulmonary hypertension through CXCL12 neutralization ligands than via CXCR4 blockade in the monocrotaline (MCT) and Sugent5416/hypoxia (SuHx) rat models of severe PAH.[43] Taken together these data suggest an important role of CXCL12 signaling, requiring both its cognate receptors, in the pathogenesis of pulmonary hypertension.

■ Chemokines and the Trafficking of Fibrocytes to the Lung

Fibrocytes present in the peripheral circulation were first identified in 1994, constitute a minor component of the circulating pool of leukocytes (<1%), and express a characteristic pattern of markers, including collagen (Col) I and CD45.[44] Subsequent studies have revealed that circulating fibrocytes express chemokine receptors such as CXCR4 and CCR7 and extracellular matrix proteins, such as procollagen I and procollagen III. Fibrocytes migrate in response to CXCL12 and traffic to the lungs in a model of bleomycin-induced pulmonary fibrosis. Treatment of bleomycin-exposed animals with specific neutralizing anti-CXCL12 antibodies inhibits intrapulmonary recruitment of fibrocytes and attenuated lung fibrosis. Levels of circulating CD45+ Col1+ cells are elevated in stable IPF patients versus controls, are transiently higher during an exacerbation and predicted survival.[45] Although fibrocytes are not an essential source of type I collagen during lung fibrosis, the licensed antifibrotic medication nintedanib inhibits the differentiation of fibrocytes from human mononuclear cells and the growth factor–induced migration of fibrocytes and their accumulation in fibrotic lesions in a bleomycin mouse model.[46,47] These findings challenge the dogma that fibroblasts and myofibroblasts arise from an intrapulmonary pool of tissue fibroblasts.[48]

The CC Chemokines

CC chemokines (Table 24-1) are chemoattractants for monocytes, T and B lymphocytes, NK cells, dendritic cells, basophils, mast cells, and eosinophils.[49] The CC chemokines are produced by an array of cells, including monocytes, alveolar macrophages, neutrophils, platelets, eosinophils, mast cells, T cells, B cells, and NK cells, as well as structural cells such as keratinocytes, mesangial cells, epithelial cells, hepatocytes, fibroblasts, smooth muscle cells, mesothelial cells, and endothelial cells.[50]

CC Chemokine Receptors

CC chemokine receptors are structurally homologous and have been identified to have specific ligand-binding profiles (Table 24-4).[50] Naïve T cells express CXCR4 and CCR7 and migrate in response to CXCL12 and CCL19. CXCR3, CXCR6, and CCR5 are expressed at higher levels on type I cells than type II, whereas CCR3, CCR4, and CCR8 are more characteristic of type II cells.[51]

CC Chemokines in Pulmonary Inflammation

The CC chemokines, CCL2, CCL3, CCL4, CCL5 have been implicated in mediating the innate host defense in animal models of *pulmonary infection.*[52,53] These studies have demonstrated that CC chemokine ligand/receptor biology plays a critical role in innate host defense and development of pulmonary inflammation that is important in eradication of microorganisms.

Mehrad et al. have shown that CCL3 and the recruitment of mononuclear cells play an important role in the eradication of invasive pulmonary aspergillosis. They demonstrated that in both immunocompetent and neutropenic mice CCL3 is induced in the lungs in response to intratracheal inoculation of *Aspergillus fumigatus.*[54] These studies indicate that CCL3 and elicitation of mononuclear cells are crucial in mediating host defense against *Aspergillus fumigatus* in the setting of neutropenia.[55]

Eosinophilic pulmonary infiltration is central to the type 2 inflammation of asthma and a subset of COPD patients, orchestrated by cytokines such as interleukins (IL-4, IL-5, IL-9, and IL-13), but also trafficked by CCL5, CCL11, CCL13, CCL17, CCL22 and CCL24.[56,57] Such eosinophilic inflammation and compensatory tissue repair in murine allergic asthma models are further dynamically regulated by subsets of lung dendritic cells and regulatory T cells via altered expression of CCL11, CCL17, CCL22, and CCL24.[58,59]

TABLE 24-4 The CC Chemokine Receptors

CCR10	CCL27, CCL28

CC Chemokines in Pulmonary Fibrosis

Animal models, such as bleomycin-induced pulmonary fibrosis, have demonstrated the presence and contribution of CC chemokines to the pathogenesis of fibrosis. CCL2 is an important cofactor for the stimulation of fibroblast collagen production and induction of the expression of TGF-β_1. Inhibition of CCL2 or CCL3 resulted in a reduction of infiltrating cells into the lungs of bleomycin-treated animals.[60,61]

Furthermore, it has been shown that CCL2 can stimulate IL-4 production, indicating that it might be involved in type II polarization.[62] IL-13 promotes bleomycin-induced fibrosis through the elaboration of CCL6.[63] Both CCL17 and CCL22 and their receptor, CCR4, are significantly elevated in the bleomycin model, and neutralization of CCL17 attenuates pulmonary fibrosis.[64] Thus, chemokines may have an important role in the switch toward a profibrotic type II phenotype.

Both CCR1 and CCR2 have been shown to play an important role in the pathogenesis in the mouse model of bleomycin-induced pulmonary fibrosis. Treatment with antibodies to CCR1 leads to a reduction in both inflammatory cell infiltrates and the development of fibrosis.[65] Similarly, CCR2$^{-/-}$ mice are protected from pulmonary fibrosis in response to bleomycin.[66] Furthermore, alveolar epithelial cells from CCR2$^{-/-}$ mice suppress fibroblast proliferation more than AECs from wild-type mice.[67] CCL2 and CCR2 have an important role in suppression of PGE2, thereby promoting fibroproliferation. Similarly, an important role for CCR2 has been seen in murine model of obliterative bronchiolitis, in which the fibrotic response associated with this disorder was attenuated in CCR2$^{-/-}$ mice.[68] Similarly, CCL2 and CCL3 are elevated in BALF and lung tissue of ILD patients.[69,70] Accordingly, targeting chemokine receptors may be an efficient way to inhibit pulmonary fibrosis.

Choi et al. described enhanced expression of the chemokines CCL7 and CCL22 in lung tissue of patients with IPF compared with nonspecific interstitial pneumonia and non-idiopathic interstitial pneumonia.[71] Furthermore, they describe increased expression of CCL5 in nonspecific interstitial pneumonia compared with usual interstitial pneumonia. Interestingly, CCL5 protein was identified in nonspecific interstitial pneumonia more prominently than usual interstitial pneumonia. This is all the more interesting as CCL5 is a major stimulus for the production of CCL7 through its interactions with CCR5. These findings raise the possibility that there is a continuum from nonspecific interstitial pneumonia to usual interstitial pneumonia with higher levels of CCL5 in nonspecific interstitial pneumonia leading to subsequent increased CCL7 expression as the disease progresses to usual interstitial pneumonia. There is considerable controversy as to whether nonspecific interstitial pneumonia is an earlier lesion of usual interstitial pneumonia.[72] Several studies have demonstrated the presence of usual interstitial pneumonia and nonspecific interstitial pneumonia patterns in the same patients, which suggests that these are overlapping processes.[72–74] The findings suggest a transition from a predominance of CCL5 to CCL7 and further support this notion. Of further interest is the previous description that CCL7 can act as a natural antagonist at the CCR5 receptor, which raises the possibility that CCL7 may play a role in regulating its own production.[75]

ADIPOKINES AND PULMONARY INFLAMMATION

With the emergence of obesity as a major epidemic linked to systemic metabolic dysfunction, concerted efforts have been made to gain a fuller understanding of the varied functions of adipose tissue, beyond that of being an energy storage organ, and leading to the discovery of various factors that are secreted by adipocytes.[76] These mainly proteinaceous endocrine factors were initially termed adipocytokines, and later, adipokines,[77] and possess pro- and anti-inflammatory activities, potentially of relevance in the context of pulmonary disorders associated with body mass index, including asthma, obstructive sleep apnea syndrome, chronic obstructive pulmonary disease, pulmonary arterial hypertension, various pulmonary infections, and lung cancer.[78] While the main source of adipocytes in the body is from deposits of subcutaneous and visceral adipose tissue, the development of obesity can give rise to collections of adipose tissue in other locations including the heart, kidneys, bone marrow, the adventitia of major blood vessels, and within the lungs. There is evidence that differential adipokine secretion and functional outcomes can occur at different sites of adiposity within the body, following the stimulus of dietary modification.[79] White adipose tissue, the major form in humans, is predominantly composed of lipid-laden adipocytes, but also adipocyte precursor cells, fibroblasts that generate extracellular matrix scaffolding, vascular (smooth muscle and endothelial) cells that provide systemic access for secreted adipokines, and macrophages and T cells that influence the immune phenotype.[80] The cellular composition of adipose tissue can vary in conditions of altered body mass, and macrophages in particular seem to traffic in larger numbers to adipose tissue under conditions of increased obesity with associated capillary rarefaction and adipose tissue hypoxia.[81]

■ Pro-inflammatory Adipokines

Beyond the “pure” effects of uncomplicated obesity upon respiratory mechanics, pulmonary gas exchange, ventilatory drive and work of breathing, there is increasing evidence of an association among obesity, adipokines and pulmonary disease states that are characterized by inflammation.[78] Most of the adipokines identified to date are pro-inflammatory in their effects (Table 24-5). Some important adipokines that are better known for their other roles, such as TNF-α, IL-6, CCL2, and CXCL5, will not be discussed here.

Leptin

Leptin, coded for by the *ob* gene on chromosome 17, is a 16-kDa protein hormone, mainly secreted by adipocytes,[82] and regulated principally by food intake, whereby fasting reduces leptin levels, and food consumption transiently increases *ob* gene expression, with leptin being initially regarded as a satiety hormone.[83,84] It is also expressed in human peripheral lung tissue, including alveolar type II pneumocytes, alveolar macrophages, and bronchial epithelial cells,[85,86] and is known to be modulated by gender, sepsis, catecholamines, glucocorticoids, and insulin.[87,88] It is now clear that leptin has pleiotropic effects, which include stimulating TNF and IL-6 production by monocytes, stimulating production of CCL3-5 by macrophages, and stimulating reactive oxygen species production, cell proliferation, and migration. In addition, leptin may have a role in lung development,[76] as it is differentially expressed by fetal rat lung fibroblasts during the time of alveolar differentiation,[89] and capable of stimulating fetal rat surfactant protein synthesis in vitro,[90] although contradictory in vivo findings were observed in fetal sheep and mice lungs.[91]

There have been extensive efforts to relate leptin to respiratory disorders, most notably with obstructive sleep apnea–hypopnea syndrome (OSAHS), chronic obstructive pulmonary disease (COPD), asthma, pneumonia, and other pulmonary infections. Some data suggest leptin has a stimulatory effect on ventilation; for example, the mutant *ob/ob* mouse, which lacks functional leptin and has a phenotype of obesity, hyperphagia, and a low resting metabolic rate, displays an elevated arterial $PaCO_2$ independent of obesity onset, which is acutely reversible through exogenous leptin replacement.[92] It has been speculated that OSAHS is a leptin-resistant state, but progress in this field has been hampered by conflicting results of leptin and leptin receptor candidate gene association studies[93,94] and trials of nasal continuous positive airway pressure.[95,96]

In chronic obstructive pulmonary disease, it has been hypothesized that the known link between the cachexia of COPD and increased mortality might somehow be related to leptin function. There appears to be an absence of the usual circadian rhythm of circulating leptin in cachectic COPD patients, as opposed to normal-weight COPD patients, with associated heart rate variability changes that raise the possibility of a role for leptin in the pathophysiology of COPD cachexia,[97] although further data are needed. The reproducible finding of elevated serum leptin levels during acute exacerbations of COPD, that track markers of the systemic inflammatory response, points to disturbance of the normal leptin feedback loop regulating food intake and energy balance, due to the influence of the acute inflammatory response and systemically administered glucocorticoids, as a possible contributing mechanism to cachexia in COPD.[98] Wild-type mice exposed chronically to cigarette smoke have increased leptin expression in bronchial epithelial cells and pneumocytes compared with air-exposed controls. *Ob/ob* mice (lacking functional leptin) that are then exposed acutely or chronically to cigarette smoke exhibit higher neutrophils and CD4+, CD8+, and dendritic cells in BAL and lung tissue than smoke-exposed wild-type mice, compatible with modulation of innate and adaptive immune cell recruitment by leptin in response to smoke.[99] Within human airways, leptin expression is increased in bronchial epithelial cells and alveolar macrophages of ex-smokers with or

TABLE 24-5 Adipokines Linked to Pulmonary Disease States

Adipokine	Pulmonary Source	Receptor	Lung Disease State
Proinflammatory Adipokines			
Leptin	Alveolar type II pneumocytes, alveolar macrophages, bronchial epithelial cells, lung endothelial cells	Leptin receptor	OSAHS, OHS, COPD, asthma, NSCLC, PAH
Apelin	Lung endothelial cells	Apelin receptor	PAH
Nampt	Lung endothelial cells	Unknown	ALI
Resistin	Unknown	Unknown	Asthma
Anti-inflammatory Adipokines			
Adiponectin	Bronchial epithelial cells	Adiponectin receptors 1 and 2, T-cadherin	COPD, asthma, ALI, PAH

OSAHS, obstructive sleep apnea-hypopnea syndrome; OHS, obesity hypoventilation syndrome; COPD, chronic obstructive pulmonary disease; NSCLC, non–small-cell lung cancer; PAH, pulmonary arterial hypertension; ALI, acute lung injury.

without severe COPD compared to never-smokers, and leptin can induce phosphorylation of the transcription factor STAT3 in lung epithelial cells, supporting the notion of a functioning leptin signaling pathway in these cells.[85]

Obesity is believed to be a risk factor for asthma, but some controversy still surrounds whether obesity is a central cause or a confounding comorbidity of asthma.[100,101] Notably, unbiased clustering approaches in severe asthma subjects have identified an obesity-related clinical asthma phenotype typified by obese female patients with late-onset asthma and lacking in eosinophilic T_H2-mediated inflammation.[102] *Ob/ob* mice appear to have elevated pulmonary resistance and increased responses to ozone and methacholine, although this could be mechanical bias from the low lung size of these mutant mice.[88] Interestingly, when a cohort of obese asthmatic women and obese female controls were studied in the setting of bariatric surgery, leptin expression and macrophage inflammation were both increased in visceral adipose tissue of asthmatics independent of BMI, and correlated with airway reactivity, but there was no association with airway inflammation measurements even though the airway epithelial cells expressed receptors for leptin, suggesting that leptin exerts a direct effect on airway epithelium (and not indirectly via enhancing airway inflammation) that is important in the pathogenesis of asthma in obesity.[103] These observations run counter to the hypothesis that leptin is merely a marker for airway inflammation in poorly controlled asthma.[104]

NAMPT (PBEF/visfatin)

The gene *NAMPT* codes for a cytokine called pre-B-cell colony stimulating factor (PBEF), also known as visfatin. Confirmatory studies of the potential receptors for extracellular NAMPT (eNAMPT), Toll-like receptor 4 (TLR4), and CCR5 are awaited.[105,106] It is now known to be produced by various cell types including adipocytes, and especially by visceral as opposed to subcutaneous fat, and has gained greater interest by the rediscovery of PBEF as NAMPT, the rate-limiting enzyme in the biosynthesis of the essential redox cofactor NAD. NAMPT is inducible in neutrophils and lung microvascular endothelial cells by endotoxin, TNF-α, and IL-1β, and in monocytes, it induces production of IL-1β, TNF-α, and IL-6, as well as the surface expression of co-stimulatory molecules CD54, CD40, and CD80.[107,108] Against this background of catalyzing the respiratory burst, and its proinflammatory and immunomodulatory capabilities, NAMPT has been found at higher concentrations in serum and BAL fluid from patients with acute lung injury.[109] Investigators have found inhibition of NAMPT ameliorates ventilatory and ischemic acute lung injury.[110,111] There have also been a number of independent candidate gene association studies that support a role for NAMPT promoter genetic variants in acute lung injury (ALI) pathogenesis.[109,112,113]

■ Anti-inflammatory Adipokines

An important anti-inflammatory adipokine is adiponectin, which is discussed below.

Adiponectin

The most intensely studied of the anti-inflammatory adipokines, and with notable evidence of a role in inflammatory lung disorders, is adiponectin, which shares some structural similarity with complement factor C1q and forms trimers that can go on to form stable hexamers or a high-molecular-weight form, all of which are detectable in blood.[80] Circulating adiponectin levels are decreased in obesity, particularly in visceral obesity, nonalcoholic fatty liver disease, and type 2 diabetes, being inversely related to insulin resistance. The adipokine is inhibited by proinflammatory factors such as TNF, IL-6, hypoxia, and oxidative stress.[76] There has been considerable interest concerning the involvement of adiponectin in pulmonary disease states. Three described adiponectin receptors (AdipoR1, AdipoR2, and T-cadherin) are expressed in the lungs, with AdipoR1 expressed by lung epithelial cells, and importantly, the baseline phenotype of mice following targeted disruption of the adiponectin gene shows evidence of emphysema-like dilated airspaces and activation of alveolar macrophages.[114,115] These same adiponectin-deficient mice develop pulmonary hypertension with evidence of perivascular inflammation,[116] as well as an exaggerated form of LPS-inducible acute lung injury that is abrogated by adiponectin.[117]

As further evidence of anti-inflammatory functionality, adiponectin can bind to apoptotic cells and facilitate their phagocytosis by macrophages, analogous to other members of the collectin family, such as C1q and surfactant proteins A and D.[118] In keeping with this intuitive role in airways disease pathobiology, a number of groups have reported increased levels of circulating adiponectin in COPD.[115,119] Adiponectin was found to be elevated in BALF of COPD patients, being highly expressed in their airway epithelium, and the adiponectin receptor AdipoR1 on lung epithelial cells was shown to be functional, releasing IL-8 in the presence of adiponectin.[115] Animal and human data suggest that short-term exposure to cigarette smoke downregulates adiponectin whereas the COPD disease state elevates its expression.[115] Higher plasma adiponectin levels were independently associated with radiologic emphysema in multiple regression analysis in a substudy of the COPDGene cohort including more than 600 current/former smokers with or without COPD.[120] In contrast, AdipoR2 is more highly expressed in the airway epithelium of obese asthma patients versus obese control subjects, and the opposite to what is observed for T-cadherin expression.[103] In mice, allergen challenge appears to decrease the pulmonary expression of all three adiponectin receptor types, and T-cadherin may play a role in transporting adiponectin into the lungs.[121] In an atopic adult study, co-exposure to diesel exhaust and allergen extract resulted in a potentially protective bronchoalveolar lavage adiponectin/leptin ratio in subjects with normal airway responsiveness, but not in those with baseline hyperresponsiveness.[122] The exact role of adiponectin signaling in asthma will require further study.

■ Adipokines and Pulmonary Hypertension

The high prevalence of pulmonary hypertension in obese subjects has previously been attributed to hypoxemia resulting from associated obstructive sleep apnea or obesity hypoventilation syndrome.[123–125] However, more recently, evidence has shown that alterations in three specific adipokines (adiponectin, apelin, and leptin) may directly contribute to pulmonary vascular dysfunction.

Adiponectin concentrations are paradoxically reduced in the plasma of obese subjects despite the expansion of adipose tissue.[126] Mice in which adiponectin has been deleted spontaneously develop elevated pulmonary arterial pressure, vascular remodeling, and perivascular inflammation as they grow older.[116] Conversely, constitutive overexpression of adiponectin in mice protects against the development of both hypoxia-induced and inflammation-induced (ovalbumin challenge) pulmonary hypertension.[127] These suggest that reduced adiponectin concentrations contribute directly to the development of pulmonary vascular dysfunction in obesity due to a loss of its normal vascular homeostatic action.

Apelin is produced and secreted by adipocytes and acts by binding to the apelin receptor.[128] It is also expressed by a wide variety of other tissues including the pulmonary vasculature.[128] Plasma apelin concentrations are increased in obese individuals.[129] Apelin-null mice develop more severe hypoxic pulmonary hypertension than wild-type mice, which is associated with endothelial dysfunction.[130] Leptin concentrations are elevated in patients with both idiopathic

PAH and scleroderma-associated PAH and in the pulmonary endothelium from these patients.[131,132] In mice, inhibiting the leptin/receptor axis can ameliorate hypoxia-induced pulmonary hypertension by targeting pulmonary artery smooth muscle cell proliferation and perivascular monocyte-derived cellular accumulation.[133] However, the exact role of apelin and leptin in the pulmonary circulation in obese humans remains to be determined.

■ Adipokines and Pulmonary Fibrosis

The elevated leptin levels observed in obese patients with type 2 diabetes mellitus has been postulated to play a role in an apparent reduction in development of and mortality from acute lung injury/acute respiratory distress syndrome (ALI/ARDS) in this patient population.[134,135] Leptin has been implicated in fibrogenesis pathways in lung tissues, as well as liver and kidney, and augments TGF-β1 signaling in lung fibroblasts by inhibiting peroxisome proliferator-activated receptor γ.[135–137] Mice with leptin resistance are protected from hyperoxia-induced acute lung injury.[138] Serum leptin is elevated in never-smokers who have subclinical interstitial lung abnormalities and lower forced vital capacity in a subset of a large multi-ethnic community-based cohort.[139] In Asian patients with acute exacerbation of idiopathic pulmonary fibrosis, plasma leptin levels are elevated and are an independent predictor of survival.[140–142] Leptin may promote pulmonary fibrosis by promoting epithelial mesenchymal transition and by inhibiting autophagy through a PI3K/Akt/mTOR pathway, but these observations need to be replicated in broader populations.[142]

GROWTH FACTORS

A variety of growth factors have been described in the lung and are described in the following sections.

■ Transforming Growth Factor β

Mammalian transforming growth factor beta (TGF-β) belongs to a superfamily of genes and exists as three closely homologous (72%–80%) dimeric isoforms: TGF-β_1, TGF-β_2, and TGF-β_3. Although the three isoforms of TGF-β appear to have overlapping biologic activity, the predominant isoform of TGF-β is TGF-β_1. There are three TGF-β receptors, and signal transduction to the nucleus is via the Smad group of proteins. Smad 1, 2, 3, 4, 5, 8, and 9 are activating signals, whereas Smad 6 and 7 are inhibitory signals of TGF-β_1 signaling.[143]

TGF-β is produced by a variety of cells, including platelets, neutrophils, eosinophils, mononuclear leukocytes, fibroblasts, and endothelial cells.[144,145] TGF-β is a pleiotropic cytokine that can modulate inflammatory and immune responses, and orchestrate fibrosis and tissue repair.[146] TGF-β is a potent immunosuppressive agent that inhibits IL-1–dependent lymphocyte proliferation.

TGF-β is chemotactic for fibroblasts and can indirectly induce their proliferation via the expression and autocrine and paracrine activity of PDGF-B. TGF-β is perhaps the most potent and efficacious promoter of extracellular matrix production–inducing gene expression and protein production of many of the constituents of extracellular matrix. Furthermore, it inhibits the generation of metalloproteinases and augments the expression of tissue inhibitors of metalloproteinases (TIMP).[144,147]

Transient overexpression of active TGF-β_1 results in prolonged and severe interstitial and pleural fibrosis.[148] Transfer of TNF-α or GM-CSF to rat lung induces pulmonary fibrosis, due in part to induction of TGF-β_1.[149] Furthermore, transient expression of IL-1β using an adenoviral vector can lead to progressive fibrosis that is associated with a sustained increase in levels of TGF-β_1.[150] Smad 3 –/– mice developed less fibrosis in response to bleomycin compared with wild-type controls.[151] In contrast, IL-7 downregulates TGF-β production and inhibits bleomycin-induced pulmonary fibrosis, and this is mediated via Smad 7 signaling.[152]

In IPF, increased expression of TGF-β has been found in bronchiolar epithelial cells, epithelial cells of honeycomb cysts, and hyperplastic type II pneumocytes. BALF from patients with IPF induces apoptosis in cultured bronchiolar epithelial cells, and this effect is attenuated using anti TGF-β_1 antibodies.[153] In the bleomycin model, in vivo administration of TGF-β_1 enhanced Fas-mediated epithelial cell apoptosis and lung injury.[153] The antifibrotic medication pirfenidone, which slows the progression of IPF and possibly also unclassifiable progressive forms of pulmonary fibrosis, has been demonstrated to inhibit TGF-β_1 synthesis and signaling among other pleiotropic, incompletely understood effects that include inhibition of fibroblast proliferation and differentiation into myofibroblasts, as well as modulation of epithelial-mesenchymal transition.[154–156] These studies support the contention that TGF-β is an important mediator of human pulmonary fibrosis.

■ TGF-β Superfamily Members and Pulmonary Hypertension

Disturbance of signaling by members of the TGF-β superfamily plays a key role in pulmonary hypertension.[157–160] The bone morphogenetic proteins (BMPs) and their receptors form part of the TGF-β superfamily, whose activities include important proangiogenic and vascular remodeling effects in endothelial and vascular smooth muscle cells.[36,161] The BMPs, like all ligands of the TGF-β superfamily, bind to transmembrane cell surface receptors formed from heterodimerization of a type 1 and type 2 receptor, many of which are expressed in the normal lung and can form a large number of different heteromeric receptor combinations binding with particular BMP ligands. BMP signaling is further modulated modified by a family of secreted extracellular glycoproteins, accessory proteins that bind directly to BMPs and prevent or enhance their interactions with BMPRs.[162,163]

The requirement for normal BMP function to maintain a healthy pulmonary circulation was first demonstrated by the identification of heterozygote inheritance of loss-of-function mutations in the gene encoding BMPR2 as the underlying cause in the rare heritable form of pulmonary arterial hypertension (HPAH) and in a significant proportion (10%–40%) of patients with IPAH without a previous family history.[164–166] These mutations cause attenuation of the normal cellular responses to the BMPs in the lung, where BMP2 and BMP4 signaling through BMP type 1 receptor (BMPR1) and BMPR2 heterodimers play particularly important roles in normal vascular homeostasis, and result in pulmonary hypertension.[160,167–171] Experimentally induced loss-of-function BMPR2 mutations in mice, or expression of dominant negative BMPR2 constructs, were sufficient to cause the development of pulmonary hypertension alone or increased susceptibility to other well-known causes of PH.[169,171–173] Conversely, overexpression of BMPR2 in the endothelium protected mice against the development of hypoxic pulmonary hypertension.[174] These data show that reduced BMP signaling in the lung either causes pulmonary hypertension or increases susceptibility to other causes of PH. Further evidence for the important role of impaired BMP signaling in the development of pulmonary hypertension has been provided by the discovery that pathogenetic mutations in GDF2, which encodes BMP9, also cause PAH by reducing plasma BMP9 and thus impairing signaling through BMPR2.[175,176]

Later studies reported that reduced BMP signaling was found in many of the common forms of pulmonary hypertension, including hypoxic pulmonary hypertension,[160,170,177] although it was not clear what mechanisms cause reduced BMP signaling in these conditions. Further work has shown that the glycoprotein BMP antagonist gremlin 1 is markedly and selectively increased in the hypoxic mouse lung and in human lungs with PAH.[36] Genetically manipulated mice with reduced gremlin 1 expression (haplodeficient) are partially protected against the development of hypoxic pulmonary hypertension.[162,178] Investigation of the mechanisms of the incomplete penetrance of PAH caused by BMPR2 mutations (~20%) shows that family members with the mutation who develop PAH have higher endothelial expression and secretion of gremlin 1 than other family members who also carry the mutation but do not develop the disease, suggesting that upregulation of gremlin 1 with a consequent further reduction in BMP signaling contributes to the pathogenesis of pulmonary vascular disease in those patients.[179]

Furthermore, the basal normoxic expression of gremlin 1 is higher in the lung than in any other organ, potentially rendering it more vulnerable to any loss of BMP signaling and may help to explain why the vascular abnormality in hereditary PAH is restricted to the pulmonary circulation even though the expression of mutant BMPR2 is ubiquitous in all vascular beds.[180] ACTRIIA-Fc, which traps ligands (activin, growth and differentiation factors GDF8, GDF11) that share receptors and effectors with BMP and TGF-β, has helped reveal a significant role for GDF8/11 and activin in attenuating pulmonary hypertension and rebalancing BMP signaling.[181]

TGF-βs are also expressed in the lung as are their type 1 receptors (TGF-β R1) ALK1 and ALK5, and TGF-β receptor type 2 (TGF-β R2) and increased TGF-β signaling has been observed in some forms of pulmonary hypertension.[157–160] Furthermore, pulmonary arterial hypertension develops in a subset of hereditary hemorrhagic telangiectasia patients who have heterozygous mutations in one of the TGF-β type 1 receptors, the ALK1 (activin receptor–like kinase 1).[182,183] Heterozygous mutations in the endoglin (ENG) gene, which codes for a TGF-β co-receptor, also are associated with the spontaneous development of pulmonary arterial hypertension.[182] Eng$^{+/-}$ mice developed pulmonary hypertension associated with loss of peripheral vasculature in adulthood but not in early postnatal life.[184] Taken together, these data indicate a requirement for normal TGF-β signaling to prevent the development of pulmonary hypertension.

■ Epidermal Growth Factor

Epidermal growth factor (EGF) is the prototype member of a family of polypeptide ligands that interact with the ERBB family of four tyrosine kinase receptors (ERBB1–4, also known as human epidermal growth factor receptor, HER1–4).[185,186] All 13 of the EGF extracellular ligands described to date, which include transforming growth factor α (TGF-α), heparin-binding (HB)-EGF, amphiregulin, epiregulin, and betacellulin among others, contain a conserved EGF domain and are made as a transmembrane protein that is then cleaved by cell surface proteases (ectodomain shedding) to release mature growth factors that bind ERBB, such as the case with EGF which binds to HER1/EGFR.[187] EGF motifs are also found in unrelated proteins including extracellular matrix and cell adhesion proteins, blood coagulation factors, and immune response proteins.[188] Control of ERBB family signaling occurs at many levels, including specific cellular patterns of ligand and receptor expression, subcellular segregation of ligands and receptors, and the diversity of intracellular receptor binding proteins that can amplify or attenuate receptor signaling and transcription factor activation, leading to varying cellular outputs of cell proliferation, adhesion, migration, differentiation, or apoptosis.[185] Dysfunctional EGF-ERBB signaling in the lung has consequently been implicated in lung tumorigenesis and lung injury.[189]

EGFR (ERBB1/HER1) is overexpressed in a large number of non–small-cell lung cancers (NSCLC), and its expression has been correlated with a poor prognosis.[190] NSCLCs will also often express EGFRs cognate ligands EGF and TGF-α, leading to receptor hyperactivity in an autocrine fashion.[191] The tyrosine kinase inhibitors gefitinib, erlotinib, and afatinib target the EGF-ERBB complex by acting as competitive inhibitors of ATP binding at the active site of the kinase. It became apparent that drug-responsive cases were enriched for somatic activating mutations in the EGFR kinase domain, with these mutations occurring at a greater frequency in nonsmokers, women, those of Asian genetic ancestry, and those with adenocarcinoma.[192] The third-generation EGFR tyrosine kinase inhibitor osimertinib selectively targets activating EGFR mutations, as well as the most common resistance mechanism to earlier TKIs, the T790M mutation in exon 20, which sterically interferes with binding of earlier-generation TKIs to the ATP-binding site of EGFR.[193]

There is overlap between the signaling events that orchestrate the proliferation, migration, and differentiation of the developing lung epithelia, and those events that are active during lung injury and repair. The importance of EGF motif signaling in lung development is apparent from the HB-EGF –/– mouse hypoplastic lung phenotype, characterized by fewer alveoli and less surfactant. Similarly, the EGFR knockout mice display alveolar collapse, reduced alveolarization, and loss of surfactant expression, resulting in a phenotype similar to the neonatal respiratory distress syndrome,[194] and exogenous EGF can rescue EGFR –/– fetal lambs from such a phenotype.[195] Later in life, there is evidence implicating EGFR signaling in an in vitro model of alveolar epithelial wound repair[196] and bronchial epithelial repair in asthma.[197] A body of evidence has also implicated EGFR signaling in the pathogenesis of pulmonary fibrosis: for example TGF-α –/– mice are protected from bleomycin-induced fibrosis,[198] as are wild-type mice exposed to bleomycin but administered gefitinib.[199] Given that ERBB tyrosine kinase inhibitors can also cause interstitial lung disease in clinical use,[200] it remains to be seen how best the complex ERBB signaling pathways can be therapeutically manipulated in the lung fibrosis arena.

■ Vascular Endothelial Growth Factor

Initially described as a growth factor for endothelial cells, vascular endothelial growth factor (VEGF) is highly expressed in many different lung cell types, and has important roles in lung development and maintenance of lung tissue integrity, through its angiogenic, lymphangiogenic, and hematopoietic roles.[201] VEGF is produced by endothelial cells, fibroblasts, neutrophils, PBMCs, and macrophages, and exists as any of five family members, VEGFA, B, C, D and placenta growth factor (PLGF); further diversity in biologic activity arises from various alternatively spliced isoforms of family members,[202] including VEGFA121, VEGFA145, VEGFA165, VEGFA189, and VEGFA206, named after the number of coded amino acids. Transcription of VEGF is induced by hypoxia, IL-1β, and many growth factors including platelet-derived growth factor, TGF-α and -β, insulin growth factor 1, fibrocyte growth factor, and FGF7 (keratinocyte growth factor). The VEGF family members have three different VEGF receptors, with VEGFA binding to VEGFR-1 and VEGFR-2. VEGFR-2 –/– mice have lethal defects in vasculogenesis and angiogenesis.[203] The role of VEGF in lung development is complex and can be highlighted by a number of observations. When embryonic murine lungs are cultured, VEGF expression, initially diffuse, is restricted over time and space to subepithelial matrix in the branching tips of the developing airways.[204] Furthermore, aberrant lung morphology has been shown to arise from targeted overexpression or underexpression of VEGF.[205,206] In bronchopulmonary dysplasia, the disease of prematurity and its attending interventions including supplemental oxygenation there was a demonstrable reduction in lung expression of VEGF, VEGFR-1 and Tie-2 associated with disrupted pulmonary vasculature.[207]

There is some evidence to suggest that VEGF may play a protective role in emphysema. Partial and transient inactivation of VEGF gene in murine lungs using an adeno-associated *Cre* recombinase virus and conditional VEGF knockout mice, VEGF*loxP*, resulted in apoptosis of alveolar and bronchial cells with ensuing air space enlargement and reduced elastic recoil, reminiscent of emphysema.[208] The low levels of VEGF expressed in human emphysematous lung[209] may be due to upstream factors that cause a reduction in expression of the major controller of VEGF expression, hypoxia-inducible factor (HIF)-1α in COPD lungs.[210]

VEGF and Pulmonary Hypertension

VEGF levels have been variably reported as increased, reduced, or unchanged in pulmonary hypertension with no consistent pattern emerging. However, studies directly examining the effect of inhibiting or stimulating VEGF receptors have produced a coherent picture. Blockade of VEGFR2 using small molecule inhibitors in rats aggravated hypoxic pulmonary hypertension, reduced pulmonary VEGFR2 expression, and increased endothelial cell apoptosis, suggesting that VEGFR2 was essential for maintaining and expanding the vascular bed in the hypoxic lung.[211] Moreover, even following return to normoxia and withdrawal of VEGFR2 blockade the pulmonary hypertension was progressive and ultimately fatal. After extended time periods in this model, complex plexiform-like lesions similar to those found in human PAH are observed.[212] Mice also show aggravation of hypoxic pulmonary hypertension in the presence of VEGFR2 blockade.[213] A mouse model of endothelial cell–specific ablative VEGFR-2 (*Kdr*) knockout in chronic hypoxic conditions led to pulmonary arterial wall thickening, muscularization, and VEGFR-3$^+$ endothelial cells obliterating the pulmonary artery vessel lumen.[214] Interestingly, pulmonary hypertension has occasionally been reported in patients receiving VEGF inhibitors such as bevacizumab as part of a cancer chemotherapy treatment program, where pulmonary vascular lesions similar to the Kdr-knockout have been seen.[214,215]

Overexpression of VEGFA in the rat lung using adenoviral vectors protected against the development of pulmonary hypertension, although no analysis of the capillaries and small intra-acinar vessels (<50 μg) was carried out so it is not possible to know if this protection was accompanied by angiogenesis.[216] Louzier et al. found that overexpression of VEGFB in the hypoxic rat lung using an adenoviral vector strategy protected against the development of hypertension and increased vessel density within the lung.[217] Thus, it is clear that the balanced actions of agonist and inhibitory members of the VEGF family are essential for normal adaptation of the pulmonary circulation to hypoxia, although the precise role of the VEGF pathway in human pulmonary hypertension is at present unclear.

■ Fibroblast Growth Factor

The fibroblast growth factor (FGF) family consists of 18 secreted polypeptide ligands that bind to one of four target cell-surface FGF receptors (FGFR), that are tyrosine kinase receptors (FGFR1–4), and that have many isoforms as a result of exon skipping and alternative splicing, the latter being generally tissue specific.[218] FGF subfamilies are grouped for their shared sequence homology and phylogeny. FGFs regulate diverse biologic processes including angiogenesis and organogenesis including proliferation, cell migration, and paracrine effects on tissue patterning. Two of the FGF ligands have particular relevance to the lung, both within the FGF subfamily including FGF7 (keratinocyte growth factor, KGF) and FGF10.[218,219]

FGF7 is expressed specifically by mesenchymal cells, including fibroblasts and vascular smooth muscle cells, and binds exclusively to the epithelial receptor FGFR2-IIIb, suggesting a paracrine loop effect in its epithelial–mesenchymal interactions. The use of a dominant-negative mutant to inhibit FGFR2-IIIb resulted in an absence of branching morphogenesis within the developing murine lung,[220] and FGF7 overexpression resulted in enlarged bronchial airspaces and papillary cystadenomas.[221] A variety of experimental data have indicated that FGF7 expression increases following acute lung injury and that FGF7 is protective, principally when used as a pretreatment, in the face of injury caused by varied insults including hyperoxia, radiation, graft-versus-host-disease following allogeneic bone marrow transplant, acid, and bleomycin,[219,222–224] but FGF7 may also partially prevent loss of barrier function in airway epithelium when given after an inciting exposure, potentially making FGF7 a more attractive therapeutic intervention were it so.[225,226] Notably, recombinant FGF7 (palifermin), which improves wound healing through cellular proliferation, is FDA-approved for the treatment of chemoradiation-induced oral mucositis.[227] In addition to FGF7, FGF10 plays a critical role in lung development, given that FGF10 −/− mice have defects in branching morphogenesis in lungs and other organs.[228] FGF10 overexpression attenuates bleomycin-induced pulmonary fibrosis in mice.[229] The triple angiokinase inhibitor nintedanib (BIBF 1120) inhibits VEGFR(1–3), platelet-derived growth factor receptors α and β, and FGFR1–3, and it slows decline in forced vital capacity—leading to its use in IPF, systemic sclerosis–associated interstitial lung disease, and other chronic fibrosing interstitial lung diseases with a progressive phenotype.[230,231]

■ Granulocyte Macrophage-Colony Stimulating Factor

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a glycosylated secreted protein produced by a variety of cells including macrophages, endothelial cells, T cells, natural killer cells, mast cells, and fibroblasts. It is defined by its ability to expand in vitro bone marrow precursor cells, via proliferation and differentiation, into colonies of mature myeloid cells, and to act as a proinflammatory cytokine.[232–234] Interest from the pulmonary field grew with the initial observation that mice lacking GM-CSF had no major perturbation of hematopoiesis, but had an unexpected finding of compromised maturation of alveolar macrophages resulting in a phenotype of pulmonary alveolar proteinosis (PAP), with defective clearing of surfactant by alveolar macrophages.[235] The major form of human PAP is classified as autoimmune (or primary) PAP, accounting for about 90% of all PAP cases.[236] Autoimmune PAP is characterized by abnormally elevated levels of GM-CSF IgG autoantibodies, which bind GM-CSF with high affinity and neutralize GM-CSF functionality, and it results in persistence of dysfunctional alveolar macrophages that are less efficient, with associated neutrophil dysfunction leading to opportunistic infections.[237] A heritable component to autoimmune PAP has been linked in Japanese subjects to HLA-DRB1*08:03, which is associated with increased levels of anti–GM-CSF antibody.[238] While whole-lung lavage remains the cornerstone of therapy for PAP, nebulized recombinant GM-CSF modestly improves lung function and functional health status and may facilitate some clearance of GM-CSF–antibody complexes from lung tissue.[239]

■ Connective Tissue Growth Factor

Connective tissue growth factor (CTGF) is a member of the structurally related CCN (*CTGF/CYR61/NOV*) gene family, which contains six genes: *CTGF*, *CYR61*, *NOV*, *ELM1*, *COP1*, and *WISP3*.[240] CTGF I is produced by vascular smooth muscle cells, fibroblasts, endothelial cells, and epithelial cells, and is activated by a number of factors, particularly TGF-β.[240] CTGF has in vitro activities that include fibroblast proliferation, fibroplasia, and extracellular matrix production.[240–242] Furthermore, its presence has been documented in skin lesions of systemic sclerosis, keloids, scar tissue, and eosinophilic fasciitis and in BALF from patients with IPF and sarcoidosis, and it induces ECM in asthmatic airway smooth muscle.[240–243] Transient overexpression of CTGF in a rat model leads to a moderate but reversible pulmonary fibrosis that is associated with increased levels of TIMP-1.[244] Overexpression of TGF-β leads to a concomitant increase in CTGF and TIMP-1, suggesting that CTGF may be a cofactor for the development of fibrosis.[244] CTGF may be responsible for some of the downstream actions of TGF-β and is a potential therapeutic target for the treatment of interstitial lung disease, now being targeted in IPF by the recombinant anti-CTGF antibody pamrevlumab in phase 3 clinical trials due to favorable tolerability and efficacy data to date in slowing disease progression.[245]

CONCLUSIONS

Chemokines, adipokines, and growth factors are now recognized to play fundamental roles in lung development, the lifelong maintenance of lung health, and the development of pulmonary disorders characterized by inflammation and/or fibrosis, some of which are modulated by body mass. The generation of complex, overlapping signaling networks is necessary for both the pathogenesis and resolution of a variety of acute and chronic lung diseases, as these mediators are fundamental to the initiation, maintenance, and final resolution of the inflammatory response. Studies that illuminate the mechanistic role of chemokines, adipokines, and growth factors in mediating lung inflammation are beginning to lead to novel targeted forms of therapies, which will significantly aid in treating enigmatic lung disease.

CHAPTER 25

Redox Signaling and Oxidative Stress in Lung Diseases

Jessy Deshane
Victor J. Thannickal

INTRODUCTION

Molecular oxygen is a prerequisite to life of all aerobic organisms. With its large surface area and extensive blood supply the human lung is engineered for its primary function in gas exchange. While oxygen is essential for its many roles in human physiology, high concentrations of oxygen or its metabolites, commonly referred to as reactive oxygen species (ROS), have the potential to cause cellular injury and contribute to disease pathogenesis. The most damaging forms of ROS are free radicals. A free radical, by definition, refers to any chemical species containing one or more unpaired electrons in their atomic or molecular orbitals. These unpaired electrons give considerable reactivity to free radical species, which can trigger chemical reactions that damage cellular constituents of living organisms. Molecular oxygen (dioxygen) is itself a radical based on the presence of unpaired electrons in its outermost orbital; however, their parallel spin retrains its reactivity. O_2 can form the superoxide anion radical ($O_2^{\bullet-}$) upon addition of an electron, thus overcoming this restraint and making $O_2^{\bullet-}$ a highly reactive species.[1,2] The photodynamic activation of oxygen can result in the formation of singlet oxygen, and its reductive activation results in the formation of hydrogen peroxide (H_2O_2) or the highly reactive hydroxyl radical ($^{\bullet}OH$).[3,4] When two free radicals share their unpaired electrons, nonradical species of lower reactivity are generated. Thus, ROS constitute both free radicals and nonradicals.

Nitric oxide ($NO^{\bullet}$) is another small gaseous molecule that serves as an important signaling molecule in diverse physiologic processes, including vasorelaxation and immune regulation during chronic inflammation in the lung.[5,6] The regulated production of $NO^{\bullet}$ by lung cells is critical for homeostasis of the lung. However, in some contexts, the reaction of $NO^{\bullet}$ with $O_2^{\bullet-}$ to form reactive nitrogen species (RNS), such as peroxynitrite ($ONOO^-$), may contribute to the pathophysiology of chronic lung diseases.[7–9]

ROS and RNS together play important roles in regulation of cell proliferation, differentiation, and survival.[10–12] ROS/RNS can inactivate enzymes including antiproteases, induce apoptosis, regulate cell proliferation, and modulate the immune-inflammatory system in the lungs and other tissues.[13–16] ROS/RNS have been implicated in initiating inflammatory responses in the lungs through the activation of transcription factors, protein kinase pathways, chromatin remodeling, and gene expression of proinflammatory mediators.[13–16] Under normal physiologic conditions, the balance between generation and elimination of ROS/RNS maintains the functional integrity of redox-sensitive signaling cascades regulating cellular phenotypes. In this context, it is important to differentiate the roles of ROS/RNS in "oxidative stress" from "redox signaling." Paradoxically, it appears that nature has co-opted the chemical reactivities of ROS/RNS to function as signaling molecules in homeostasis and normal cellular physiology.

Redox homeostasis of cells/tissues is maintained by the regulated balance of oxidant production and antioxidant systems, both enzymatic and non-enzymatic. However, an increase in oxidant generation in excess of the capacity of cells/tissues to detoxify or scavenge reactive species leads to oxidative stress.[10,17,18] Oxidative stress typically causes damage to cellular components in an indiscriminate manner. Such states are accelerated in the presence of transition metals, such as iron and copper, and/or specific monooxygenases or oxidases.[13,15,16] It is also important to recognize that aberrations in redox signaling or oxidative stress may contribute to the pathogenesis of lung diseases. In this chapter, we review the physiology of ROS and RNS; cellular antioxidant systems; and the role of oxidative stress and redox signaling in disease development and progression of selected chronic lung diseases.

METABOLISM OF REACTIVE OXYGEN/NITROGEN SPECIES (ROS/RNS)

Metabolism of reactive oxygen and nitrogen species includes consideration of enzymatic and non-enzymatic sources of ROS and RNS, mechanisms to detoxify these species, and a variety of cellular sources and regulation of ROS and RNS.

■ Enzymatic and Non-Enzymatic Sources of ROS

The primary ROS include superoxide anion ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($^{\bullet}OH$), which can be generated from both enzymatic and non-enzymatic sources. The human lung is constantly exposed to ambient air, which may contain environmental toxins capable of inducing ROS generation.[13,19] ROS may be also be generated by electron transfer reactions in the mitochondria and endoplasmic reticulum (ER), from xenobiotics, and a range of metabolic enzymes that catalyze oxidation reactions.[19] The major endogenous ROS/RNS and the primary mechanisms for their generation are summarized in Table 25-1.

TABLE 25-1 Key Reactive Oxygen and Nitrogen Species

Reactive Species	Formula	Chemical Reaction		
Superoxide	$O_2^{\bullet-}$	$NADPH + 2O_2$	$\longleftrightarrow$	$NADP+ + 2O_2^{\bullet-} + H^+$
		$2O_2^{\bullet-} + H+$	$\longrightarrow$	$O_2 + H_2O_2$
Hydrogen peroxide	H_2O_2	$Hypoxanthine + H_2O + O_2$	$\rightleftarrows$	$Xanthine + H_2O_2$
		$Xanthine + H_2O + O_2$	$\rightleftarrows$	$Uric\ acid + H_2O_2$
Hydroxyl radical	$^{\bullet}OH$	$Fe^2 + H_2O_2$		$Fe^{3+} + OH^- + {}^{\bullet}OH$
Hypochlorous acid	HOCl	$H_2O_2 + Cl^-$	$\longrightarrow$	$HOCl + H_2O$
Peroxyl radicals	$ROO^{\bullet}$	$R^{\bullet} + O_2$	$\longrightarrow$	$ROO^{\bullet}$
Peroxynitrite	$ONOO^-$	$O_2^{\bullet} + NO$	$\longrightarrow$	$ONOO^-$
		$H_2O_2 + NO_2^-$	$\longrightarrow$	$ONOO^- + H_2O$

The highly reactive $O_2^{\bullet -}$ formed by the addition of an electron to molecular oxygen is unstable, with a half-life of milliseconds. The major site for producing $O_2^{\bullet -}$ is the mitochondria, which is also the primary site for ATP generation in any cell. During mitochondrial electron transport, there is an estimated leak of 1%–3% of electrons to oxygen resulting in the formation of $O_2^{\bullet -}$.[16] $O_2^{\bullet -}$ generated in the mitochondria, due to its negative charge, does not cross membranes and is released into the mitochondrial matrix where it targets proteins with heme moieties or iron sulfur clusters to cause loss of protein or enzymatic function.[20] The steady-state levels of intramitochondrial $O_2^{\bullet -}$ concentrations are maintained at very low levels by detoxifying enzymes. ER is another intracellular compartment in which enzymes detoxify lipid-soluble drugs and other toxic metabolites, and reduce molecular O_2 to produce $O_2^{\bullet -}$ and/or H_2O_2, while oxidizing unsaturated fatty acids and xenobiotics.[19,20]

The NADPH oxidase (NOX) gene family encompasses enzymes, the primary function of which is the regulated generation of ROS. NOX enzymes form a membrane-bound multi-component complex that is present in phagocytes and nonphagocytic cells in the lung.[15,16,18] NOX enzymes play crucial roles in host defense, signal transduction, and hormone synthesis in eukaryotes. There are seven mammalian NOX homologs constituting NOX1–5 and DUOX1 and DUOX2.[21–24] The best-characterized NOX isoform is NOX2, which is essential for microbicidal killing activity of phagocytes. NOX2, upon activation, generates ROS by coordinated assembly and activation of the NOX2 enzymatic complex, which is composed of the membrane-associated flavocytochrome b558 ($gp91^{phox}$), $p22^{phox}$, and the various cytosolic cofactors ($p47^{phox}$, $p67^{phox}$, and $p40^{phox}$, and the GTPase Rac1). This complex then mediates the transmembrane electron transfer electrons from NADPH to molecular O_2 to generate $O_2^{\bullet -}$ or H_2O_2.[15,16,18]

Similar to NOX2, activation of NOX1 and NOX3 also requires association with $p22^{phox}$ and assembly with Rac 1 and cytosolic cofactors ($p47^{phox}$ and $p67^{phox}$ or their homologs, NOX organizer 1 [NOXO1] and NOX activator 1 [NOXA1]). NOX4 also requires $p22^{phox}$ but is constitutively active and is activated independently of other cofactors.[16,21–24] Expression of NOX1 and NOX4 in fibroblasts results in increased levels of both $O_2^{\bullet -}$ and H_2O_2, implying that these, unlike the phagocytic NOX2, possess intrinsic basal activity. NOX5 and DUOX1/2 differ from the other NOX homologs and contain additional intracellular Ca^{2+}-binding EF-hand domain regions, and are regulated by Ca^{2+} signaling.[16,21–24] The dual oxidases, DUOXs, are composed of the NOX-like region at the C-terminal half, two EF-hands, a membrane-spanning region, and a peroxidase-like domain at the N-terminus. DUOXs do not require cytosolic regulatory components for their activity.[16,21–24] However, the transmembrane maturation factors DUOXA1 and DUOXA2 are essential for ER-to-Golgi transition, maturation, and targeting DUOXs to the plasma membrane as functional complexes. Although initially identified in the thyroid gland, DUOX1 and DUOX2 are the primary sources of H_2O_2 production in the airway epithelium.[25] The NOX/DUOX isoforms are expressed widely in the lung extending from the proximal trachea and large airways to terminal bronchioles and alveoli[16,21–25] (Table 25-2).

TABLE 25-2 Enzymatic Sources for ROS and RNS

Enzyme	Distribution in Lung	Lung Cell Types
DUOX1, DUOX2, NOX2, NOX4	Trachea and upper airways	Airway epithelial cells
NOX1, NOX2, NOX4	Pulmonary vasculature	Pulmonary artery endothelial cells
NOX4	Pulmonary vasculature	Pulmonary artery smooth muscle cells
DUOX1, DUOX2, NOX2, NOX4	Lower airways/ alveolus	Airway epithelial cells
NOX3	Airway alveolus	Endothelial cells
NOX4	Airway alveolus	Myofibroblasts
NOX2, NOX4	Alveolar space/ blood	Monocytes, macrophages, neutrophils, eosinophils
NOS1 (neuronal)	Trachea, bronchus, airways	Airway epithelial cells Neutrophils Neurons
NOS2 (inducible)	Airways, alveolus, alveolar space/ blood	Airway and vascular smooth muscle cells Type II pneumocytes Fibroblasts Macrophages Monocytes Neutrophils Eosinophils Mast cells
NOS3 (endothelial)	Airways, pulmonary vasculature	Airway epithelial cells Type II pneumocytes Pulmonary artery smooth muscle cells Endothelial cells Macrophages

In biologic systems, dismutation reaction of $O_2^{\bullet -}$ generates H_2O_2, either spontaneously or by enzymatic catalysis by superoxide dismutases (SODs). $O_2^{\bullet -}$ can be generated by molybdenum hydroxylase reactions involving xanthine, sulfite and aldehyde oxidases, dihydroorotate and flavoprotein dehydrogenases, and tryptophan dioxygenases, as well as arachidonic acid metabolism.[26,27] Certain oxidases such as monoamine and amino acid oxidases can generate H_2O_2 directly without the intermediate formation of $O_2^{\bullet -}$.[17] During chronic inflammation in the lung, H_2O_2 is produced by both resident and inflammatory cells of the lung.[26,27] The oxidizing potential of H_2O_2 is amplified by inflammatory cell–derived heme peroxidases such as myeloperoxidase (MPO) and eosinophil peroxidase (EPO).[28–32] The hydroxyl radical, $^{\bullet}OH$, is the neutral form of the hydroxide ion, which is highly reactive towards cellular constituents, more so than $O_2^{\bullet -}$ or H_2O_2. This radical contributes to most of the reactivity by $O_2^{\bullet -}$ and H_2O_2 in a series of reactions that are catalyzed by transition metal ions. Excess $O_2^{\bullet -}$ targets Fe-S cluster-containing enzymes and catalyzes production of $^{\bullet}OH$ from H_2O_2 by reducing free iron (Fe^{3+} to Fe^{2+}) in a Fenton chemistry reaction (see Table 25-1). MPO and EPO enzymes represent an alternate pathway for $^{\bullet}OH$ formation in vivo. MPO uses Cl^- as substrate to generate hypochlorous acid, while EPO uses Br^- to generate brominating species. The hypohalous acids then generate $^{\bullet}OH$ by reaction with $O_2^{\bullet -}$.[33–38] Both these enzymes can accelerate oxidative modifications of proteins, in particular bromination and chlorination.

■ Enzymatic and Non-Enzymatic Sources of RNS

An important RNS in the lung is nitric oxide ($NO^{\bullet}$), which is endogenously generated by specific nitric oxide synthases (NOS). These NOS enzymes metabolize L-arginine to $NO^{\bullet}$ and L-citrulline via a five-electron oxidation reaction.[6,39–48] This reaction requires a dimeric enzyme, oxygen, NADPH, and the co-factors flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), tetrahydrobiopterin (BH_4), calmodulin, and iron protoporphyrin. Active NOS enzymes exist in the dimeric form with each monomer consisting of an N-terminal oxygenase domain that binds heme, BH_4, and substrate L-arginine. The cofactors FAD, FMN, and NADPH bind the C-terminal end of the NOS monomer. There are three different NOS isoforms, all of which are expressed in the lung, the inducible form iNOS or NOS2, neuronal NOS or NOS1, and the endothelial NOS enzyme NOS3 (Table 25-2).

The NOS1 and NOS3 enzymes are calcium dependent and produce picomolar levels of NO, while nanomolar levels are generated by the calcium-independent iNOS. $NO^\bullet$ synthesis by iNOS is regulated by the availability of the substrate L-arginine and cofactor BH_4. Transfer of electrons occur from the carboxy-reductase domain to the heme iron of the oxygenase domain, which then binds oxygen and oxidizes L-arginine to generate the end-products, $NO^\bullet$ and citrulline.[6,39–48] Uncoupling of NOS enzymes can contribute to the formation of $O_2^{\bullet-}$ from NADPH oxidation under low arginine conditions. Arginase, an enzyme that competes with the NOSs for L-arginine, decreases the arginine availability for NOS. Arginase is a critical enzyme in the urea cycle and converts arginine to ornithine, and then to urea; it can promote uncoupling of NOSs to generate $O_2^{\bullet-}$.[49,50] About 40% of the highly reactive and highly diffusible $NO^\bullet$ is consumed in chemical reactions and, when metabolized, gives rise to reactive intermediates. $NO^\bullet$ reacts with O_2 yielding nitrite (NO_2^-), and recycling of nitrite causes regeneration of bioactive $NO^\bullet$. NO_2^- is also a substrate for the heme peroxidases MPO and EPO, which oxidize nitrite to nitrogen dioxide radical ($NO_2^\bullet$). $NO^\bullet$ is also oxidized to methemoglobin and NO_3^- by reaction with oxyhemoglobin. $NO^\bullet$ reacts with $O_2^{\bullet-}$ to form peroxynitrite ($ONOO^-$), which mediates tyrosine nitration that may result in either the loss or gain of function of proteins.[7–9,51]

In acidic environments, the protonation of $ONOO^-$ results in the formation of ONOOH (peroxynitrous acid), which is then decomposed to both NO_3^- via intermediate $^\bullet OH$ and NO_2.[52] ONOOH can also react with thiol residues to form S-nitrosothiols, and the reaction is referred to as S-nitrosation or S-nitrosylation. A wide variety of proteins including kinases, ion channels, and transcription factors are susceptible to S-nitrosylation. S-nitrosothiols (SNOs) are important molecules in the signaling of $NO^\bullet$ bioactivity in the respiratory system.[53–57] SNOs are present in the airway epithelial lining fluid in μmol concentrations, can influence airway tone, and possess substantially greater half-lives than $NO^\bullet$ in the lung. It has also been reported that iNOS can specifically bind to cyclooxygenase 2 (COX-2) and S-nitrosylate COX-2, upregulate its catalytic activity, and enhance prostaglandin E2 production. Thus, S-nitrosylation represents an important signaling pathway for $NO^\bullet$.[53–57] Under physiologic conditions, interaction with metal centers of enzymes and S-nitrosylation are the major mechanisms for biologic actions of $NO^\bullet$. In biologic systems, the levels of $O_2^{\bullet-}$ are in the 10^{-11} to 10^{-10} M range, while that of NO is 10^{-9} to 10^{-7} M. Under these conditions, $ONOO^-$ is formed at a low rate by the reaction of $NO^\bullet$ with $O_2^{\bullet-}$ with a 1:1 stoichiometry.[7–9,51,53–57] However, under pathophysiologic conditions, $ONOO^-$ and its derivatives are formed at high levels and may cause irreversible damage to the mitochondrial electron transport chain, inhibit ATP synthesis, and induce cytochrome c release and caspase-dependent apoptosis. RNS also mediate lipid peroxidation, protein oxidation and nitration, enzyme inactivation, and even cell necrosis.[7–9,51,53–57]

■ Mechanisms to Detoxify ROS/RNS

ROS/RNS play a key role in the initiation, amplification, and persistence of inflammation associated with chronic lung diseases.[15–18,58,59] Similar to the formation of ROS/RNS, the removal or detoxification of these species may involve enzymatic and non-enzymatic mechanisms. Non-enzymatic systems constitute the first line of defense against ROS/RNS.

The low-molecular-weight non-enzymatic antioxidants in the lung include glutathione, vitamins C and E, beta-carotene, uric acid, thiols, and taurine. The larger-molecular-weight antioxidants include lactoferrin, albumin, ceruloplasmin, and transferrin; these molecules mediate their antioxidant function primarily by binding heavy metals, making them unavailable for participation in the Fenton reaction to produce free radicals such as hydroxyl radical.[15,18,26,59,60] Non-enzymatic antioxidant activities may also include hydrophilic quenching of free radicals and protection of critical sulfhydryl groups on proteins to inhibition of lipid peroxidation.

Although non-enzymatic antioxidants are the first line of defense against different ROS, several enzymatic antioxidants work in concert with non-enzymatic antioxidants to form a tightly regulated antioxidant network. The major components of the pulmonary enzymatic antioxidant defense systems are SODs, catalase, and glutathione peroxidases. Peroxiredoxins, thioredoxins, glutaredoxins, heme oxygenases, and reductases also are involved in cellular adaptation and protection against oxidative stress in the lung. The enzymatic reactions that catalyze the elimination of ROS/RNS are summarized in Fig. 25-1.

Superoxide Dismutases

The $O_2^{\bullet-}$ radical is a primary oxidant in chronic lung inflammation.[15,17,61] It participates in the generation of other reactive metabolites, H_2O_2, $^\bullet OH$, and $ONOO^-$. SODs represent a key defense against reactive species generated during normal metabolism or inflammatory states. SODs are ubiquitous enzymes that catalyze the dismutation of $O_2^{\bullet-}$ radical to the weaker oxidant, H_2O_2 (see Fig. 25-1). The function of SOD extends beyond its catalysis of $O_2^{\bullet-}$ dismutation to its participation in the regulation of normal cellular homeostasis. H_2O_2 formed from the SOD-catalyzed reaction may function as a signaling molecule at low concentrations. By reducing steady-state concentrations of $O_2^{\bullet-}$, which reacts with $NO^\bullet$ to form $ONOO^-$, SOD may serve to promote vasoreactivity and reduce inflammation.[15,61]

There are three mammalian SOD isozymes: the intracellular copper-zinc SOD (CuZn-SOD), the mitochondrial manganese SOD (Mn-SOD), and extracellular SOD (EC-SOD).[61] The structural and catalytic characteristics of these SOD isozymes are highlighted in Table 25-3.[62–65] Given the complexity of the human lung with its plethora of different cell types, it is conceivable that these isozymes are expressed differentially in specific lung cells with subcellular compartmentalization, as summarized in Table 25-4.[66–79]

Figure 25-1 Enzymatic mechanisms to detoxify reactive oxygen and nitrogen species.

TABLE 25-3 Characteristics of Superoxide Dismutases

SOD	Structure	Metal Ions	Type of Enzymatic Activity	Intracellular SOD Activity
Mn-SOD	Homotetramer	Mn and Zn	$O_2^{\bullet -}$ Dismutation	10%
CuZn-SOD	Homodimer	Cu and Zn	$O_2^{\bullet -}$ Dismutation Peroxidation Nitration	90%
EC-SOD	Homotetramer	Cu and Zn	$O_2^{\bullet -}$ Dismutation Peroxidation	0%

Aside from dismutating $O_2^{\bullet -}$ radical by the cyclic oxidation-reduction of its metal ion Cu^{2+}, CuZn-SOD exhibits peroxidase activity.[65] At high levels, H_2O_2 may reduce the Cu^{2+} to either Cu^{+}-O or Cu^{2+}-OH that may oxidize the histidine residue in the monomer and inactivate or oxidize lung proteins.[80–82] CuZn-SOD also nitrates tyrosine residues in proteins via peroxynitrite[83–87] and catalyzes the release of NO from nitrosothiols.[88] Although Mn-SOD has similar dismutase activity, it does not elicit peroxidation or nitration, and it is inactivated by tyrosine nitration but not by hydrogen peroxide or cyanide.

EC-SOD is the primary extracellular SOD in the lung.[72,89,90] The EC-SOD has an active site that can be inhibited by H_2O_2 and cyanide, similar to CuZn-SOD.[74–76] EC-SOD has an arginine- and lysine-rich heparin/matrix binding domain at its C-terminal region.[91–94] Its extracellular localization is maintained by the interaction of this domain with heparin and heparin sulfate proteoglycans on diverse lung cell types and in the extracellular matrix (ECM) of the lung. This heparin/matrix binding polybasic region is sensitive to proteolysis, leading to reduced affinity of EC-SOD for ECM and increased release of EC-SOD in plasma.[72,91–97] EC-SOD is abundant in the lung at both the mRNA and protein levels.[91–94] As indicated in Table 25-4, the wide cellular distribution of EC-SOD is consistent with robust EC-SOD activity in the human lung (8-fold > liver, 6-fold > brain, 2- to 3-fold > heart, and 1- to 2-fold > kidney).[61] In comparison, CuZn-SOD and Mn-SOD activities are much lower. The lower activities of CuZn-SOD and Mn-SOD in the lung suggest that cytoplasmic production of $O_2^{\bullet -}$ is lower in lung cells, compared with the metabolically more active cells of the liver and kidney. The dense airway and vascular network in the lung and the higher potential for extracellular inflammatory events resulting from direct exposure of the lung to the external environment may account for high EC-SOD levels in the lung. Even with its high lung localization, EC-SOD is not present at sufficient concentrations to justify its role as the sole scavenger of $O_2^{\bullet -}$ across the entire extracellular space. While CuZn-SOD and Mn-SOD function mainly as bulk scavengers of the $O_2^{\bullet -}$ radicals, the relatively high levels of EC-SOD in the lung and its binding specificity to the ECM components provide protection for the lung matrix.[14,98]

The lack of abnormalities in CuZn-SOD-deficient mice suggest that pathologic consequences of mutations are perhaps due to gain of compensatory functions of the enzyme, including its peroxidase or nitration reactions, and not associated only with the complete loss of SOD activity.[97,99] EC-SOD-overexpressing mice were only partially protected from hyperoxia-induced lung injury, influenza, bleomycin, and hemorrhagic shock,[14,61,98] suggesting that EC-SOD may not be sufficient to attenuate oxidative stress in pathologic states in which

TABLE 25-4 Enzymatic Mechanisms to Detoxify or Remove ROS/RNS

Antioxidant Enzymes	Acronym	Expression of Antioxidant Enzymes in Lung Cell Types	Cellular Distribution
Superoxide Dismutase	SOD		
MnSOD		Alveolar type II epithelial cells, septal tip of the alveolar duct, arterioles near the airways, aveolar macrophages	Mitochondria
EC-SOD		Bronchial epithelium, alveolar epithelium, epithelial cells lining intrapulmonary airways, ECM, endothelial cells lining arteries and veins, alveolar macrophages	Plasma membrane
CuZnSOD		Bronchial epithelium, alveolar epithelium, mesenchymal cells, fibroblasts, arterioles, capillary endothelial cells	Cytosol, nucleus, lysosome, peroxisomes
Catalase	CAT	Airway and alveolar epithelial cells, type II pneumocytes, alveolar macrophages	Peroxisomes, mitochondria
Glutathione peroxidase 1	GSH-Px	Airway epithelial cells, bronchial epithelial cells, alveolar macrophages	Cytosol, mitochondria
Thioredoxin	TRX1 & 2	Bronchial epithelium, alveolar epithelium, macrophages	Cytosol, mitochondria
Thioredoxin peroxidase	TRXPrx	Bronchial epithelial cells, type II pneumocytes, macrophages	Cytosol
Thioredoxin reductase	TRR	Bronchial epithelium, alveolar epithelium, macrophages	Cytosol, mitochondria
Glutaredoxin	Glrx	Bronchial epithelium, alveolar macrophages	Plasma membrane, cytoplasmic vacuoles, nucleus
Glutathione S transferase	GST	Bronchiolar Clara and alveolar type II cells, bronchial epithelial cells	Plasma membrane, cytosol, microsomes, mitochondria
Peroxiredoxin	PRX	Bronchial epithelium, alveolar epithelium, macrophages	Cytosol, nuclear matrix, peroxisomes, mitochondria
Heme oxygenase	HO	Alveolar type II cells, lung fibroblasts, monocytes, alveolar macrophages	Microsomes, mitochondria, endoplasmic reticulum

the EC-SOD system is overwhelmed. Under hyperoxia, mice lacking EC-SOD show shortened survival and extensive lung damage.[14,61,98] Thus, although other antioxidant enzymes may compensate for the loss of EC-SOD under homeostatic conditions, during inflammatory stress, EC-SOD is essential for protecting the lung and limiting injury. More than 90 genetic polymorphisms have been identified in CuZn-SOD, several in association with neurodegenerative diseases.[62] The Arg 213-gly polymorphism in EC-SOD (R213G) is found in 4% to 6% of the human population and influences chronic obstructive pulmonary disease[100,101] and acute lung injury.[102]

Catalase

H_2O_2 is reduced to water by catalase (CAT) and the glutathione peroxidases (Fig. 25-1). CAT is a metalloprotein oxidoreductase enzyme widely expressed in lung cells[103–107] (see Table 25-4). In the presence of excess H_2O_2, CAT undergoes alternate divalent oxidation and reduction at its heme-containing active site. Catalase degrades H_2O_2 to O_2 and water.[103–107] Although catalase is the principal scavenger of H_2O_2, it is unable to metabolize large molecular peroxides including lipid peroxides. The gene for catalase is not induced by oxidant stress. However, post-translational tyrosine phosphorylation of CAT upregulates its activity,[108] whereas oxidation of tyrosine residues inhibits CAT activity.[8]

Glutathione Peroxidases

Glutathione peroxidases (GSH-Pxs) are selenocysteine-containing tetrameric enzymes that utilize reduced glutathione (GSH), a low-molecular-weight tripeptide, as an electron donor and catalyze the biotransformation of various organic and inorganic peroxides, including H_2O_2 and lipid peroxides, to their corresponding alcohols. The detoxification of peroxides by GSH-Pxs occurs via bidirectional second-order kinetics and is a saturation-limited process.[26,109] GSH-Px1, GSH-Px2, GSH-Px3, and GSH-Px4 are the four glutathione peroxidases.[26,109] GSH-Px1 is a ubiquitous intracellular form and is the predominant isoform that catalyzes the removal of inorganic peroxides and lipid peroxides hydroperoxides.[26,109–112] GSH-Px-2 is localized to the gastrointestinal epithelia with substrate specificities similar to that of GSH-Px1. GSH-Px3 is a secreted form able to reduce lipid hydroperoxides.[111,112] This extracellular isoform accounts for 57% of the GSH-Px activity in the epithelial lining fluid, and GSH-Px-1 contributes 40%.[111,112] The fourth isoform, GSH-Px-4, is an intracellular peroxidase that preferentially catalyzes the peroxidation of phospholipid hydroperoxides.[110]

Thioredoxins

Thioredoxins (TRXs), which contain an active site cysteine, serve as redox sensors while also reducing H_2O_2.[113,114] H_2O_2 oxidizes the reduced dithiol group (-SH HS-) in TRX to a disulfide bridge (-S-S-). TRXs can reduce protein disulfides (-SH) and protein sulfenic acid intermediates (-SO_3H) by cysteine thiol-disulfide exchanges.[10,11] Two human TRXs are expressed widely in various lung cell types (see Table 25-4). In addition to its direct antioxidant function, TRX, in cooperation with peroxiredoxins, augments gene expression of other antioxidant enzymes, including SOD.[115–119] TRXs also participate in refolding of oxidized proteins and activate transcription factors by reducing cysteines present in the DNA binding site.[120] TRX can be activated by hypoxia, lipopolysaccharide, H_2O_2, microbial infections, and photochemicals. Thus, TRXs are powerful redox modulators, protect cells against oxidative stress, and participate in cell proliferation and survival.[115–119]

Glutaredoxins

Glutaredoxins (GRX) are thiol-disulfide oxidoreductases with antioxidant capacity in human lung[18,121–124] (see Table 25-4). GRX regulates cellular redox state and redox-dependent signaling pathways via modulation of protein glutathionylation; it regulates the intracellular and extracellular homeostasis of glutathionylated proteins and GSH.[18,121–125] These enzymes use glutathione as a cofactor and catalyze the reversible exchange of glutathione with protein thiol groups (see chemical reactions, Table 25-2). GRX enzymes are dependent on GSH/GSSG concentrations.[126]

Glutathione-S-Transferases

Glutathione-S-transferases (GSTs) are detoxification enzymes that require intracellular GSH for their catalytic activity. These antioxidant enzymes inactivate secondary metabolites, such as unsaturated aldehydes, epoxides, and hydroperoxides.[127] Three major families of GSTs have been described: the cytosolic GST, mitochondrial GST, and membrane-associated microsomal GST[60] (see Table 25-4). GSTs regulate eicosanoid and glutathione metabolism.[60,128] Under conditions of oxidative stress, cytosolic GST interacts with peroxiredoxins.[127] GST family enzymes are expressed in normal lung, mainly in the airways. They protect cells against a number of oxidizing species. GSTs have high genetic variability and are implicated in the development of smoking-related nonmalignant and malignant diseases.[60,129–132]

Peroxiredoxins

Peroxiredoxins (PRXs) are broad-spectrum peroxidases that detoxify or reduce H_2O_2, peroxynitrite, and organic hydroperoxides (ROOH).[133,134] These are nonseleno-peroxidases whose antioxidant properties are dependent on redox-active cysteines.[134] Six different PRXs have been found in human lung[135,136] (see Table 25-4). These PRXs differ widely in their specificities for H_2O_2 and lipid and phospholipid hydroperoxides.[135–139] PRX V and VI function as peroxynitrite reductases and are protective in ROS/RNS-mediated lung injury.[135–137,140,141] PRXs also regulate peroxide-mediated signaling cascades related to cell proliferation, differentiation, and apoptosis by modulating cytokine-mediated induction of H_2O_2.[18,134,138,139]

Heme Oxygenases

Heme oxygenase (HO) catalyzes the breakdown of pro-oxidant heme to generate equimolar amounts of carbon monoxide, ferrous iron, and biliverdin (Fig. 25-1). Biliverdin is then converted by biliverdin reductase to bilirubin, the antioxidant end-product of the HO reaction.[142–145] CO transported to the lung has vasodilatory and antiapoptotic properties.[146–151] Iron is used for heme synthesis in the cells required for heme-containing proteins or transported to the bone marrow and other tissues.[18,142,145,152,153] There are three isoforms of HO: the inducible HO-1 and the constitutive forms, HO-2 and HO-3. During oxidative stress, transcriptional activation results in rapid induction of HO-1.[142,145,146] This adaptive response of HO-1 confers protection during inflammation and oxidative stress. HO-1 is expressed widely in the lung (see Table 25-4). Consistent with the antioxidant properties of HO-1, mice deficient in HO-1 are more susceptible to oxidative stress.[154,155] Overexpression or induction of HO-1 suppresses inflammation in several models of chronic lung disease.[18,142,145,152,153]

■ Cellular Sources and Regulation of ROS/RNS

Cellular sources of ROS/RNS include immune cells, epithelial cells, endothelial cells, and fibroblasts.

Immune Cells

Inflammation is an adaptive response to infectious and noninfectious tissue injury. Recruited inflammatory cells emigrate from the pulmonary microcirculation into the airspaces where they become activated to generate ROS/RNS.

$NO^\bullet$ participates in pathogen killing by macrophages.[156] $NO^\bullet$ also delays fusion of phagosomes with lysosomes to form a functional phagolysosome, which enhances antigen processing/presentation of macrophages. Macrophages scavenge endogenous dying cells. Phagocytosis of dying cells requires the secretion of alarmins by dying cells to attract and pre-activate phagocytes; these signals by dying cells ensure specific recognition and phagocytosis/efferocytosis, all of which involve redox regulation.[157,158]

Beyond the chemical interactions of $NO^\bullet$ and ROS that cooperatively eradicate pathogens, these redox-active biomolecules regulate cellular metabolism, inflammation, and tissue repair functions. Cellular supply of substrates/cofactors for iNOS activity, including arginine, is required for $NO^\bullet$ production. However, in the absence of arginine or BH4, uncoupled NOS becomes a $O_2^{\bullet-}/H_2O_2$ generator. The flavin-binding sites of the reductase domain of iNOS, eNOS, and nNOS are a source of $O_2^{\bullet-}$ generation in the absence of arginine.[156,159–162] Therefore, metabolic pathways that control arginine and BH4 play a role in determining $NO^\bullet$ – $O_2^{\bullet-}$ balance. Cellular arginine levels are dependent on uptake and transport mechanisms and the activation of NOS-arginase enzymatic systems that use arginine. Arginase activation produces ornithine, a starting metabolite for the production of polyamines that are critical molecules supporting DNA stabilization, ion channel transport, and cell proliferation.[156,159–162] Arginase is regulated by NOS and NOX activities; N-hydroxyarginine, a product of NOS, inhibits arginase, while $O_2^{\bullet-}$ increases arginase activity.[156,159–162] High arginase activity is associated with elevated ROS and low $NO^\bullet$ fluxes. $NO^\bullet$ antagonizes NOX2 assembly through the activation of PPARγ, which, in turn, inhibits expression of the p47 subunit required for NOX2 activation.[156,159–162] Thus, $O_2^{\bullet-}$ production is suppressed when NOS activity and $NO^\bullet$ levels are high. $NO^\bullet$ also inhibits COX2 activity, reducing COX2-dependent ROS production.[163] Thus, as $NO^\bullet$ levels decline, ROS generation may increase via multiple mechanisms.

The balance between $NO^\bullet$ and ROS may play a key role in the orchestration and resolution of inflammation. RNS and ROS actively control innate and adaptive immune signaling. This aspect of redox function is evident in cells of myeloid lineage, such as monocytes, macrophages, and neutrophils. RNS and ROS produced by these cells participate in induction, maintenance, and/or termination of proinflammatory and anti-inflammatory signaling. Similar to the effect of $NO^\bullet$ on pathogen eradication, the temporal and spatial concentration profiles of $NO^\bullet$ are key determinants of immune-mediated processes.[156,159–162] A relationship between increasing steady-state levels of $NO^\bullet$ has been linked to regulation of expression of tumor suppressor gene p53 and apoptosis in murine and human macrophage cell lines.[164,165] Concentration- and time-dependent changes in the functional profiles of $NO^\bullet$ are evident from NO-mediated regulation of cell survival protein signaling cascade.[166–170]

Macrophages rely primarily on the NOX2 complex to produce ROS,[5,17,158,169] although the oxidative burst of macrophages is less intense than that of neutrophils. Induction of the proinflammatory phase of an innate immune response is an early response in the immune activation process. This is defined as "classic activation" in macrophages (also called M1 macrophages) and is associated with the production and release of proinflammatory cytokines, proteases including MMP-9, and transcription factors such as NF-κB, as well as RNS and ROS, including $NO^\bullet$ and $O_2^{\bullet-}$. In addition to a role in pathogen eradication, the localized levels of ROS/RNS may dictate integrated signaling and the type of immune activation and determination of cellular phenotypes; ROS/RNS may also regulate cross-talk between proinflammatory and resolution pathways. Classic (proinflammatory) activation of macrophages is followed by an anti-inflammatory healing/tissue repair phase, which is the ideal outcome of a successful innate immune response. These phases of the innate immune response are initiated by the pathogens or tissue injury, but are rapidly re-enforced by the actions of anti-inflammatory cytokines released from macrophages that function in an autocrine manner.[158,159,171–173] These cytokines initiate downregulation of the proinflammatory phase and induction of the repair or tissue remodeling phase.

$NO^\bullet$ also affects function of T lymphocytes.[156,174–177] Low $NO^\bullet$ concentrations promote differentiation of IFN-γ-producing Th1 (T helper 1) in mice and humans, mediated by cGMP activation.[178] During the immune repair/restoration phase, the collective activity of IL-4, IL-13, IL-10, and TGF-β suppress iNOS expression, thereby decreasing $NO^\bullet$ and shifting in favor of ROS.[156,174–178] A $NO^\bullet$-independent role for arginase has been identified in the differentiation of alternatively activated macrophages. Although arginase expression in macrophages is prominently associated with Th2 responses, part of its function is to sequester arginine away from effector T cells resulting in a reduced Th2 response; reconstitution with exogenous arginine blocks this reduced Th2 response. In general, low $NO^\bullet$ favors Th2 responses, and high $NO^\bullet$ augments Th1 responses, suggesting that a $NO^\bullet$/ROS balance may be a critical determinant of immune polarity.[156,179,180] Naïve lymphocytes exposed to high-μM concentrations of $NO^\bullet$, however, regulate the expansion and proliferation of regulatory T cells within lymphoid tissue.[156]

This concentration-dependent regulation by $NO^\bullet$ is seen in immunosuppression by heterogeneous immature myeloid cells called myeloid-derived suppressor cells (MDSCs).[181,182] Free radical–producing subsets of these MDSCs are critical regulators of allergic airway inflammation.[183,184] $NO^\bullet$-producing cells suppress T cell proliferation and airway hyper-responsiveness (AHR), while $O_2^{\bullet-}$ enhances T cell proliferation and exacerbates AHR.[183,184] Immunosuppression by MDSCs also occurs in the tumor microenvironment, in which $NO^\bullet$-mediated increase in cGMP activation facilitates their binding to cytotoxic lymphocytes to reduce their proliferation.[185,186] Peroxynitrite and H_2O_2 are produced by the combined and cooperative activities of NADPH oxidase, arginase, and iNOS in different MDSC subsets. These drive several molecular blocks in T cells, including the loss of TCRζ-chain expression, interference with IL-2 receptor–mediated signaling and nitration, and subsequent desensitization of the TCR.[185,186] Signal transducer and activator of transcription 3 (STAT3) is a critical regulator of MDSC. STAT3-mediated upregulation of the NADPH oxidase and ROS levels enhances the suppressive potential of MDSCs.[156,185,186]

Inflammasome activation is an innate immune response to pathogens, but it also accompanies the development of autoimmune and chronic inflammatory diseases. Inflammasomes are multicomponent platforms that sense a variety of danger signals, including bacteria, viruses, and pathogenic crystals; they aggregate through a family of Nod-like receptors and consist of caspase 1 to process proinflammatory cytokines for activation.[187–189] Inflammasome activation starts with a priming signal followed by an activation signal. Studies with ROS scavengers suggest a role of ROS in inflammasome activation.[187–191]

Epithelial Cells

The epithelium of the airways and the alveoli is exposed to high levels of oxygen and to other environmental oxidizing species. Although inflammatory cells are major producers of RNS/ROS, resident lung cells such as epithelial cells possess enzymatic systems for regulated production of RNS and ROS. DUOX enzymes are the primary contributors of H_2O_2 in the airway epithelium.[25,192] DUOXs are expressed in ciliated surface cells, but not in nonciliated cells or basal cells of the upper airway. The levels of expression of DUOX1 and DUOX2 are selectively regulated by cytokines, with Th1 cytokines regulating DUOX2 and Th2 cytokines regulating DUOX1.[19,21,193,194] The highly inducible DUOX2 mediates host responses to infection and inflammation, while DUOX1 is constitutively expressed in non-inflamed airways; DUOX2 plays a role in innate immunity, cell signaling, and mucus production.[19,21,193,194] The airway epithelium participates in innate immune response through the secretion of immune effectors such as mucin, antimicrobial peptides, and ROS to entrap or kill invading microbes. Epithelial cells use microbial pattern recognition receptors for innate immune system recognition to discriminate self from non-self.[19,21,193,194] The release of cytokines/chemokines by the epithelium induces neutrophil recruitment and the activation of transcription factors augmenting the inflammatory response. Lactoperoxidase (LPO), a heme-containing peroxidase, in concert with DUOX-generated H_2O_2 generates hypohalous acids that kill pathogens.[25,195] A functional difference between the airway DUOX/LPO system and the phagocytic NOX2/MPO system is that the phagocytic system is active only during the respiratory burst, whereas DUOX generates H_2O_2 continuously.[19,21,193,194]

Endothelial Cells

Endothelial cells (ECs) also participate in innate immunity and crosstalk with immune cells. The importance of ECs in inflammation-induced vascular dysfunction is dependent on their ability to produce and respond to ROS and RNS. Inflammation may alter the balance between $NO^\bullet$ and $O_2^{\bullet-}$ within and surrounding ECs, which is necessary for normal vascular function. ROS produced by the endothelium play an important role in vascular pathology.[196,197] ROS can quench $NO^\bullet$ and mediate proinflammatory signaling. Targeting ROS-quenching enzymes catalase and SOD in ECs alleviates toxic effects of excessive ROS and suppresses proinflammatory mechanisms, including endothelial cytokine activation and barrier disruption.[198–200] Pulmonary EC-derived ROS play a pivotal role in EC activation and function. Alterations in EC phenotype contribute to vascular tone, permeability, and inflammatory responses and, thus, have been implicated in lung diseases, including pulmonary hypertension, ischemic-reperfusion injury, and adult respiratory distress syndrome.[201–203] Contrasting effects of NOS isoforms occur during ischemia reperfusion (IR) injury, where eNOS appears to be protective and iNOS detrimental. Under homeostatic conditions, the low NO flux generated by eNOS prevents leukocyte recruitment and associated tissue damage through scavenging of ROS. However, when iNOS expression increases, $NO^\bullet$ levels rise and induce tissue injury.[201–203] Thus, the beneficial effects of specific NOS isoforms depend on the type of primary damaging event.

Fibroblasts

Fibroblasts and fibroblast-like mesenchymal cells participate in innate immunity and in tissue repair. Such cells are typically resident within the adult human lung;[204] however, studies have reported fibroblast-like cells derived from bone marrow cells[205] or epithelial cells, the latter in a process known as epithelial-to-mesenchymal transition (EMT).[206] EMT is a process that allows epithelial cells to lose their polarity and specialized junctional structures, to undergo cytoskeletal reorganization, and to acquire morphologic and functional features of mesenchymal cells. Myofibroblasts are the primary "effector" cells in tissue remodeling and pulmonary fibrosis.[207–209] Activation of the NADPH oxidase isoform, NOX4, mediates generation of H_2O_2, myofibroblast differentiation, contractility, and extracellular matrix production in response to TGF-β1.[210] Additionally, NOX4 may play a profibrotic role by inducing apoptosis of lung epithelial cells, while myofibroblasts themselves acquire an apoptosis-resistant phenotype. Epithelial cell death may also be mediated indirectly by the paracrine secretion of H_2O_2 by activated myofibroblasts, supporting the concept that NOX4 may be responsible for both myofibroblast activation and epithelial cell disrepair.[211]

OXIDATIVE STRESS IN VARIOUS LUNG DISORDERS

Below we consider oxidative stress in a variety of common clinical disorders, including asthma, emphysema, pulmonary fibrosis, pulmonary hypertension, and acute respiratory distress syndrome (ARDS) (Fig. 25-2).

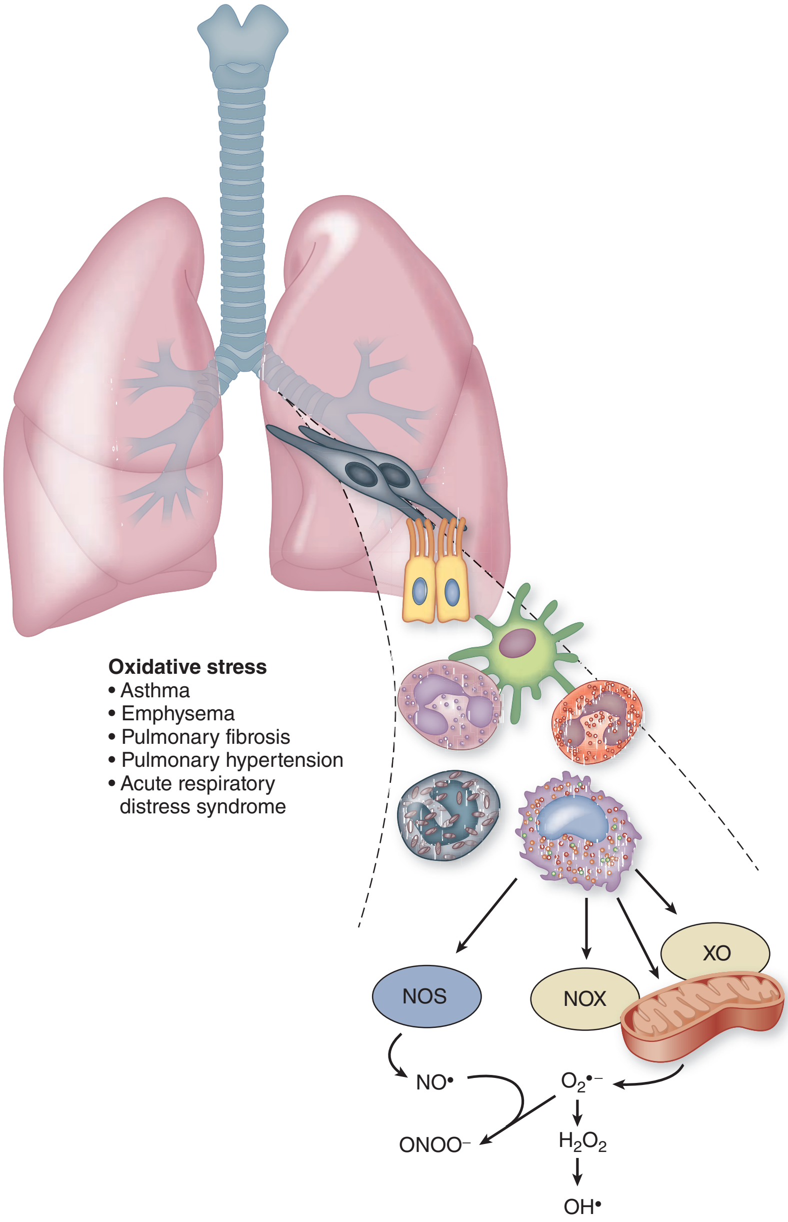

Figure 25-2 Oxidants initiate a number of pathologic processes with a multitude of complex mechanisms that contribute to pathogenesis of both acute and chronic inflammatory diseases of the lung. Resident lung cells and recruited inflammatory cells together orchestrate these multilevel processes by regulating enzymatic pathways to balance the generation and metabolism of oxidants.

Asthma

Asthma is a chronic inflammatory airway disease.[212,213] ROS and RNS have been implicated in the pathogenesis of asthma.[20,214–217] Dysregulation in pathways that leads to oxidative stress or its defense may contribute to the initiation and severity of asthma.[8,20,214–219] Recruitment of inflammatory cells and ROS production have been documented in the airways of asthmatic subjects.[20,113,215,220–223] $O_2^{\bullet -}$ generation was observed highest in airspace cells at the sites of antigen challenge.[214] Leukocyte activation with induction of NADPH oxidase and production of $O_2^{\bullet -}$ and H_2O_2 correlate negatively with FEV_1 in asthmatic subjects.[223] Besides airway macrophages and eosinophils, blood eosinophils and monocytes also are major sources of ROS in asthmatic patients.[214,219,224]

Airway inflammation–associated oxidative stress in asthma may induce oxidative modifications of proteins or lipids.[89,90,225] Increased numbers of eosinophils and neutrophils, in association with higher expression of peroxidases and other markers of eosinophil activation, are found in BAL and bronchial tissues of asthmatics.[226,227] Oxidant products of neutrophil/eosinophil activation, 3-bromotyrosine, and MPO-mediated oxidants such as chlorotyrosine are increased in asthmatics compared with control subjects; these have been implicated in the pathophysiology of severe asthma.[228,229] Other reactive products including malondialdehyde, thiobarbituric acid reactive products, and 8-isoprostane, a biomarker of lipid peroxidation, also are elevated in exhaled breath condensates of adults and children with asthma.[230–235] The precise mechanisms by which ROS exacerbate asthma are not known, but they may involve effects on airway smooth muscle, mucin secretion, and T cell responses.[59,236] ROS can decrease β-adrenergic function in lungs and sensitize airway smooth muscle to acetylcholine-induced contraction.[103,237] H_2O_2 activates mitogen-activated kinases in tracheal myocytes and stimulates contraction of tracheal smooth muscle cells.[236] ROS also stimulates mucin secretion,[103,237] contributes to Th2 cell differentiation,[180] and promotes T cell proliferation via arginase and NADPH oxidase pathways.[183,184] Proinflammatory cytokines are elevated during airway inflammation, which activate oxidases leading to increases in ROS, the targets of which include receptor kinases, phosphatases, phospholipids, or nonreceptor tyrosine kinases.[16,238,239]

RNS metabolism, in particular that involving $NO^{\bullet}$, is dysregulated in asthma. Exhaled $NO^{\bullet}$ is increased in asthmatics and is associated with airway inflammation.[54,55,240] Despite the expression and distribution of all three NOS enzymes in the airway, it is primarily iNOS that contributes to exhaled $NO^{\bullet}$. Induction of iNOS is observed at both transcriptional and translational levels principally in steroid-naïve patients.[41–43] In mild asthmatics, $NO^{\bullet}$, nitrate, and S-nitrosothiols (SNO) are enhanced in the lower airways.[54] Following antigen challenge, levels of $NO^{\bullet}$ decrease, while nitrate increases without perturbing levels of nitrite and SNO.[54] Decreasing $NO^{\bullet}$ levels correlate with increased nitrotyrosine formation from reaction of $NO^{\bullet}$ with $O_2^{\bullet -}$.[54] Peroxynitrite, thus formed during inflammation, is toxic to microbes; however, it can also cause airway hyperresponsiveness. Nitrate can be generated from peroxidase-mediated RNS production.[54,241] S-nitrosothiols are primarily formed during the late asthmatic response.[54,241] Thus, persistent increases in ROS and $NO^{\bullet}$ lead to RNS formation and subsequent oxidation and nitration of proteins, which contributes to the dysregulation of airway inflammation in asthma.[15] $NO^{\bullet}$ synthesis can reduce airway resistance mediated by increased production of the bronchodilator S-nitrosoglutathione (GSNO).[242–246]

Two mechanisms to co-opt beneficial effects of $NO^{\bullet}$ signaling are (1) shifting $NO^{\bullet}$ to a more stable species, such as GSNO, or (2) reducing the local concentrations of ROS, potentially by augmenting the concentration of antioxidant enzymes in the extracellular space. Elevated $NO^{\bullet}$ has also been attributed to the greater catabolic breakdown of the storage pools of GSNO during changes in the redox state of the lungs.[242–244] GSNOR, a glutathione-dependent formaldehyde dehydrogenase, reduces GSNO to hydroxylamine, which is converted to NO by catalase.[246–248] GSNOR-deficient mice are protected from methacholine hyperreactivity following allergen sensitization and challenge, implicating GSNO in controlling airway hyperreactivity.[246–248]

High levels of ROS may overwhelm antioxidant defenses, causing significant loss of antioxidant activity in asthma.[8,67,70,214,218] Global loss of SOD activity, due to SOD deficiency, loss of circulating SOD activity, or inactivation of SOD via oxidative modification, reflects the increased oxidative stress in asthmatics patients.[8,67,70,214,218] Oxidative modification–mediated reduction of catalase activity also is observed in asthmatics.[8] Although airway glutathione is increased in asthmatic patients, the ratio of oxidized to reduced glutathione is elevated, reflecting an oxidizing microenvironment. Inhalation of exogenous ROS and RNS from exposures to environmental pollutants including ozone, diesel exhaust particles, and oxidant components of tobacco smoke all contribute to additive oxidative stress, airway hyperreactivity, and inflammation in asthma.

In addition to airway inflammation and bronchial hyperresponsiveness, pathologic airway remodeling is associated with asthma.[222,249–251] In fact, airway remodeling has been shown to be responsible for the rapid decline in lung function in treatment-resistant asthmatics compared with non-asthmatics.[252,253] The proliferation of resident airway smooth muscle (ASM) cells and persistent activation of fibroblasts[254] contribute to increase in ASM mass and subepithelial fibrosis, the key cellular and structural features of asthmatic airway remodeling.[255] The TGF-β-induced activation of the ROS-generating enzyme NOX4, which induces myofibroblast differentiation,[210] is implicated in ASM proliferation and hypercontractility in asthma,[256,257] as well as in epithelial ciliary dysfunction in neutrophilic asthma. Ciliary dysfunction is increased in neutrophilic asthma associated with increased NOX4 expression and is attenuated by NOX inhibition.[258] NOX4 expression has been shown to be higher in both ASMs and fibroblasts in asthmatics compared with non-asthmatics.[256,257,259,260] NOX4 small interfering RNA knockdown and the pharmacologic inhibitors diphenyleneiodonium and apocynin abrogated the agonist-induced increased contraction in primary ASM from bronchial biopsies of asthmatics.[256] These data suggest a role for NOX4 overexpression in the promotion of oxidative stress and consequent airway smooth muscle hypercontractility in asthma, and they implicate NOX4 as a potential novel target for asthma therapy. Recent studies also show that a mechanosensitive ion channel mediates lung fibroblast differentiation and house dust mite–induced airway remodeling via a novel interaction of the channel TRPV4, which integrates TGFβ1 and ROS signaling through NOX4.[259] This TRPV4–NOX4 interaction may be amenable to therapeutic targeting of lung remodeling associated with asthma.

Emphysema

Emphysema is a dominant phenotype of chronic obstructive pulmonary disease,[261–264] defined pathologically by airspace enlargement and destruction of alveolar septae.[261–264] Important contributing factors to the pathobiology of emphysema include inflammation, alveolar epithelial cell injury/apoptosis, and protease-antiprotease and oxidant-antioxidant imbalances.[263–268] Inflammatory cells are recruited to the alveolar environment where they release elastases, cytokines, and oxidants that may then perpetuate the cycle of epithelial injury and inflammation.[263–268] In addition to inflammation, oxidative stress caused by cigarette smoke inhalation contributes to the pathogenesis of emphysema. Cigarette smoke contains $O_2^{\bullet -}$, ${}^{\bullet}OH$, and H_2O_2.[269] ROS are also generated by the chronic inflammation characteristic of emphysema, which persists even after smoking cessation. Activated macrophages and neutrophils, present in high numbers in the emphysematous lung, are major producers of ROS.[270–275] The cytoplasmic redox changes and cellular damage caused by cigarette smoke may in part be mediated by ROS generated by NOX enzymes, including NOX4 in conjunction with the decrease in cellular antioxidant enzymatic defenses.[260] The expression of the ROS-generating enzymes, specifically NOX4, is increased also in primary ASM of COPD and healthy controls with >20 pack-year history compared to control subjects without a significant smoking history.[276] The generation of hydrogen peroxide–induced reactive oxygen species by these ASMs in COPD was markedly attenuated by NOX4 inhibition.[276]

Oxidative stress originating from constituents of cigarette smoke or products of inflammatory cells can overcome the antioxidative capacity of lung tissues and diminish antiprotease defenses.[277,278] A major consequence of oxidative stress is the activation of the transcription factor nuclear factor-κB (NF-κB), which activates transcription of proinflammatory cytokines.[264,277–279] Cigarette smoke also inhibits histone deacetylase, further promoting the release of proinflammatory cytokines.[280] Therefore, oxidant injury and lung inflammation act in concert to increase alveolar destruction or compromise maintenance and repair of alveolar structures. Antioxidant defenses are determinants of susceptibility to emphysema. A protective role for Nrf2, a transcription factor that regulates multiple critical antioxidant enzymes, has been identified in pulmonary emphysema.[281–284] SOD mimetics abrogate alveolar cell apoptosis and emphysema in mouse models,[285] further supporting the link between oxidative stress and apoptosis.[286,287]

■ Pulmonary Fibrosis

Pulmonary fibrosis may result from a number of infectious and noninfectious injuries; by far, the most lethal form is idiopathic pulmonary fibrosis (IPF). IPF is characterized by exuberant extracellular matrix deposition, tissue contraction, and apoptosis-resistance of (myo)fibroblasts, alongside apoptosis-prone and aberrantly differentiated alveolar type 2 cells.[18,288] This loss of epithelial-mesenchymal homeostasis and communication is central to the pathogenesis of IPF.[207,209] Myofibroblasts are key effector cells in tissue remodeling and fibrosis, typically contained in fibroblastic foci, which are a pathologic hallmark of IPF. Chronic inflammation, aberrant wound healing, and degenerative aging processes have all been proposed as contributing to the pathogenesis of IPF.[289] Oxidative stress is common to these processes and is implicated in IPF pathogenesis.[290–292] Lung tissues and bronchoalveolar lavage fluid from IPF patients demonstrate a signature profile of oxidatively damaged proteins.[293–296]

NOX enzymes are a major source of ROS production in pulmonary fibrosis.[208,297–300] Several NOX isoforms, including NOX1,[301–303] NOX2,[304–307] and NOX4,[210,299,308] have been implicated in tissue fibrosis. In addition to NOX enzymes, another potential source of ROS implicated in fibrosis is the mitochondria.[309,310] Epithelial cell death is a prominent feature in the IPF lung.[299,311,312] During acute lung injury in mice, NOX1-mediated ROS generation by endothelial and epithelial cells induces cell death.[313,314] NOX4 is expressed in hyperplastic alveolar type II cells in the lungs of IPF patients[308] and may mediate fibrogenic effects by promoting alveolar epithelial cell death.[215] NOX4-deficient mice are protected from bleomycin induced pulmonary fibrosis with reduced levels of epithelial cell apoptosis in vivo.[215] EMT has been proposed to contribute to the accumulation of myofibroblasts in lung fibrosis.[315,316] ROS has also been shown to promote EMT.[317,318] A role for NOX4 in mediating myofibroblast differentiation and lung fibrosis has been identified.[210] NOX4 mRNA expression is induced by a profibrotic cytokine, transforming growth factor β1 (TGF-β1), while other NOX/DUOX isoforms were unaffected. NOX4-dependent generation of ROS, specifically H_2O_2, is required for TGF-β1-induced myofibroblast differentiation, ECM generation, and contractility of lung myofibroblasts.[210] Genetic or pharmacologic targeting of NOX4 attenuates lung fibrogenesis in murine models of lung injury. Myofibroblasts from IPF patients also produce high levels of H_2O_2 in response to TGF-β1.[211] Additionally, NOX4 may also contribute to pulmonary vascular remodeling associated with IPF.[319]

ROS generation from alveolar inflammatory cells, primarily neutrophils and macrophages, may promote alveolar epithelial cell injury in IPF.[290,320] Mice deficient in NOX2 are protected from bleomycin-induced lung injury and fibrosis, suggesting a role for inflammatory injury in this model.[321] The protection in $p47^{phox-/-}$ mice was accompanied by enhanced neutrophilic inflammation and MMP-9 activity.[321] Interestingly, airway neutrophils isolated from IPF patients exhibit elevated expression of $p47^{phox}$ and $p67^{phox}$,[322] supporting roles for the NOX2 isoform and neutrophilic inflammation in IPF. MMPs and tissue inhibitors of matrix metalloproteinases play a role in homeostasis and turnover of the ECM. In IPF, oxidation of the cysteine switch of MMPs by ROS activates the latent forms of MMPs.[211,290,323] ROS also regulates MMPs at the transcriptional level.[211,290,323] Thus, oxidative stress, from exogenous sources and multiple endogenous enzymatic sources, contributes to altered cellular homeostasis, including resident cells, recruited inflammatory cells, and their activated products.

Several clinical trials testing therapies for IPF have not demonstrated efficacy. The use of the antioxidant N-acetylcysteine (NAC) was initially suggested to benefit patients with IPF by reducing oxidative stress in the lung.[324] But NAC as a monotherapy or as triple therapy—a three-drug regimen consisting of azathioprine, prednisone, and acetylcysteine—has not demonstrated efficacy in slowing the progression of IPF.[325,326] The antifibrotic drugs pirfenidone, a pyridine derivative, and nintedanib, a potent intracellular inhibitor of tyrosine kinases, have been associated with significant slowing of respiratory deterioration in IPF and perhaps prolonged survival.[327–329] However, the responses to these antifibrotic treatments are heterogeneous and are limited by side effects and tolerability. Novel therapeutic approaches, including combination therapies and the development of novel compounds, are being actively pursued.

Numerous potential molecular targets of novel therapeutic agents are currently being explored in early clinical trials. Recently, a small molecule NOX4/NOX1 dual inhibitor has been developed, showing good oral bioavailability and tolerability when administered orally in an animal model of pulmonary fibrosis.[298] GKT137831 (setanaxib) is an orally available, small organic molecule of the pyrazolopyridine dione chemical class; it is a selective inhibitor of NOX4/1 and the first drug in this class of NOX inhibitors to enter clinical trials. A phase 2, placebo-controlled, multicenter, randomized trial to test GKT137831 in ambulatory patients with IPF is currently ongoing (NCT03865927). In the past, several attempts to therapeutically target activated myofibroblast-like cells referred to as cancer associated fibroblasts (CAFs) in the tumor microenvironment have been unsuccessful and, possibly, compounded by poor understanding of the heterogeneity of cells and lack of specific CAF targets.

Recent studies have shown that the NOX4/1 inhibitor GKT13783 not only prevents differentiation of CAFs but normalizes them to a quiescent state of activation.[330] These studies reveal the CAF dependency on continuous NOX4-dependent ROS generation and provide proof of concept for specific targeting of NOX enzymes to overcome the exclusion of T cells and reshaping the CAF-regulated immune microenvironment. Thus, combination approaches utilizing direct targeting of NOX4 activity in CAFs and immunotherapy are predicted to provide improvement of clinical outcomes for CAF-rich tumors that respond poorly to checkpoint immunotherapy. Such treatment strategies with NOX4 inhibitors may have beneficial outcomes for IPF, as recent epidemiologic evidence also supports an association between IPF and lung cancer; such association of two lethal diseases carries a very poor outcome.[331–334] In IPF patients, lung tumors develop adjacent to fibrotic areas and are different histologically from non-IPF-associated lung tumors. There is a higher prevalence of lung cancer in the combined IPF and emphysema syndrome compared with fibrosis only.[331–334]

■ Pulmonary Hypertension

Pulmonary arterial hypertension (PAH) is a disorder of the pulmonary circulation characterized by endothelial dysfunction and intimal and smooth muscle proliferation.[335,336] Increased expression of ROS-generating enzymes, uncoupling of NOS enzymes, and mitochondrial dysfunction all contribute to the oxidative stress in PAH.[335,336] Upstream dysregulation of ROS/$NO^{\bullet}$ redox homeostasis impairs vascular tone, which then triggers the activation of antiapoptotic and mitogenic pathways, leading to cell proliferation and obliteration of the vasculature.[335,336]

ROS derived from the NOX2 and NOX4 isoforms contribute to the long-term responses of the pulmonary vasculature to hypoxia.[337–340] Increased NOX4 expression in pulmonary artery smooth muscle cells (PASMCs) has been linked to hypoxia-dependent PAH in mice.[340] Levels of the NOX1 and -2 regulatory proteins, $p47^{phox}$ and Rac1, are increased in both the endothelial and SMC layers of pulmonary arteries[341–343] and accompanied by an increase in NOX-derived $O_2^{\bullet-}$.[341–343] NOX-derived ROS is associated with medial thickening, disordered proliferation and migration, impaired angiogenesis, and disturbed fibrinolysis.[341–345] Another source of vascular ROS is xanthine oxidoreductases (XOR), including xanthine dehydrogenase (XD) and xanthine oxidase (XO). In PAH, XO activity dominates over XD activity and is a significant source of ROS production. XO is increased in idiopathic PAH patients compared with healthy controls.[345]

In a rat model of chronic hypoxia–induced PAH, lung XO activity was enhanced and inhibition of XO activity with allopurinol reduced right ventricular hypertrophy and pulmonary vascular thickening.[341–344,346] Clinical studies have also demonstrated alterations of TGF-β1 expression in adult PAH patients.[347] In hypoxia-dependent PAH in mice, hypoxia increases the expression of TGF-β1 and NOX4 expression.[339,340] TGF-β-induced NOX4 expression and NOX4-mediated ROS production have been implicated in PASMC proliferation.[348,349] TGF-β1 also induces proangiogenic effects by upregulating VEGF.[350] In PASMCs, cyclic stretch induces VEGF expression, at both the mRNA and protein levels;[351] this is preceded by both increased expression and secretion of TGF-β1 and an increase in ROS generation by the activation of NOX enzymes.[348,349] In models of spontaneously developing PAH, mitochondrial dysfunction and hyperpolarization are associated with reduction in ROS production.[352,353] Decreases in ROS inhibit an $O_2^{\bullet-}$ sensitive K^+ channel leading to pulmonary vascular constriction.[352–354]

Nitrosative stress with increased nitrated eNOS is an early contributor to the development of PAH.[341,355–358] The vasodilatory effects of cGMP are mediated through protein kinase G (PKG).[341,355–358] However, nitration of PKG attenuates the kinetic activity of PKG, impairs vasodilation, and increases smooth muscle proliferation.[359] This nitration-dependent reduction in PKG activity is observed in lungs of patients with PAH.[359] Nitration of carnitine acetyl transferase, an enzyme that maintains normal mitochondrial function, is another indicator of early nitrosative stress in PAH.[360]

Alterations in arginine metabolism also have been noted in models of PAH,[342] where the activity of arginase, which catalyzes the hydrolysis of L-arginine to L-ornithine and urea, is increased[159,342,361,362] and the activity of the caveolar enzymes involved in the recycling of L-citrulline and other L-arginine byproducts back to L-arginine is attenuated.[159,342,361,362] Further, increased arginase activity is associated with formation of polyamines and L-proline, which promote smooth muscle cell growth and collagen synthesis. Additionally, uncoupling of NOS enzymes occurs when L-arginine becomes limited, resulting in the production of ROS.[343,363–365] Therefore, high arginase activity may promote aberrant pulmonary vascular remodeling and neointima formation in PAH.[159,361,362]

■ Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a severe form of acute lung injury and a syndrome of acute pulmonary inflammation.[366,367] ARDS is characterized by sudden onset, impaired gas exchange, and an increase in pulmonary capillary permeability.[366–368] Oxidative damage by ROS and RNS has been implicated in the pulmonary vascular endothelial damage that characterizes ARD. Several factors contribute to the intracellular and extracellular oxidant stress in ARDS patients.[366–368] The high inspiratory concentrations of oxygen required to achieve adequate arterial oxygenation, infection, or extrapulmonary inflammation lead to increased ROS production. This, combined with decreased antioxidant capacity of tissues resulting from consumption of the natural antioxidants, leads to cellular damage and loss of vasomotor control.[366–368] Measurements of antioxidant concentrations have revealed an oxidant-antioxidant imbalance in ARDS patients. The production of toxic levels of ROS and RNS not only leads to damage of key molecules in cells but can signal changes in cellular responses such as proliferation, apoptosis, and necrosis.[366–368] H_2O_2 has been detected in the exhaled breath, while myeloperoxidase and oxidized α1-antitrypsin have been detected in BAL of ARDS patients.[366–368]

Nitration and oxidation of alveolar space proteins including the surfactants have been identified ex vivo in patient samples with ARDS.[366–368] Although the nature of these oxidized proteins has not been well defined, recent studies indicate the potential aggregation and cross-linking of extracellular matrix proteins, specifically fibronectin, in the presence of an inflammatory microenvironment that includes inflammatory cell infiltration and heme peroxidases.[369] Overabundance of ROS also induces adhesion molecules and cytokines that contribute to endothelial injury.[370–372]

CONCLUSION

Oxidative stress is implicated in the pathogenesis of both acute and chronic inflammatory and fibrotic lung diseases, some of which are discussed here. The lungs are exposed to exogenous oxidants from the environment, in addition to endogenous generation of ROS/RNS from resident and recruited inflammatory cells. Several measures of oxidative stress have been used to estimate oxidative stress within the lungs;[373–379] however, current approaches do not adequately differentiate between different oxidative mechanisms. Further investigations are needed to discover oxidative stress biomarkers that correlate and differentiate between various types of oxidative injury. While progress has been made to delineate mechanisms through which oxidants initiate and propagate cell and tissue damage, specific signaling pathways and mechanisms of activation are not well understood. Elucidation of these mechanisms may provide strategies for intervention to prevent or protect from disease pathogenesis or progression. A better understanding of factors that influence individual susceptibility will also be useful in risk stratification of patients. Investigations on how early life exposures to oxidants impact airway morphology, immune function, and the airway epigenome may aid in determining susceptibility, disease expression, and progression.

CHAPTER 26

Fibroblasts in Lung Homeostasis and Disease

Yong Zhou
Victor J. Thannickal

INTRODUCTION

Fibroblasts are the primary cellular source responsible for synthesis and remodeling of the extracellular matrix (ECM). These cells are in communication with the surrounding microenvironment and play a key role in lung homoeostasis. Following lung injury, fibroblasts are activated and undergo myofibroblast differentiation. Myofibroblasts are key effector cells for lung repair following injury. In addition to fibroblasts, perivascular pericytes and mesenchymal stem cells (MSCs) of bone marrow (BM) origins contribute to myofibroblast population. There is evidence that type II alveolar epithelial cells can differentiate into myofibroblasts in vitro through a process known as epithelial-mesenchymal transition (EMT); however, the role of EMT in fibrogenesis in vivo remains controversial. Myofibroblasts express α—smooth muscle actin (α-SMA), develop robust actin filaments (stress fibers), and acquire contractile activity. The function and behavior of myofibroblasts are regulated by both biochemical and physical cues in the surrounding microenvironment. The fate of myofibroblasts is a key determinant of whether an injury-repair response will resolve or progress into fibrosis. Destruction and aberrant remodeling of the ECM is a common feature of many lung diseases, including pulmonary fibrosis, asthma, chronic obstructive pulmonary disease (COPD), and lung cancer. Targeting myofibroblasts and tissue remodeling may provide a novel and effective strategy for treating a number of chronic lung diseases.

FIBROBLAST BASICS

The following discussion focuses on a description of fibroblasts and their functions.

What Are Fibroblasts?

Fibroblasts were described as early as in the late 19th century, based on their location and their microscopic appearance.[1] These cells are elongated cells that display a spindle-shaped morphology with extended cell processes.[2] Fibroblasts are ubiquitous in tissues and organs throughout the body and communicate with other cells such as epithelial cells (Fig. 26-1). Despite its discovery over a century, a reliable and specific molecular marker that identifies the fibroblast is currently lacking. Many indicators of fibroblast phenotype have been suggested in the previous studies (e.g., fibroblast-specific protein 1, vimentin, prolyl-4-hydroxylase, procollagen-Iα2, etc.).[3] However, none is specific to fibroblasts or present in all fibroblasts. Currently, fibroblasts are identified by their ability to adhere to plastic and their lack of markers that indicate other cell lineages. Identification of better cellular markers with absolute specificity for fibroblasts will aid in the study of sources, differentiation, and phenotypic plasticity of fibroblasts.

Tissue-Specific Fibroblasts and Fibroblast Heterogeneity

Fibroblasts isolated from different tissues display a considerable degree of heterogeneity in phenotype and activity.[4] Such diversity is evident by divergent and specific gene expression patterns among fibroblasts isolated from distinct anatomical locations.[5] For example, fetal skin fibroblasts express high levels of collagen types I and V, whereas fetal lung fibroblasts lack collagen I and V expression.[5] Instead, fetal lung fibroblasts exclusively express lung-specific forkhead family transcription factors FOXF1 and FOXP1.[5] Tissue-specific fibroblasts may provide location-specific signaling for a given anatomic origin as well as important positional cues for wound healing and tissue regeneration. Besides the differences in fibroblasts from different anatomic sites, fibroblasts derived from a single tissue are often composed of subsets of different fibroblasts.[6] Fibroblast subpopulations isolated from lung differ in expression of surface markers such as Thy-1, cytoskeletal composition, lipid content, and cytokine profile.[7,8] Fibroblasts isolated from lungs with active fibrotic disease such as in the fibroblastic foci of human idiopathic pulmonary fibrosis (IPF) are morphologically and functionally distinct from fibroblasts isolated from normal lungs,[9] suggesting that selective expansion of specific fibroblast subsets is associated with the pathogenesis of this disease.

With the advent of new technologies including transgenic lineage tracing and single-cell RNA sequencing (RNAseq), significant

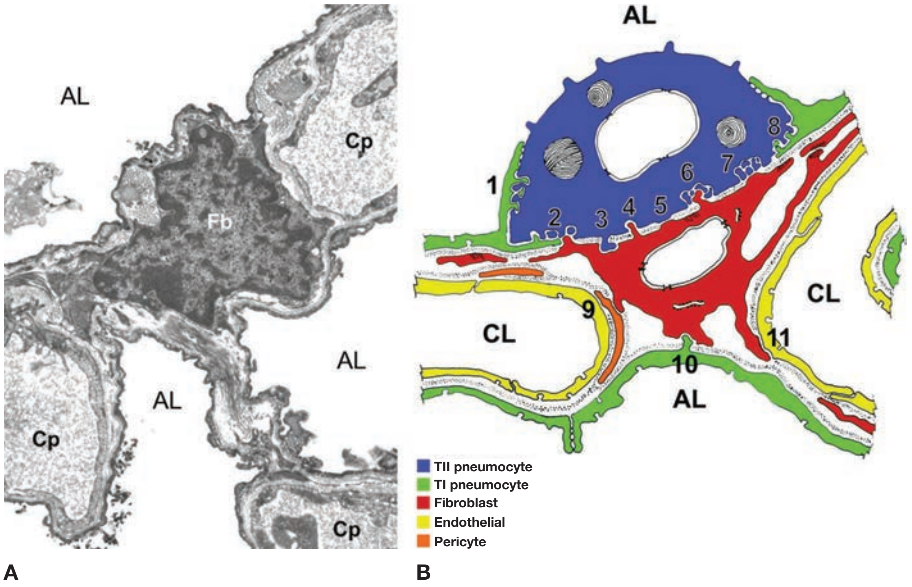

Figure 26-1 An interstitial fibroblast in the alveolar wall. **A.** Transmission electron microscopic image showing the structural organization of the alveolar wall in canine lung. AL: alveolar lumen, Cp: capillary, Fb: fibroblast. **B.** Summary of fibroblast (red) relationships with type I (green) and type II (purple) alveolar epithelial cells, capillary endothelial cells (yellow), and pericytes (orange) in human and rabbit alveolar walls. *(Reproduced with permission from Burns AR, Smith CW, Walker DC. Unique structural features that influence neutro phil emigration into the lung. Physiol Rev. 2003;83(2):309–336.)*

advances have been made to characterize fibroblast heterogeneity. For example, clonal cell labeling strategies with multicolor reporters identified a diversity of mesenchymal populations with different locations, patterns of migration, recruitment mechanisms, and lineage boundaries in the developing mouse lung.[10] Single-cell and population-based RNA sequencing revealed functionally distinct myofibrogenic mesenchymal cell type (Axin2$^+$) as well as mesenchymal alveolar niche cell type (Pdgfra$^+$Axin2$^-$) that is critical for alveolar epithelial cell growth and self-renewal.[11] Similarly, single-cell analyses found distinct mesenchymal niches that drive airway (Lgr6$^+$) and alveolar (Lgr5$^+$) differentiation.[12] More recent transcriptomic analyses conducted at single-cell resolution demonstrated a novel profibrotic mesenchymal population (Pdgfrb^{hi}) along with known mesenchymal cell subtypes in bleomycin injury–induced mouse lung fibrosis.[13] The existence of different fibroblast lineages may contribute to the functional heterogeneity of fibroblasts, resulting in fibroblasts that may respond differently to environmental stimuli or signals.

■ Fibroblast Functions

The important functions of fibroblasts include deposition of ECM, regulation of inflammation, and wound healing.[14] Fibroblasts produce ECM-degrading proteases such as matrix metalloproteinases (MMPs) and their inhibitors, tissue inhibitors of metalloproteinases (TIMPs), supporting their crucial roles in regulating ECM turnover and homeostasis.[15]

ECM Production

One of the major functions of fibroblasts is the production of ECM. The ECM in the lung provides an essential scaffold on which cells can proliferate and differentiate. It also provides the lung with tensile strength and elasticity that are essential for ventilation. Lung ECM is composed of fibrillar proteins, glycoproteins, proteoglycans, and polysaccharides, each of which has distinct biochemical and biomechanical properties; these include collagens, elastin, fibronectin, proteoglycans (PGs), hyaluronan (HA), laminin, vitronectin, and thrombospondin.[16] Type I and type III collagens are the most abundant collagens in the lung interstitium (ratio 3–6:1). Collagen IV is mainly localized to basement membranes. A fibroblast is estimated to synthesize approximately 3.5 million procollagen molecules/cell/day.[17,18] Depending on tissue type and age, 10% to 90% of synthesized procollagens are intracellularly degraded by lysosomal enzymes (e.g., cathepsins B, D, and L). It is postulated that regulation of procollagen degrading rate may provide an important mechanism for rapid secretion of collagen in response to injury without de novo synthesis of new proteins.

Secretion of Proteolytic Enzymes and Inhibitors

The ECM is a dynamic structure that undergoes constant remodeling. Remodeling of the ECM is regulated by complex mechanisms including stimulatory and inhibitory mediators derived from resident cells in the local environment.[18] Fibroblasts synthesize a variety of proteolytic enzymes and inhibitors that enable them to control the assembly and turnover of the ECM. MMPs are either secreted by fibroblasts as inactive zymogens or anchored to the cell surface. Activation of MMPs occurs by disruption of interactions between the prodomain and the catalytic domain through either the proteolytic cleavage or the conformational change of the proenzymes.[19] MMPs function as proteinases that degrade most ECM proteins. Proteolysis of the ECM macromolecules by MMPs results in the release of cryptic fragments and neo-epitopes that promote angiogenesis and cellular migration.[20,21] MMPs also have critical roles in the post-translational regulation of other proteins including latent growth factors stored within the ECM, membrane receptors, and other proteases.[22] Hence, MMPs impact cell behavior both through modulation of cell-matrix interactions and through regulation of other signaling molecules. MMPs themselves are regulated by their endogenous inhibitors TIMPs. TIMPs block MMP activity by noncovalently binding to the MMP active site. A tight balance between MMP proteolysis and TIMP expression is required for maintaining lung homeostasis.[23]

Innate Immune Function

Fibroblasts are capable of synthesizing many inflammatory cytokines that are initially thought to be exclusively produced by inflammatory cells.[24] Fibroblast-derived cytokines play an important role in the amplification and perpetuation of the immune response. Fibroblasts generate constitutive and cytokine-induced C-C and C-X-C chemokines that recruit inflammatory and immune cells to the injured cites.[25] Lung fibroblast–derived granulocyte macrophage-colony stimulating factor promotes the survival of eosinophils, which contributes to the fibrotic response in the lung.[26,27] Direct contacts between fibroblasts and T cells promote the production of adhesion molecules and cytokines by the T cells.[28] Interactions between fibroblasts and mast cells facilitate de novo production of eotaxin, a potent eosinophil chemattractant.[29] Interactions between fibroblasts and inflammatory cells are bidirectional. Th2 cells produce IL-4 that recognizes specific receptors on fibroblasts and modulates fibroblast proliferation and biosynthetic capacity.[30] Eosinophils release mitogens that augment fibroblast proliferation and collagen production.[31,32] Fibroblasts are the main producers of ECM proteins. Since ECM components affect multiple functions and properties of inflammatory and immune cells,[33,34] it suggests a further regulatory role of fibroblasts in innate immune response by the effects on the ECM.

Regulation of Tissue Interstitial Fluid Pressure and Microhemodynamics

Fibroblasts regulate tissue interstitial fluid volume, pressure, and microcirculation hemodynamics by generation of actomyosin-derived forces and transmission of the forces to the ECM via transmembrane integrins.[35] Such mechanical interactions between fibroblasts and matrix are subjected to modulation by soluble factors, such as PDGF that results in increased interstitial fluid pressure, and TNF-α that leads to decreased interstitial fluid pressure.[36,37] Fibroblasts express ecto-5′-nucleotidase (CD73) and soluble guanylyl cyclase (cGC) that affect hemodynamics,[38] suggesting a role of fibroblasts in the regulation of the microcirculation.

Fibroblasts Support Epithelial Stem Cell Niches

Normal structure and function of the lung is maintained in homeostasis and reconstituted following diverse injuries by regionally defined stem/progenitor cells.[39–51] Stem cells reside in unique tissue microenvironments, known as the stem cell "niche," which constitutes stem cell progeny, other niche-support cells including mesenchymal/stromal cells (fibroblasts, smooth muscle cells, endothelial cells, immune cells), and the surrounding extracellular matrix (ECM).[11,12,52–57] The stem cell niche provides instructive cues for stem cell self-renewal and differentiation.[58–61] Lipofibroblasts (LIFs) are adipocyte-like fibroblasts located close to AT2 stem cells,[62,63] representing a special niche for AT2 stem cells. LIFs contribute to the maturation of alveolar epithelial cells and the formation of surfactant, a phospholipoprotein complex produced by AT2 cells involved in the reduction of surface tension.[64] The growth of AT2 stem cells in Matrigel to form alveolosphere-like structures, known as organoids, is drastically enhanced when co-cultured with LIFs.[41,65] Pdgfrα$^+$ lung fibroblast population has been defined as an AT2 niche in mouse lungs[11,41,66] (Fig. 26-2). Pdgfrα$^+$ fibroblast

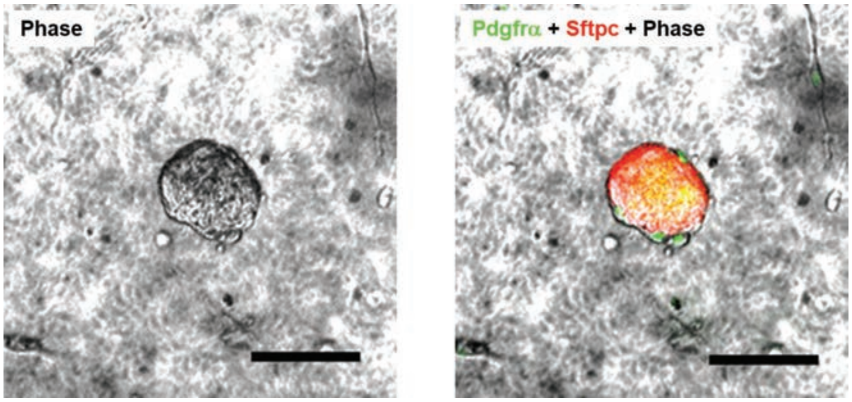

Figure 26-2 An alveolar organoid formed in 3D Matrigel. Pdgfrα$^+$ lung mesenchymal niche cells (green) were co-cultured with Sftpc$^+$ AT2 cells (red) in Matrigel. Images were taken at day 11. Scale bar: 100 µm

lineage contributes to the lipofibroblast pool of the lung.[67] Discrete lung stem cell niches along the proximal-distal axis of the respiratory tree regulate the reparative and regenerative function of region-specific lung stem cells.[54,68–70] In addition to Pdgfrα$^+$ LIFs and AT2, other fibroblast lineages, including EpCAM$^-$Sca-1$^+$, Axin2-Pa$^+$, Lgr6$^+$, Lgr5$^+$, and Gli2$^+$Gli1$^-$Hh^{low} support lung epithelial stem cells located in the airway and bronchoalveolar duct junctions (BADJ) that participate in repair/regeneration of injured lungs.[11,12,71,72]

MYOFIBROBLASTS: EFFECTOR CELLS IN TISSUE REPAIR

Below we consider a number of functional aspects of myofibroblasts, after first reviewing some historic context. Included are a discussion of the origin of myofibroblasts, factors that influence the cell's activity and differentiation, the cell's role in tissue homeostasis and repair, and the fate of the myofibroblast.

■ Historic Context

Myofibroblasts were first identified as fibroblastic cells with a strong muscle cell–like contractile filamentous apparatus in the granulation tissue of healing wounds.[73] These cells are present in organs with increased remodeling, such as in development, inflammation, fibrosis, cancer invasion, and metastasis.[74] Myofibroblasts display prominent cytoplasmic actin microfilaments (stress fibers) (Fig. 26-3). They are connected to one another with adherens and gap junctions as well as to the ECM with focal adhesion complexes (FAs).[75]

Myofibroblasts may be further classified into subtypes based on the presence or absence of vimentin, desmin, and/or α smooth muscle actin (α-SMA) in cytoskeletal filaments. Expression of these proteins varies upon tissue types and is subjected to the regulation by environmental factors.[76] Alternatively, myofibroblasts can be simply classified into two subpopulations, proto-myofibroblasts and mature myofibroblasts.[77] Proto-myofibroblasts are partly differentiated myofibroblasts that contain α-SMA-negative actin stress fibers, whereas mature myofibroblasts possess extensive networks of α-SMA-positive stress fibers and large FAs (termed supermature FAs). α-SMA has been the most widely used marker for identification of myofibroblasts (Fig. 26-3). However, a study of fibrosis in multiple organs found that only a minority of collagen-producing cells co-expressed α-SMA in the fibrotic lung and kidney,[78] suggesting non-myofibroblasts are important contributors to the deposition of collagen in the fibrotic ECM. Additionally, myofibroblasts themselves are heterogeneous with a number of other markers and modulators (Table 26-1). Heterogeneity among fibroblasts and

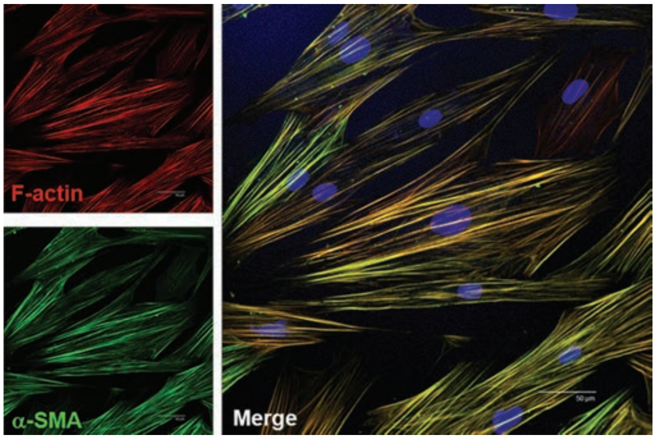

Figure 26-3 Myofibroblasts are characterized by de novo synthesis of α-SMA synthesis and incorporation of α-SMA into filamentous actin stress fibers. Scale bar: 50 µm

TABLE 26-1 Myofibroblast Markers

Marker	Cellular Overlap
Cytoskeletal component	
α-SMA[251]	Smooth muscle cells
Desmin[252]	Hepatic stellate cells, cardiomyocytes
Cofilin[253]	Smooth muscle cells
GB 42-antigen[254]	Smooth muscle cells
Palladin 4Ig[255]	Smooth muscle cells
Tropomyosin 1[256]	Cardiomyocytes
Cell membrane receptor	
Angiotensin II type 1 receptor (AT1R)[257]	Cardiomyocytes, smooth muscle cells
Integrin $\alpha_{11}\beta_1$[258]	Musculoskeletal cells
Thy 1[199]	Lipofibroblasts
Endosialin[259]	Cardiomyocytes, smooth muscle cells, adipocytes
Cadherin 11[260]	Tenocytes, endothelial cells, mesenchymal cells
Frizzled 2[261]	Smooth muscle cells
CD82[262]	T cells
AOC3[263]	Vascular smooth muscle cells
CKAP4[264]	Bladder epithelial cells
Extracellular protein	
Collagen I, III, IV, V, VI[265]	Various cells
Tenascin C[266]	Smooth muscle cells
Fibronectin ED-A[267]	Smooth muscle cells
Osteopondin[268]	Osteoblasts, osteocytes, chondrocytes
Periostin[269]	Preosteoblasts, cardiac myocytes

myofibroblasts remain an important area for future investigations, as the behavior and fate of these cells may differ, and potentially determine, pathologic states.

Origin of Myofibroblasts

The precise origin of myofibroblasts remains unsolved at present. Studies have suggested that local fibroblasts, perivascular pericytes, bone marrow (BM)-derived mesenchymal stem cells (MSCs), tissue MSCs, and epithelial/endothelial cells (through epithelial/endothelial-mesenchymal transition) are among potential cellular sources for myofibroblast population.

Resident Fibroblasts-Mesenchymal Stem Cells

Fibroblasts are the most widely accepted origin for myofibroblasts.[79,80] Fibroblasts influx into injured sites from the surrounding tissue and differentiate into myofibroblasts in response to extracellular stimuli including biochemical and physical cues.[81] These stimuli induce intrinsic changes in gene expression and stress fiber formation that characterizes myofibroblast differentiation.

MSCs that reside in tissues lack hematopoietic and leukocyte markers, but may express α-SMA.[82] Tissue MSCs have been described in the dermal sheath that surrounds the hair follicle facing epithelial stem cells.[83] These MSCs are involved in papilla regeneration and differentiate into myofibroblasts in response to environmental insults. It has been reported that MSCs from subcutaneous fat are responsible for collagen accumulation in scars.[84] Following lung injury, myofibroblasts were found to originate from perivascular and peribronchial sources.[85] It is likely that there are tissue MSCs in the human adult lung,[86] which become activated and undergo myofibroblast differentiation in response to lung injury. In support of this notion, a previous study has provided evidence for isolation of postnatal MSCs from different organs including liver, kidney, and lung.[87]

Pericytes

Pericytes are perivascular cells located on the abluminal side of endothelial cells in microvasculature.[88] These cells share developmental origins with fibroblasts, but they differ from fibroblasts by the fact that pericytes anatomically connect with endothelial cells through cell processes within capillary basement membrane, whereas fibroblasts do not directly interact with endothelial cells.[89] The normal function of pericytes includes the regulation of vascular tone and blood flow through expression of contractile microfilaments (actin, myosin) and intermediate filaments (desmin, vimentin).[90] Microvascular pericytes differentiate into myofibroblasts in diffuse cutaneous systemic sclerosis, providing a link between microvascular damage and skin fibrosis.[91] Recent studies using the genetic fate-mapping approach have clearly demonstrated that pericytes are a major cellular source of myofibroblasts in animal models of acute injury to muscle, dermis and kidney.[92,93] In addition, hepatic stellate cells, pericyte-like cells in the liver, are the primary myofibroblast progenitors in mouse models of alcoholic and toxic liver fibrosis.[94]

Bone Marrow–Derived Mesenchymal Cells

BM-derived MSCs are self-renewable, multipotent progenitor cells with the capacity to differentiate into lineage-specific cells that form bone, cartilage, fat, tendon, and muscle.[95] Compared with hematopoietic stem cells, MSCs are more radio-resistant and reside mostly in BM stroma. BM-derived MSCs do not express hematopoietic markers and can be isolated as Lin^- $CD45^-$ $CD31^-$ $CD34^-$ $CD133^-$ Sca-1+ Vitamin A^- cells.[96] In vitro evidence for a BM origin of myofibroblasts was first presented more than four decades ago. By plating BM cells on culture dishes, colonies consisting of cells exhibiting elongated or polygonal cytoplasm and clear nuclei were formed.[97] Transplantation studies using Y chromosome or green fluorescent protein (GFP) as a marker of donor cells provide in vivo evidence that (myo)fibroblasts in wounded skin, lung fibrosis, and intestinal fibrosis may derive from the BM.[98] There is evidence that monocytes may represent the major BM-derived cell population that contributes to myofibroblasts in fibrotic lesions, at least in some contexts.[99]

Circulating fibrocytes express markers of hematopoietic cells (CD34), leukocytes (CD11b, CD13, and CD45) and fibroblast products (collagens I and III, fibronectin). These cells are distinguished from monocytes/macrophages, dendritic cells, and B cells by their lack of expression of specific markers for these cell lineages. Circulating fibrocytes migrate into injured tissues and have been identified in a number of fibrotic conditions.[100] Studies have identified the potential for fibrocytes to participate in wound healing and pathologic scarring.[100,101] However, the direct contribution of fibrocytes to myofibroblast population during wound healing and fibrosis remains controversial. Evidence for and against fibrocyte-to-myofibroblast differentiation exist.[98,102] It is likely that instead of direct differentiation into myofibroblasts, circulating fibrocytes contribute to fibrosis by production of profibrogenic paracrine mediators that target resident cells.

Epithelial-to-Mesenchymal Transition

Epithelial-to-mesenchymal transition (EMT) refers to as a process through which fully differentiated epithelial cells lose their epithelial characteristics (e.g., apico-basal polarity, polygonal cell shape, tight and adherens junctions) and acquire properties of mesenchymal cells (e.g., elongated cell shape, increased motility, contractility). Epithelial cells undergoing EMT are characterized by downregulation of epithelial markers (e.g., E-cadherin, ZO-1) and concomitant upregulation of mesenchymal markers (e.g., FSP1, α-SMA) in the injured epithelium.[103] There is overwhelming evidence that primary epithelial cells cultured in vitro undergo EMT in response to a stimulatory input of soluble growth factors (e.g., TGF-β, EGF, HGF) and/or ECM components (e.g., collagen).[104] However, the concept of in vivo fibrogenic EMT has been challenged by new epithelial lineage tracking studies in a variety of models of kidney, lung, and liver fibrosis in animals.[105]

Factors Regulating Fibroblast Activation and Myofibroblast Differentiation

Fibroblasts isolated from the site of a healing wound or from fibrotic tissue secrete higher levels of ECM constituents and proliferate more than their normal counterparts isolated from healthy organs.[106] Such increased activity is referred to as "fibroblast activation." Activated fibroblasts express α-smooth-muscle actin, leading to the term "myofibroblasts." Fibroblast activation and differentiation into myofibroblasts are regulated by various stimuli, including biochemical factors, biophysical cues from the ECM, and epigenetic modifications.

Growth Factor and Cytokine-Mediated Activation

Fibroblasts become activated by stimulation with cytokines such as TGF-β1, PDGF, and FGF-2, which are released from injured epithelial cells, infiltrating mononuclear cells such as monocytes and macrophages as well as the ECM.[107–110] TGF-β1 is a pluripotent cytokine that plays a central role in the development of fibrosis. TGF-β1 is sequestered in a latent form (termed latent TGF-β1) in the ECM.[111] Latent TGF-β1 becomes activated in a spatially and temporally regulated fashion in response to injury.[111] Active TGF-β1 binds to its membrane receptors (TGF-βRI and TGF-βR2) which signal through both Smad-dependent canonical pathway and Smad-independent noncanonical pathway that promote fibrotic gene expression.[77] Active TGF-β1 also increases the assembly of stress fibers and focal adhesions that are required for the development of cellular contractility.[77] In addition, prototypic cytokines produced by CD4+ T cells such as interleukin (IL)13/IL4 and IL17 exert profibrotic effects on fibroblasts and play a crucial role in the development of fibrosis.[112,113]

Components of Vascular/Coagulation System

Coagulation proteases such as factor Xa and thrombin activate fibroblasts through receptor-mediated effects elicited by a high-affinity thrombin receptor, proteinase-activated receptor (PAR)-1.[114] PAR-1 signaling promotes fibroblast proliferation via the autocrine production of PDGF and CTGF, and drives fibroblasts differentiation into myofibroblasts via αvβ5-dependent TGF-β activation.[115,116] Thrombin upregulates expression of the fibrinolysis inhibitor plasminogen activator inhibitor (PAI)-1, resulting in increased fibrin matrix.[117] Fibrin matrix inhibits surfactant function and contributes to alveolar collapse and traction of remaining airspaces (honeycombing).[114] Lysophosphatidic acid (LPA), a platelet-derived molecule during blood coagulation, promotes fibroblast activation and pulmonary fibrosis by activation of latent TGF-β1 through LPA receptor.[118] Endothelin 1 (ET-1), an activator of extrinsic coagulation cascade, exerts potent mitogenic and profibrotic effects on fibroblasts.[119] Transgenic mice expressing human ET-1 transgene have been shown to develop progressive pulmonary fibrosis.[119]

Reactive Oxygen Species

Accumulating evidence indicates that oxidative stress and reactive oxygen species (ROS) production, mainly in the form of superoxide and hydrogen peroxide, play a significant role in myofibroblast differentiation.[120] The NAD(P)H oxidases of the Nox family have been identified as the enzyme system that is primarily responsible for ROS generation by fibroblasts in response to injury and are recognized as key mediators of myofibroblast differentiation and matrix accumulation in lung fibrosis.[121] Nox4, the most abundant Nox isoform in the lung, has been characterized as a "constitutively active" enzyme, meaning that the enzymatic activity of Nox4 is primarily regulated at the level of gene expression. TGF-β1 increases Nox4 expression and ROS production in lung fibroblasts, which mediates TGF-β1-dependent myofibroblast differentiation.[121] A similar mechanism for myofibroblast differentiation has been demonstrated in cardiac fibroblasts, renal fibroblasts, and mesangial cells.[122,123] Nox4 is also associated with TGF-β1-induced cellular contractility in lung myofibroblasts and cytoskeletal remodeling in vascular smooth muscle cells as well as endothelial cells.[121,124,125] Together, these results indicate that Nox-derived ROS regulate fibroblast morphology, contractility, and differentiation.

Mechanical Stress

Fibroblasts respond to mechanical cues, including externally applied forces, interstitial fluid flow, and matrix rigidity sensed through internally generated forces. Externally applied forces such as stretch provoke diverse fibroblast signaling responses, including activation of mitogen-activated protein (MAP) kinases,[126] Akt,[127] and focal adhesion kinase (FAK). It has been shown that stretch augments TGF-β release and signaling, and promotes the myofibroblast phenotype.[128,129] The continuous interactions between cell-generated forces and the resistance of matrix to cellular forces strengthen cell-matrix contacts and develop α-SMA-positive stress fibers characterizing myofibroblast differentiation.[77,130] Normal lung fibroblasts grown on polyacrylamide gels with a stiffness grade similar to fibrotic lungs undergo myofibroblast differentiation.[131] The effects of matrix stiffening on myofibroblast differentiation may occur through TGF-β-dependent intrinsic and/or TGF-β-independent extrinsic mechanotransduction[131,132] (see below). Interstitial fluid flow induces fibroblast proliferation, collagen alignment, and fibroblast-to-myofibroblast differentiation in the absence of exogenous mediators.[133,134] $\alpha_1\beta_1$ integrin appears to play an important role in the specific response to interstitial fluid flow.[133] Taken together, these results suggest that fibroblasts are mechanosensitive and are programmed for matrix production, contraction, and differentiation in the presence of mechanical stimuli.

Metabolic Regulators

Emerging evidence indicates that lung fibroblasts undergo dramatic metabolic reprogramming in lung fibrosis in both human and mice. These metabolic reprogramming events are critical to fibroblast proliferation, transition from quiescent to activated states, and synthetic activities.[135–139] A hallmark feature of these metabolic reprogramming events is the elevation of aerobic glycolysis. It has been found that rate-limiting enzymes involved in glycolysis are dramatically upregulated in activated lung fibroblasts, which is associated with a marked increase in glycolytic flux.[139,140] An augmented glycolysis is thought to meet increasing energy demands of activated lung fibroblasts. Although glycolysis is considered an inefficient means for generating ATP (two ATP molecules by glycolysis vs. 36 ATP by oxidative phosphorylation), aerobic glycolysis can produce ATP at a faster rate than oxidative phosphorylation. Aerobic glycolysis also generates byproducts, such as lactate, that could be important for fibroblasts. Lactate production serves as an energy source for neighboring cells, and its conversion to lactic acid may potentially result in activation of latent TGF-β1 by lowering extracellular pH.[141,142] Additionally, aerobic glycolysis may favor anabolic metabolism and promote proliferative/activated states by diverting glycolytic intermediates involved in the synthesis of nucleotides, lipids, or amino acids. Glucose-6-phosphate is an essential substrate for the pentose phosphate pathway (PPP), producing ribose-5-phosphate for the synthesis of nucleotides (ATP and GTP) and NADPH for the de novo synthesis of lipids.[137,143]

Along with an increase in glycolysis, glutaminolysis is also increased in activated lung fibroblasts.[144,145] It has been reported that glutaminase levels were significantly increased in both TGF-β1-stimulated mouse lung fibroblasts and fibroblasts from patients with IPF.[144] Succinate, a byproduct of glutaminolysis, has been found to stabilize HIF1α expression, thereby augmenting levels of glycolytic enzymes and enhancing metabolic reprogramming.[140]

Epigenetic Regulation

The findings that specific signatures of gene profile in myofibroblasts are "memorized" over passages suggest that epigenetic modifications may be involved in the regulation of myofibroblast differentiation.[146] Epigenetic regulation of myofibroblastic phenotype involves DNA methylation, histone modification, and sequence-specific microRNAs (miRNAs). DNA methylation at CpG islands is associated with expression of myofibroblast marker α-SMA in lung cells. Type II alveolar epithelial cells that do not express α-SMA exhibit high levels of methylation at the three CpG islands in the regulatory regions of ACTA2 gene encoding α-SMA protein, whereas lung (myo) fibroblasts exhibit significantly low levels of DNA methylation at these sites.[147] Inhibition of DNA methyltransferase (DNMT) induces α-SMA expression, whereas overexpression of DNMT suppresses α-SMA expression in lung fibroblasts.[147] Inhibition of DNA methylation activates PPARγ and NF-κB, transcription factors known to suppress ACTA2 gene expression,[148] suggesting that modifications of DNA methylation may also indirectly regulate α-SMA expression by inactivation of PPARγ and NF-κB. Histone acetylation has been shown to regulate myofibroblast differentiation. It has been shown that histone deacetylase (HDAC)4 is an essential epigenetic regulator of TGF-β1-induced skin fibroblast-to-myofibroblast differentiation.[149] HDAC8 binds to α-SMA, and the binding is likely to regulate actin cytoskeleton-derived cellular contractility.[150]

miRNAs are single-stranded RNA molecules that target multiple mRNAs and induce silencing of multiple transcripts. It has been shown that miR-21 mediates TGF-β1-induced lung myofibroblast differentiation by targeting Smad7, a major inhibitor of TGF-β signaling.[151] In contrast, downregulation of miRNA let-7d expression by TGF-β results in increased mesenchymal gene expression (e.g., ACTA2) in multiple epithelial cell lines, indicative of EMT.[152]

miR-132 inhibits MeCP2 and PPARγ expression, resulting in enhanced α-SMA expression in lung fibroblasts.[148]

Other Factors

Wnt ligands induce fibroblast activation and collagen synthesis.[153] β-catenin, a transcription factor and a downstream signal transducer of Wnt signaling, was found to accumulate in the nuclei of cells located in the fibroblastic foci of IPF lungs.[154] Selective inhibition of β-catenin-mediated transcription attenuates lung fibrosis in a bleomycin-induced mouse model.[155] These studies suggest a crucial role of the Wnt/β-catenin signal in fibroblast activation and lung fibrosis. Integrins have been implicated in the differentiation of protomyofibroblasts into mature myofibroblasts.[156] Integrin $\alpha_5\beta_1$ is associated with α-SMA expression in differentiating myofibroblasts.[156] Large clusters of $\alpha_5\beta_1$ are present in the FAs of mature myofibroblasts.[156] Additionally, environmental stimuli including hypoxia and hyperglycemia, as well as direct contacts between fibroblasts and leukocytes, have been reported to be associated with fibroblast activation.[157,158]

■ Mechanical Aspects of Myofibroblasts

Important in detailing myofibroblast function is consideration of the cell's mechanical properties.

Myofibroblast Contractility

Acquisition of contractility similar to smooth muscle cells is a defining feature of myofibroblasts. Myofibroblasts generate intracellular contractile forces by ATP-powered sliding of actin–myosin filaments.[159] Compared with Ca^{2+}-regulated rapid and reversible contraction in smooth muscle cells, myofibroblast contraction is relatively slow, sustained, and nonreversible.[160] Myofibroblast contractility is primarily regulated by the Rho family of small GTPases (Rho, Rac, and Cdc 42) and their downstream targets, primarily myosin light chain kinase (MLCK) and myosin light chain phosphatase (MLCP).[77] α-SMA expression and incorporation of α-SMA into stress fibers contribute to myofibroblast contractility.[161] However, the mechanism by which α-SMA regulates myofibroblast contractile force formation is not clear. Myofibroblast contractility facilitates a normal wound healing process by limiting and closing the exposed surface area of the wound. Myofibroblasts disappear from the wound site when a normal repair process is successfully completed. The persistence of myofibroblasts is associated with aberrant wound repair and leads to tissue fibrosis/scarring. Increasing evidence suggests that myofibroblast contractility may provide a feed-forward mechanism (known as mechanotransduction, see below) that sustains fibrosis. Inhibiting myofibroblast contractility by targeting Rho/Rho kinase (ROCK)/actin cytoskeleton signal pathway selectively activates mitochondria-dependent intrinsic apoptotic pathway in myofibroblasts and ameliorates bleomycin-induced mouse lung fibrosis.[162] Disruption of myofibroblast contraction interrupts septa formation,[163] supporting a critical role for myofibroblasts in normal alveologenesis.

Sensing Matrix Stiffness

The ECM in healthy organs has well-defined mechanical properties that fall within a physiologic range.[164] Changes in matrix stiffness that occur in pathologic states, such as fibrosis and cancer, have profound effects on cell morphology, proliferation, migration, and gene expression.[164] Characterization of the mechanical properties of normal and fibrotic lung matrix demonstrates increased matrix rigidity in both human IPF and experimental models of lung fibrosis.[165,166] It is believed that protein cross-linking enzymes such as lysyl oxidase (LOXL2) and tissue transglutaminase (TG2) and/or matrix degrading enzymes such as MMPs regulate the stiffness of ECM, although the precise mechanisms remain to be determined. Fibroblasts sense changes in matrix stiffness by cell-matrix adhesions.[167] Transmembrane integrins at FAs act as direct mechanosensors on the cell membrane by providing a physical link between intracellular actin cytoskeleton and the ECM. The cytoplasmic domain of integrins interacts with signaling molecules at the FA sites (e.g., FAK and c-Src). Thus, integrins also act as indirect mechanosensors to regulate cell function and behavior by modulating FA signals.[168] Matrix stiffness sensing depends largely on cellular contractility and actin cytoskeleton integrity. Fibroblast contractility generates cytoskeletal tension that serves to transmit mechanical information from the ECM. Disruption of actin cytoskeleton-mediated contractility blocks matrix stiffening–induced myofibroblast differentiation.[131]

Mechanotransduction in Myofibroblasts

Mechanotransduction is a process in which cells sense mechanical stimuli and convert mechanical signals into biochemical signals. Recent studies suggest that mechanotransduction in myofibroblasts with prolonged survival/resistance to apoptosis may provide a feed-forward mechanism for progression of fibrosis, as in IPF. It has been reported that lung myofibroblast contraction promotes latent TGF-β activation, the most potent fibrogenic cytokine characterized to date, in the extracellular compartment[132,169] (Fig. 26-4). In this process, the actomyosin apparatus in myofibroblasts generates contractile forces that are transmitted across the cell membrane to the ECM. The force transmission results in a conformational change of the ECM-bound latent TGF-β1 complex, resulting in the release/exposure of active TGF-β1 from the latent complex. The finding suggests an extrinsic mechanotransduction pathway in which mechanical forces derived from intracellular stress fibers are transduced to the extracellular matrix and converted into TGF-β1 fibrogenic signal capable of regulating fibrosis.

In contrast to TGF-β-mediated extrinsic mechanotransduction pathway, an intrinsic mechanotransduction pathway in which the myofibroblast contractile signal is converted into a nuclear signal by transcription factor co-activator megakaryocytic leukemia protein (MKL) 1 (also known as MAL/MRTF-A) also has been identified[131]

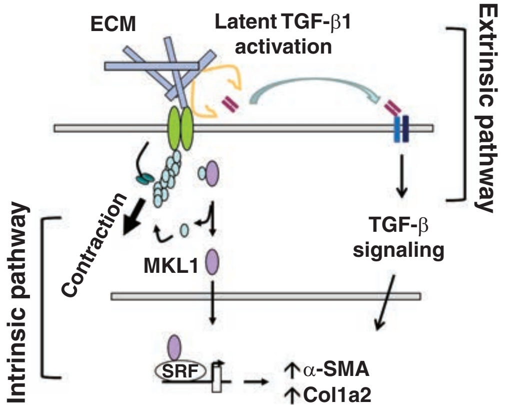

Figure 26-4 Contractile forces promote myofibroblast differentiation via intrinsic and extrinsic mechanotransduction pathways. In the intrinsic mechanotransduction pathway, mechanical stimuli from stiff/fibrotic ECM promote G-actin polymerization into F-actin. This results in the release of MKL1 and its nuclear translocation. MKL1 binds to SRF in the nucleus to form a transactivation complex and activates fibrotic gene expression that specifies myofibroblast differentiation. In the extrinsic mechanotransduction pathway, actomyosin-generated contractile forces pull against stiff/fibrotic ECM. This results in a conformational change of latent TGF-β1 complex, which releases active TGF-β1 from the latent molecule. Active TGF-β1 then binds to its receptors on the cell membrane and initiates TGF-β signaling that promotes fibrotic gene expression.

(Fig. 26-4). MKL1 is a serum response factor (SRF) co-activator that constitutively binds to monomeric G-actin in the cytoplasm.[170] In response to matrix stiffening, normal lung fibroblasts undergo extensive actin cytoskeletal remodeling and develop contractile forces. This changes actin cytoskeletal dynamics that favors G-actin polymerization into F-actin. Polymerization of G-actin into F-actin results in the release of MKL1 from G-actin. The liberated MKL1 enters into nucleus, where it binds to SRF and targets to the CArG sequence in the promoter region of ACTA2 gene and COL1A2 gene, leading to gene activation.[171] TGF-β neutralizing antibody does not block MKL1-mediated α-SMA expression,[131] suggesting that MKL1-mediated intrinsic mechanotransduction is independent of TGF-β-dependent extrinsic mechanotransduction. In addition to sensing mechanical stimuli, integrins are important mechanotransducers that allow bi-directional transduction and conversion of external forces into intracellular response (outside-in signaling) and internal forces (e.g., stress fiber–derived contractile forces) into extracellular and/or FA signals (inside-out signaling).[77,172] Besides integrins, stretch-activated ion channels, receptor tyrosine kinases (RTKs), CD44, and syndecan-4 are potential mediators of mechanotransduction as well.[173–176] However, mechanical stress may also regulate gene expression in fibroblasts through mechanotransduction-independent mechanisms. It has been shown that cyclic strain increases the mRNA level of tenascin-C within 1 h in cultured fibroblasts,[177] and this induction does not require synthesis of new proteins.[178]

■ Myofibroblasts in Tissue Homeostasis and Repair

Myofibroblasts play a role in the regulation of differentiation and homeostasis of adjacent epithelia. Such mesenchymal–epithelial interactions are crucial for morphogenesis and organogenesis.[179] Myofibroblasts regulate epithelia by secretion of soluble growth factors and production of basement membrane molecules.[180]

Myofibroblasts play important roles in both normal and aberrant wound repair. As mentioned above, myofibroblast contractility facilitates wound closure. During the resolution phase, myofibroblasts produce MMPs and TIMPs that change the local microenvironment from a balance favoring ECM deposition to matrix degradation.[181] Interconnected gap junctions of myofibroblasts allow the electrical signals created by cyclic ion movements to be transmitted through the syncytium and the length of the resident organ.[182] Myofibroblasts sustain their activated state in fibrosis/hypertrophic scarring even when the initial insults have regressed. Myofibroblasts in such a sustained state of activation continue to secrete ECM constituents, growth factors, and cytokines. These result in a self-perpetuating autocrine loop that further stimulates myofibroblast differentiation and prevents normal resolution of tissue injury. In addition to fibrosis/hypertrophic scars, diseases associated with myofibroblastic phenotype include inflammatory pseudotumors, cancer metastasis, and neoplastic transformation of the myofibroblasts themselves.

■ The Fate of Myofibroblasts

The fate of myofibroblasts is a key determinant between normal repair and fibrosis. In normal wound healing, myofibroblasts gradually disappear after wounds are closed. Persistent myofibroblast differentiation is associated with pathologic wound healing and fibrosis. Understanding of the physiologic clearance of activated fibroblasts is particularly important for developing therapeutic strategies for persistent/progressive fibrosis such as IPF.

Figure 26-5 Mechanosensitive signaling in myofibroblasts as a target for antifibrotic therapy. In response to extracellular biomechanical and biochemical stimuli, such as matrix stiffness and active TGF-β1, lung fibroblasts undergo actin cytoskeleton remodeling and activation of the actomyosin contractile system, which result in MKL1 translocation from cytoplasm to nucleus, where it activates fibrotic genes that specify myofibroblast differentiation. Inhibition of ROCK blocks actin cytoskeletal reorganization, fibroblast acquisition of contractile activity, and MKL1 nuclear translocation, preventing fibroblast-to-myofibroblast differentiation. On the other hand, ROCK inhibition disrupts actin cytoskeleton required for myofibroblast contractility in pre-existing myofibroblasts. This deactivates constitutively activated MKL1 nuclear signal in myofibroblasts, resulting in downregulation of the antiapoptotic protein Bcl-2 and activation of the intrinsic apoptotic pathway.

Apoptosis

Apoptosis has been suggested as an intriguing possibility for the elimination of myofibroblasts from healing wounds and reversible fibrosis.[183] An earlier study has observed that myofibroblasts undergo apoptosis in granulation tissue on which a vascularized skin flap is grafted.[184] Reduced growth factor and increased MMP expression appear to link to myofibroblast cell death.[185] Disruption of cell-matrix interactions using RGD peptides or soluble fibronectin promotes myofibroblast anoikis, a type of apoptosis that is induced by inadequate or inappropriate cell-matrix interactions.[186] In reversible liver fibrosis, hepatic stellate cell (HSC)-derived myofibroblasts undergo apoptosis in parallel to the reduction of the total number of HSCs in the recovery phase.[187] Hepatic myofibroblast apoptosis appears to occur by a Fas ligand (APO-1/CD95)-mediated extrinsic pathway.[187] Pharmacologic inhibition of ROCK, such as with fasudil, inhibits actin polymerization and downregulates constitutive expression of the antiapoptotic protein Bcl-2 in IPF lung myofibroblasts; this results in release of cytochrome *c* from mitochondria, triggering the mitochondria-dependent intrinsic apoptosis pathway. Furthermore, fasudil-induced myofibroblast apoptosis ameliorates bleomycin-induced lung fibrosis in mice.[162] This study indicates that targeting mechanosensitive signaling in myofibroblasts may offer an effective approach for treatment of fibrotic disorders (Fig. 26-5).

Interestingly, mitochondria in stiff matrix-activated lung myofibroblasts were found to load with proapoptotic BH3 proteins, thus increasing their mitochondrial priming. Myofibroblasts in this "primed for death" state were prone to undergo apoptosis and became reliant on antiapoptotic proteins for their survival. This creates a therapeutic opportunity to treat lung fibrosis by inducing myofibroblast apoptosis with BH3 mimetics, which have been shown to be effective in experimental models of lung fibrosis.[188]

Dedifferentiation

A recent study showed that HSC-derived myofibroblasts regress to a more quiescent state upon the removal of the fibrogenic stimuli in a carbon tetrachloride-induced mouse model of liver fibrosis.[94] The finding suggests that reversion of myofibroblasts to a more quiescent phenotype may be a second possibility folsis,[94] suggesting that myofibroblast regression may be an intermediate step towards the resolution of fibrosis. Although regression to an inactive precursor cell may limit the activity of myofibroblasts, this does not appear to completely eliminate the potential for re-activation. In large skin wounds, myofibroblasts can generate lipid-filled adipocytes that regenerate hair follicles.[189] It has been suggested that myofibroblasts undergo a dedifferentiation event that is controlled by mitogen(s)/ERK/MAPK/CDKs, as opposed to TGF-β1/ALK5/MyoD-dependent myofibroblast differentiation during fibrosis formation.[190] The reversibility of the fibrotic response in mouse lungs triggered by bleomycin administration was used to investigate the fate of myofibroblasts following fibrosis resolution. Results show that a subset of activated myofibroblasts transitioned to a lipofibroblast-like phenotype,[191] supporting the myofibroblast dedifferentiation as an essential process in fibroblast resolution.

Senescence

Cellular senescence is associated with the loss of the ability of cells to replicate their genome and enter permanent growth arrest in the G1/G0 cell-cycle phase.[192] Although senescent fibroblasts do not respond to mitogens, they remain metabolically active and are resistant to apoptosis. Cellular senescence often occurs by telomere shortening and subsequent activation of p53 and p21 and/or inactivation of pRB and activation of p16.[192] Senescence may also be triggered by other forms of cellular damage, including oxidative stress, DNA damage and oncogene activation.[192] Myofibroblast senescence has been proposed as an antifibrotic mechanism by limiting the proliferative capacity of fibrogenic fibroblasts and/or by modulating the cellular microenvironment.[193,194] However, this basic assertion is inconsistent with the clinical observation of an increased risk of fibrotic disease with advancing age. This highlights the complexities of cellular senescence in tissue injury repair processes, and supports the concept that the plasticity and fate of senescent cells may be altered with aging which, ultimately, determines the outcome of the tissue repair response.

MYOFIBROBLASTS IN LUNG DEVELOPMENT AND DISEASE

Important considerations in any discussion of myofibroblasts include their role in alveogenesis and in a variety of disease states, including pulmonary fibrosis, asthma, emphysema, and non–small-cell lung cancer.

Alveologenesis

Lung development is a complex process involving reciprocal interactions between mesoderm-derived mesenchyme and endoderm-derived epithelium. Alveolar myofibroblasts are present during alveologenesis but absent in the adult lung.[195] Myofibroblasts surround the distal lung epithelial tubules and buds in the pseudoglandular stage of lung development. The absence of alveolar myofibroblasts is associated with deficient secondary septation and the failure of alveolar development.[196] Although alveolar myofibroblasts play an essential role in the morphogenesis of pulmonary alveolar septa, mechanisms involved in the regulation of alveolar myofibroblast survival and clearance in the process of alveologenesis are poorly understood and need further investigation.

Pulmonary Fibrosis

Pulmonary fibrosis is characterized by excessive synthesis and deposition of ECM proteins in the lung parenchyma, resulting in deficient gas exchange. IPF is the most common and lethal diffuse fibrosing lung disease, with a mortality rate that exceeds that of many cancers. Currently, there is no FDA-approved pharmacologic therapy for patients with IPF. The pathogenesis of IPF remains elusive. The current paradigm posits that repeated alveolar epithelial injury and persistent myofibroblast activation are central to the progression of IPF.[197] Regardless of the origins, myofibroblasts isolated from IPF lungs have increased migratory activity, ability to deposit ECM, and prolonged survival/resistance to apoptosis compared to their normal conterparts.[197] Abnormal myofibroblast survival is a key determinant of whether fibrosis will progress or resolve.[198] The survival of IPF myofibroblasts has been found to be regulated by multiple antiapoptotic signals.[199] These include enhanced responsiveness to growth factors and fibrotic cytokines; impaired cyclooxygenase-2 expression and consequential reduction in prostaglandin E2 production; decreased caveolin 1 (CAV1) and PTEN expression; and increased antiapoptotic protein expression, as well as signals from the extracellular microenvironment. Myofibroblasts isolated from fibrotic lungs induce cytotoxic effects on epithelial cells. Co-culturing of myofibroblasts with lung epithelial cells results in epithelial cell apoptosis by FAS–Fas ligand (FAS–FasL)-dependent and -independent mechanisms.[200,201] Epithelial cell apoptosis can cause further lung injury that augments lung fibrosis. Myofibroblasts produce cytokines and growth factors that signal to the epithelium, resulting in damage to the alveolar basement membrane that prevents re-epithelialization.[202] Myofibroblast-produced chemokines promote the recruitment of immune cells and fibrocytes that actively participate in fibrotic progression.[203,204]

Asthma

Airway remodeling in patients with asthma encompasses the structural alterations that lead to persistent airflow limitation. Both smooth muscle cells and (myo)fibroblasts have been implicated in the pathogenesis of airway remodeling in asthmatic airways. In asthmatic patients, susceptibility to injury and aberrant repair responses result in fibroblast activation and myofibroblast differentiation, leading to subepithelial fibrosis.[205] Reduced airway remodeling in anti-leukotriene therapy is due, in part, to diminished myofibroblasts in asthmatic airways.[206] Viral infections are major triggers of acute asthma exacerbations.[207] The susceptibility to viral infections in asthmatic patients is not limited to epithelial cells. Rhinoviruses have been detected in subepithelial cells including fibroblasts, likely due to the disrupted and inflamed epithelium.[208] Fibroblasts from asthmatic patients have enhanced abilities for replication of rhinoviruses and subsequent production of IL-6 and IL-8, resulting in vigorous proinflammatory responses.[209] TGF-β augments rhinovirus replication in fibroblasts isolated from asthmatic patients.[210]

Emphysema

Emphysema is characterized by the progressive destruction of pulmonary alveoli. A vast majority of cases of pulmonary emphysema are associated with chronic lung injury induced by cigarette smoke. Chronic smoke exposure induces inflammation, protease/

antiprotease imbalance, oxidative stress, and death of bronchiolar and alveolar epithelial and endothelial cells.[211] Cigarette smoke reduces lung fibroblast proliferation and migration and induces fibroblast apoptosis.[212,213] In addition to the cytotoxic effects, cigarette smoke inhibits elastin synthesis and cross-linking in fetal lung fibroblasts.[214,215] Interactions between fibroblasts and alveolar epithelial cells are greatly reduced in the emphysematous lung,[216] suggesting that the repair and regeneration function of fibroblasts are impaired. Emphysema fibroblasts display features of myofibroblast differentiation and senescent phenotype characterized by enlarged morphology and cell cycle arrest.[217,218]

■ Non–Small-Cell Lung Cancer (NSCLC)

Carcinoma-associated fibroblasts (CAFs) constitute a major portion of reactive tumor stroma. CAFs express α-SMA and high levels of collagens and ED-A FN, indicating that these cells are of myofibroblast characteristics.[219] CAFs are responsible for dense ECM deposition around tumors and thus have been considered as a defense mechanism for tumor growth. In established tumors, CAFs synthesize cytokines/growth factors (e.g., TGF-β1) and ECM-degrading proteases (e.g., MMPs) that promote angiogenesis, recruitment of inflammatory cells, cancer cell proliferation, invasion, and metastasis.[3] CAF-associated prognostic factors have been identified in NSCLC. In adenocarcinomas, carbonic anhydrase IX expression has been found a better prognostic predictor in CAFs than in cancer cells.[220] Expression of podoplanin, a lymphatic endothelial cell marker, in CAFs is associated with shorter survival in patients with NSCLC.[221] In squamous cell carcinomas, MMP-2 expression in CAFs is found to be a significant unfavorable prognostic factor.[222] While expression of PDGF-B, PDGF-C, and PDGFR-α in cancer cells is associated with a negative prognosis, expression of PDGF-A, PDGF-B, PDGF-D, and PDGFR-α in CAFs is a favorable prognostic indicator.[223] Additionally, it has been found that stromal expression of PDGF-B, PDGF-D, and PDGFR-α is associated with less nodal metastasis.[224] Clinical prognostic values of TGF-β and FGF in NSCLC have been evaluated in the previous studies.[225–228] Due to the conflicting results, the prognostic roles of TGF-β and FGF2 in NSCLC remain uncertain.

TARGETING MYOFIBROBLASTS AND MATRIX REMODELING FOR LUNG DISEASE THERAPIES

Tissue remodeling in response to injury is a common pathologic feature observed in many lung diseases including IPF. Dysregulation of fibroblast function and matrix metabolism are crucial to the aberrant injury repair in IPF lungs. Currently, there are no treatments that specifically target myofibroblast-associated pathologies in IPF. Pirfenidone is an FDA-approved drug for IPF treatment. It inhibits fibroblast proliferation and collagen synthesis.[229,230]

PDGF is a potent mitogen and chemoattractant for fibroblasts and induces procollagen production by fibroblasts in vitro. Targeting PDGF receptor with imatinib mesylate, a tyrosine kinase inhibitor, has been shown to prevent bleomycin-induced mouse lung fibrosis.[231] However, a randomized, placebo-controlled trial showed that imatinib does not improve survival or lung function in patients with mild to moderate IPF.[232]

TGF-β1 is the most potent inducer of fibroblast ECM production characterized to date and promotes fibroblast to myofibroblast differentiation. Several types of pharmacotherapy to block TGF-β have been developed including antibodies, soluble receptors, intracellular signaling pathway inhibitors, and agents that target the cell surface receptors for TGF-β (TGF-βRI/II).[233,234] A phase 1 clinical trial with TGF-β neutralizing antibody has begun in patients with IPF. Orally active TGF-βRI kinase inhibitors have been shown to attenuate bleomycin-induced mouse lung fibrosis.[235] Since TGF-β has important homeostatic functions in the regulation of immune response and tumor suppression, therapeutic strategies that directly block TGF-β may yield undesirable side effects. Alternatively, targeting latent TGF-β activation has become a more favorable approach for antifibrotic therapy. Integrins are important mediators for in vivo activation of latent TGF-β.[236] $\alpha_v\beta_6$ integrin plays the primary role in regulating epithelial latent TGF-β1 activation.[237] Mouse studies have shown that inhibition of $\alpha_v\beta_6$ integrin blocks bleomycin- and radiation-induced lung fibrosis, and this integrin is also abnormally regulated in human fibrotic diseases.[237] BG00011, a humanized monoclonal antibody to integrin $\alpha_v\beta_6$, demonstrated TGF-β suppression in phase 2A clinical trial in IPF. $\alpha_v\beta_5$ integrin regulates mechanical tension-induced latent TGF-β1 activation in lung (myo) fibroblasts.[132] This integrin is co-expressed with α-SMA positive myofibroblasts, but absent on hyperplastic epithelial cells in the fibroblastic foci in IPF.[238] The GPI-linked Thy-1 blocks mechanical tension–induced latent TGF-β1 activation, presumably by disruption of the binding of latent TGF-β1 with $\alpha_v\beta_5$ integrin.[169]

Emerging preclinical evidence suggests that targeting metabolic pathways could be effective in the treatment of pulmonary fibrosis. Pharmacologic or genetic approaches to inhibiting the glycolytic enzyme 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 3 (PFKFB3) reduced fibroblast activation in vitro and dramatically ameliorated the severity of pulmonary fibrosis in mice.[140] It remains to be determined whether chronic use of glycolytic inhibitors will be safe in animals or, more importantly, in humans. Pharmacologic (CB-839 or BPTES) and genetic approaches to inhibiting glutaminolysis can significantly suppress collagen gene transcription in lung fibroblasts.[144,145] Inhibition of amino acid biosynthesis might be effective in reducing fibrotic responses.[239,240] AMPK functions to restore energy balance by inhibiting processes that consume ATP and by stimulating processes the lead to the production of new ATP. AMPK activation is reduced in lungs of mice during pulmonary fibrosis. Treatment of mice with the AMPK activator metformin markedly improved fibrosis resolution capacity in the bleomycin injury model.[241]

Inhibition of excess ECM generation, deposition, and stabilization, and increasing matrix degradation, have become important targets for pharmacologic therapy. Cytokines including CTGF, PDGF, ET1, and IGF can induce fibroblast/myofibroblast activation and regulate matrix production. Inhibition of all of these cytokines can inhibit pulmonary fibrosis in a variety of in vivo models of fibrosis.[112,242–244] MMPs, including MMP 1, 3, and 7, among others, have been implicated in the pathogenesis of pulmonary fibrosis,[245] although the exact role of the MMPs in the pathogenesis of pulmonary fibrosis remains not known. Matrix cross-linking enzymes are responsible for the regulation of ECM stabilization. Cross-linking makes matrix potentially more resistant to degradation and may favor fibrosis progression. TG2 induces the cross-linking of collagen and fibronectin, resulting in stabilization of the matrix.[246] TG2 is elevated in many forms of human and murine pulmonary fibrosis.[246] Inhibition of the extracellular cross-linking function of TG2 results in inhibition of ECM generation and cross-linking in the lung.[246] Irreversible inhibitors of TG2 have been developed and are available from several commercial sources. LOXL2, another matrix cross-linking protein, catalyzes the first step in the formation of cross-links in collagens and elastin.[247] LOXL2 cross-links fibrillar collagen, making it more resistant to homeostatic turnover. LOXL2 is induced by TGF-β and is upregulated in IPF.[248,249] Administration of a monoclonal anti-LOXL2 antibody (AB0023) in either a prophylactic manner or a therapeutic manner significantly attenuates bleomycin-induced fibrosis in mice.[249]

Drug targeting systems for delivering therapeutic agents to myofibroblasts utilize cell surface targets. As a general targeting strategy, ligands such as peptides, antibodies, aptamers, or other moieties are designed against receptors overexpressed by myofibroblasts.[250]

These ligands are either directly conjugated to the therapeutic molecule or to a (nano)carrier incorporating a therapeutic agent. Drug targeting to subpopulations of myofibroblasts will be a highly appealing approach since it allows to specifically hamper the disease-inducing functions of myofibroblasts while leaving the rest unaffected. To achieve this would require the identification of specific surface markers delineating myofibroblast subpopulations.

CONCLUSION AND PERSPECTIVES

An understanding of the physiology and pathophysiology of fibroblasts has greatly advanced in the past few decades. It has become increasingly clear that fibroblasts and myofibroblasts play important roles in human health and disease. Despite this, many fundamental questions remain to be answered. The origins of myofibroblasts remain to be clarified. It is not known whether myofibroblasts of various origins exhibit different characteristics and functions in the injury and repair process. Identification of specific markers for fibroblasts will allow their specific isolation and more precise characterization, both in vitro and in vivo. Additionally, specific markers could facilitate genetic animal studies allowing the specific targeting of these cells. The independent and interactive roles of cytokines, ECM, and mechanical forces in the regulation of the structure and function of fibroblasts and myofibroblasts need to be characterized.

The identification of myofibroblasts as key cells and potential targets in fibrotic diseases such as IPF has led to the concept that targeting these cells may be a promising approach for disease therapy. Interesting approaches that target myofibroblasts and the ECM include termination of myofibroblast persistence by inducing their apoptosis or their reversion to nonfibrogenic cell phenotypes; interference with collagen cross-linking and ECM stiffening by controlling the activities of protein cross-linking enzymes and nonenzymatic crosslinking mediators such as advanced glycation end products (AGEs); and the use of miRNAs and metabolic modulators as potential therapeutic strategies. We believe that these novel approaches will eventually lead to more effective treatments for patients with fibrotic lung diseases.

CHAPTER 27

Approach to the Patient with Respiratory Symptoms

Michael A. Grippi
Jeffrey P. Callen

The most common respiratory complaints prompting medical evaluation are shortness of breath and cough. Less frequent are hemoptysis and thoracic pain. As in any medical assessment, a detailed history and thorough physical examination are of paramount importance. Use of plain chest radiography for routine screening, once popular in the hope of uncovering silent disease amenable to therapy, is not routinely employed, as it has not been proven to decrease mortality or to be cost-effective. Chest radiography is now usually reserved for patients who have clinical manifestations of thoracic disease; serial chest radiographs often provide invaluable clues regarding the underlying problem. More sophisticated imaging techniques, including computed tomography (CT),[1,2] along with tests of lung function, help complete the clinical picture.

HISTORY

Although seasoned clinicians may be adept at quickly spotting telltale diagnostic clues, a comprehensive medical history is central to patient evaluation. The history should include a detailed inventory of exposure to airborne substances that may result in lung injury. One of the most common offenders is cigarette smoke. An attempt should be made to quantify the exposure.

Often, the workplace is the site where toxic air is inhaled. An almost forgotten exposure to a toxic inhalant 20 years ago may explain certain types of pulmonary or pleural diseases. Symptoms that appear to improve during weekends or other periods away from work may be a clue to an occupational exposure that causes a respiratory ailment. A newly installed home humidifier or an air conditioning system that incorporates stagnant pools of water can point the way to resolving a mysterious illness. Brief residence in an area where either cryptococcosis (southwestern United States) or histoplasmosis (southern and midwestern United States) is endemic may help clarify the nature of an illness that mimics tuberculosis. A recent visit to a South or Central American country may bring into focus a more remote possibility (e.g., South American blastomycosis) (Fig. 27-1).

The history should include a thorough evaluation of prior and current medical problems. Rheumatologic disorders, such as systemic sclerosis (scleroderma), may be associated with interstitial lung disease, aspiration pneumonia due to esophageal involvement, or pulmonary vascular disease. Certain malignancies often metastasize to the lung (e.g., breast or colon carcinoma), or predispose to development of venous thromboembolism (e.g., pancreatic carcinoma). Infection with the human immunodeficiency virus (HIV) should not be overlooked, since pulmonary complications are often the initial presentation of acquired immunodeficiency syndrome (AIDS). Other causes of immunodeficiency, such as hematologic malignancy, or prior administration of chemotherapeutic agents, should heighten suspicion of infection as the cause of respiratory symptoms, as well as potential pulmonary drug toxicity.

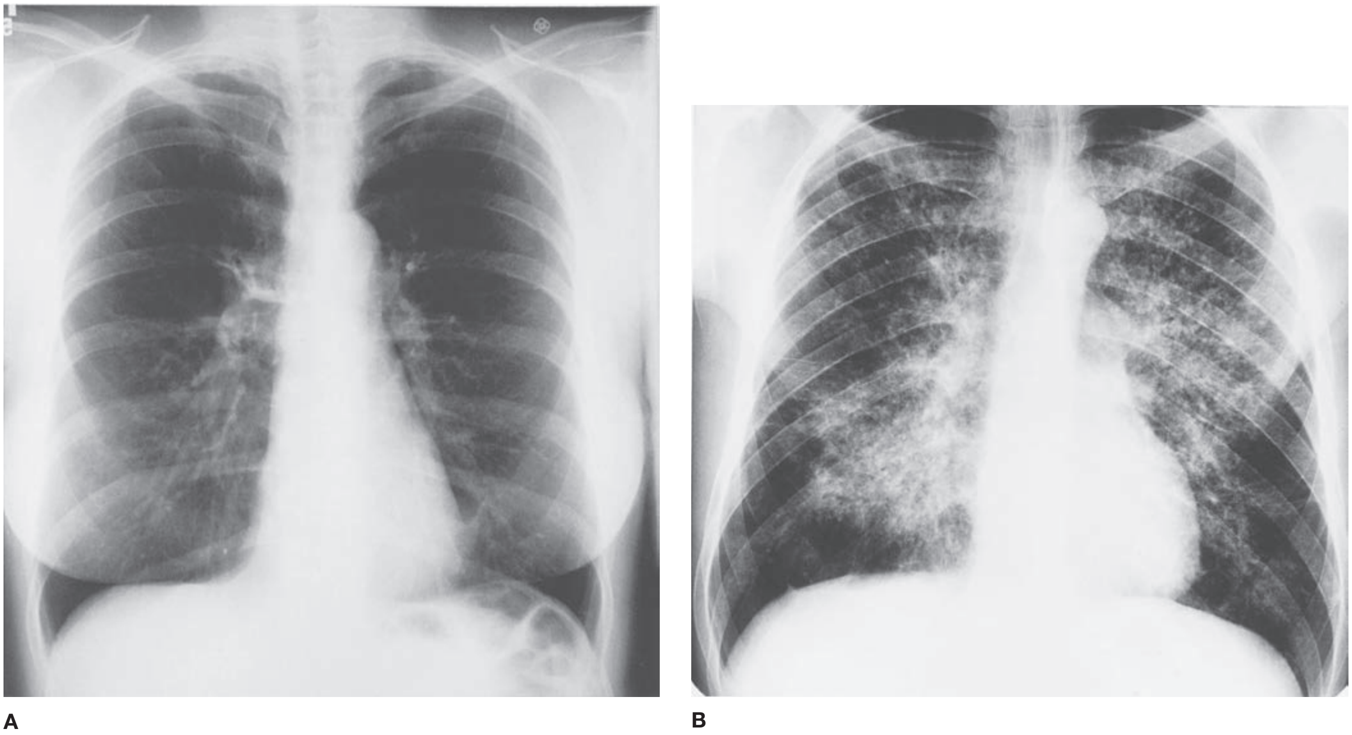

Figure 27-1 Exposure in an endemic area. **A.** Clear lung fields. **B.** South American blastomycosis. *(Reproduced with permission from Dr. Nelson Porto.)*

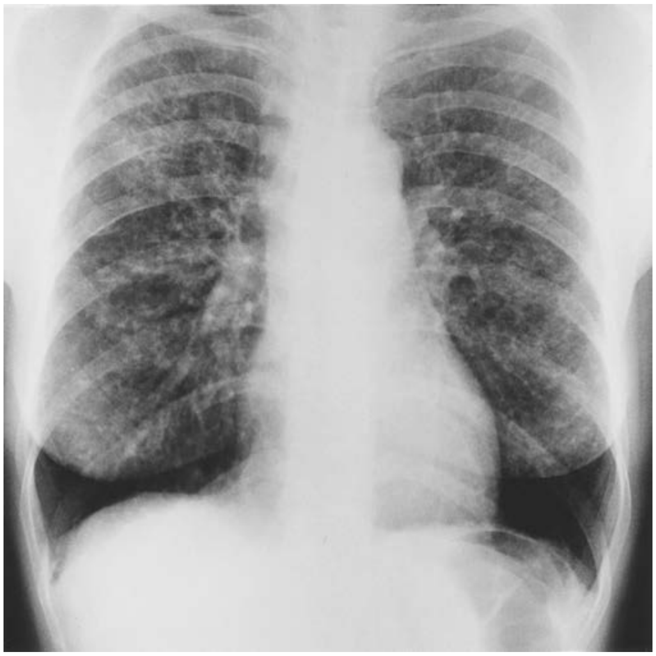

Figure 27-2 Nitrofurantoin hypersensitivity pneumonitis. The ingestion of nitrofurantoin was accompanied by the appearance of patchy interstitial and alveolar changes throughout both lungs.

Indeed, many pharmacologic agents, including chemotherapeutic and nonchemotherapeutic agents, have a propensity for inflicting lung damage (see Chapters 65 and 66). Classic examples include bleomycin, nitrofurantoin, and methotrexate (Fig. 27-2), but the number of drugs implicated in producing lung injury has grown exponentially in recent years. Beta blockers, administered as part of a cardiac regimen, may evoke bronchoconstriction. Even a common medication, such as aspirin, may, on rare occasion, cause a severe pulmonary disorder (e.g., pulmonary edema).

Finally, the family history is an essential ingredient of the medical inventory. This history can uncover a heritable disease of the lungs (e.g., cystic fibrosis [CF], α_1-antitrypsin deficiency, alveolar microlithiasis, hereditary telangiectasia).

PHYSICAL EXAMINATION

Before the widespread use of chest radiography, physical examination, along with the history, played a pivotal role in the diagnosis of pulmonary disease. The advent of chest radiography and chest CT imaging has de-emphasized the value of the physical examination. Nonetheless, the physical examination remains a valuable diagnostic measure in the appraisal of chest disease.[3,4]

■ General Aspects

Important clues are often available before examination of the chest. For example, neglected pyorrheal teeth raise the prospect of necrotizing aspiration pneumonia. A lacerated tongue suggests that a convulsive episode may have led to aspiration (Fig. 27-3). Pursing of the lips during expiration ("pursed-lip breathing") may be seen in patients with chronic obstructive pulmonary disease (COPD). Subtle changes in consciousness or coordination may signal that metastasis has occurred to the brain from a primary carcinoma of the lung. In the patient with COPD, a clouded sensorium or a disturbed personality can signify acute elevation in arterial P_{CO_2}.

Inspection of the skin often provides clues to diseases of the chest; a more detailed discussion of notable cutaneous manifestations in respiratory disorders is provided later in this chapter. Evidence to support the diagnosis of pulmonary sarcoidosis may be found in the eyes and skin. Petechiae, purpura, necrosis, and/or ulceration of the skin may reflect a systemic vasculitis. The skin lesions of neurofibromatosis type 1 (von Recklinghausen disease) may signify that a solitary pulmonary nodule in the paraspinal region may be a neurofibroma. A minute skin abscess may turn out to be the source of multiple lung abscesses. Distinctive scars over the antecubital veins of a drug addict can help to clarify the etiology of old lesions in the lungs, as well as of a newly discovered lung abscess. Erythema nodosum (EN) is frequently due to sarcoidosis, but may also occur in patients with tuberculosis, histoplasmosis, or coccidioidomycosis. Skin papules in Birt–Hogg–Dubé syndrome

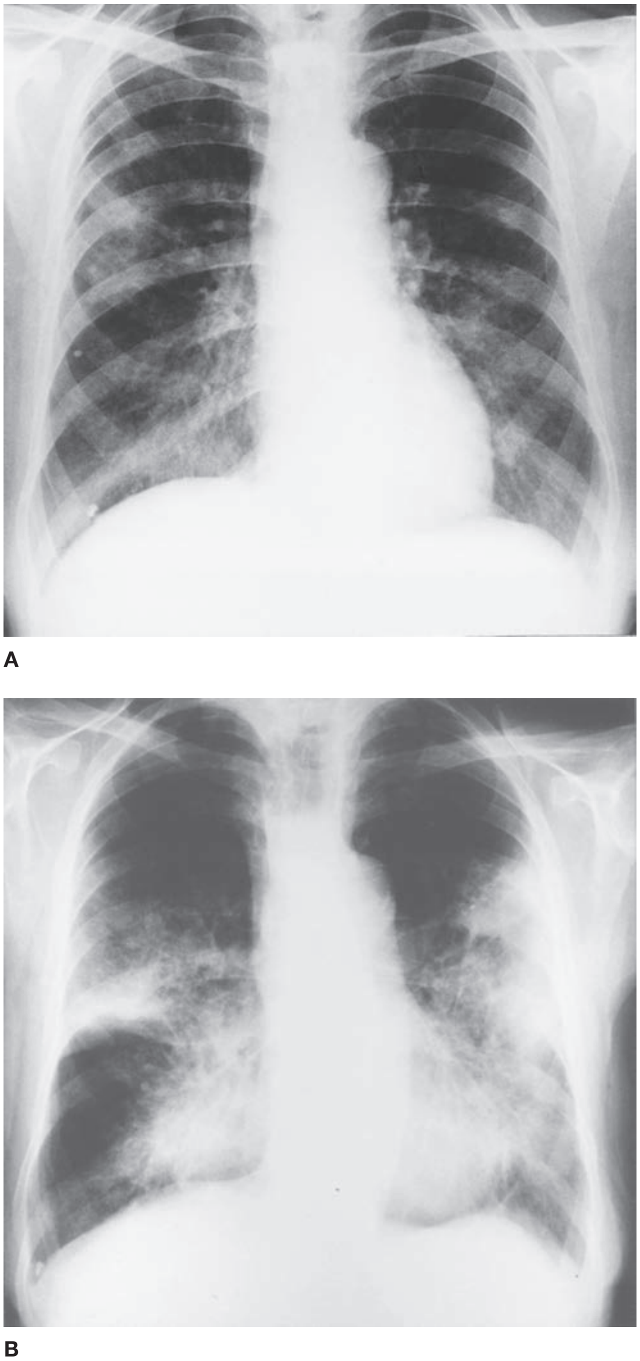

Figure 27-3 Chronic aspiration pneumonia. **A.** Chronic aspiration pneumonia in a 72-year-old man hospitalized for repair of hernia. Patchy infiltrates bilaterally. No pulmonary symptoms. Initiating cause was achalasia of esophagus. **B.** Eighteen months later. Persistent cough and breathlessness.

TABLE 27-1 Clinical Disorders Commonly Associated with Clubbing of Digits

Pulmonary and thoracic
Primary lung cancer
Bronchiectasis
Cystic fibrosis
Lung abscess
Pulmonary fibrosis
Pulmonary arteriovenous malformations
Empyema
Mesothelioma
Neurogenic diaphragmatic tumors
Cardiac
Congenital
Subacute bacterial endocarditis
Gastrointestinal and hepatic
Hepatic cirrhosis
Chronic ulcerative colitis
Regional enteritis (Crohn's disease)

(see "Pulmonary-Cutaneous Syndromes," below) may antedate the pulmonary manifestations of cystic lung lesions and pneumothorax by decades.[5]

A variety of endocrine syndromes may accompany carcinoma of the lung. An altered mental status may be due to hyponatremia caused by the syndrome of inappropriate antidiuretic hormone (SIADH). Clubbing of the digits may accompany various clinical disorders, including idiopathic pulmonary fibrosis, bronchiectasis, and certain carcinomas of the lung (Table 27-1).[6] A puffy face, neck, and eyelids, coupled with dilated veins of the neck, shoulder, thorax, and upper arm (i.e., superior vena cava syndrome) may constitute the first clinical evidence of obstruction of the superior vena cava by a neoplasm of the lung. Although the causes of superior vena cava syndrome are many and diverse, at least 80% are attributable to a primary carcinoma of the lung (Fig. 27-4). In the patient in whom a neoplasm has evoked acute signs and symptoms of increased systemic venous pressure that progresses rapidly (e.g., to laryngeal edema), early diagnosis and prompt treatment of the neoplasm can be lifesaving. The presence of Horner syndrome—unilateral ptosis, miosis, and anhidrosis—in a patient with a carcinoma of the lung suggests a pulmonary sulcus tumor with involvement of the ipsilateral sympathetic pathway within the thorax (Fig. 27-5).

■ Inspection of the Chest

Observation of the chest from the foot of the bed can be informative: a visible lag in expansion of one side of the thorax localizes a pleural effusion, pulmonary infection, or paralyzed diaphragm. The respiratory pattern may be informative: patients with severe airflow obstruction often take slow, deep breaths, whereas rapid and shallow breaths are often seen with restrictive processes, such as interstitial lung disease or kyphoscoliosis. Inspection of the chest and abdomen in the supine position may reveal paradoxical inward movement of the abdomen, indicative of respiratory muscle weakness.[7]

■ Palpation of the Chest

Over the years, the role of palpation in examination of the chest has been considerably devalued. Nonetheless, palpation may provide helpful diagnostic clues as well as confirmatory evidence for other

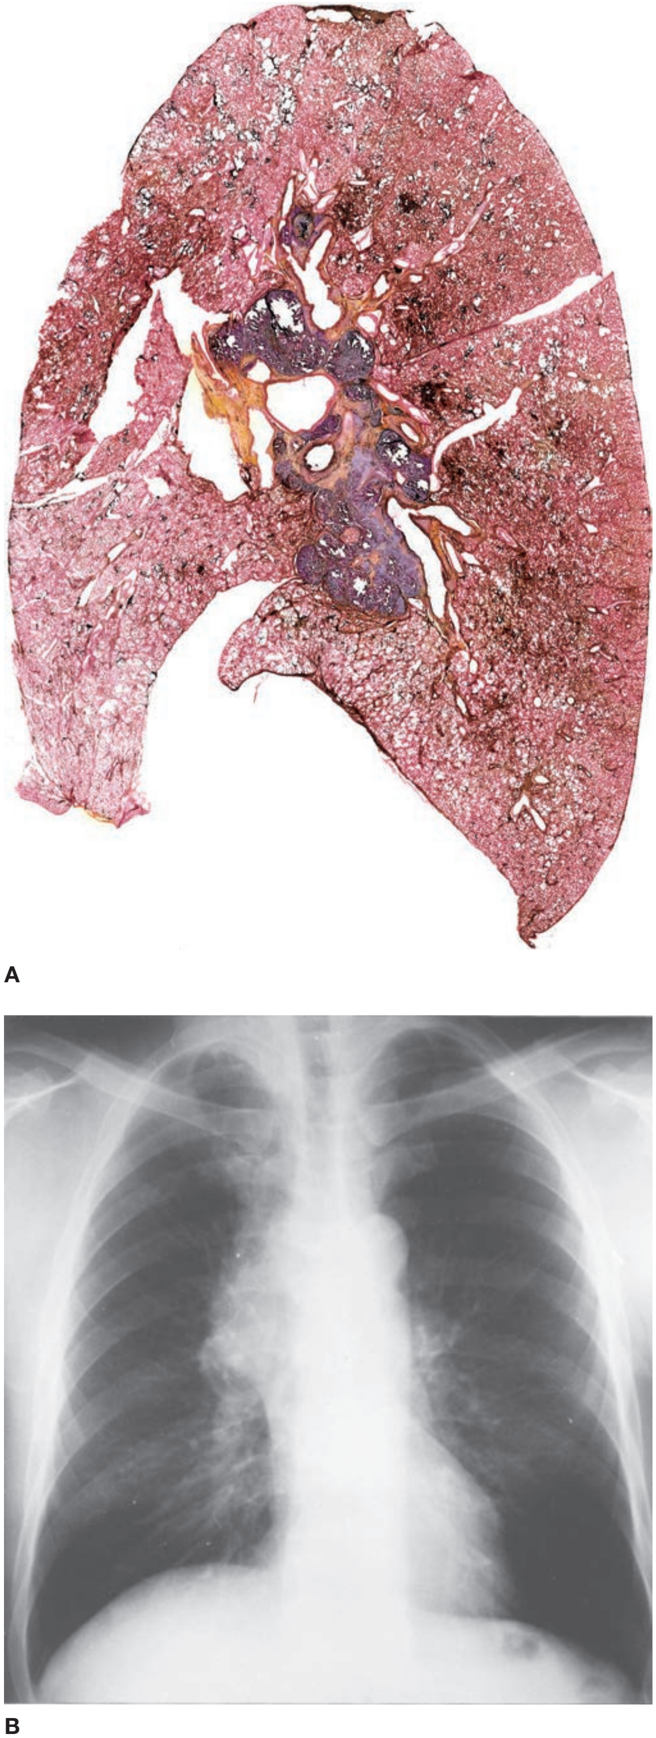

Figure 27-4 Local invasiveness of carcinoma of the lung. **A.** Sagittal section of the lung illustrating a carcinoma *(blue)* of the lung in the vicinity of the hilus. **B.** Chest radiograph showing right hilar mass.

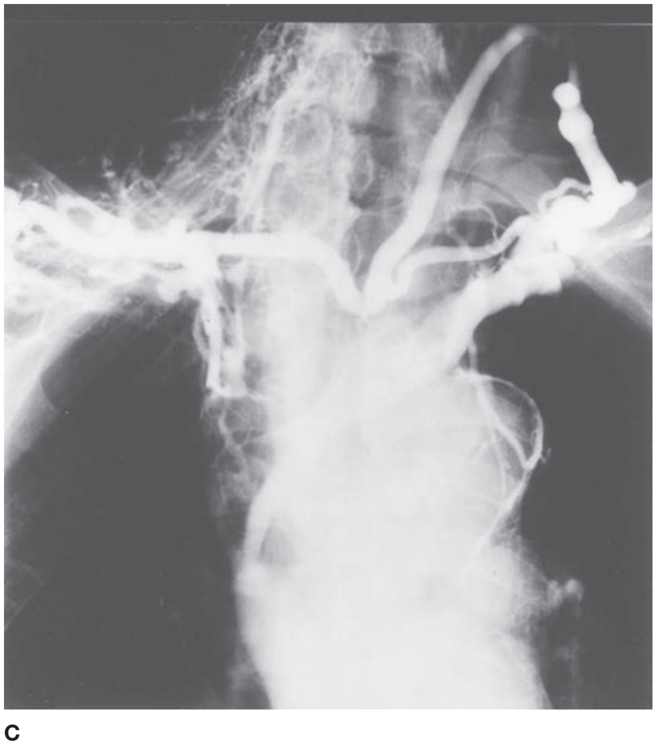

Figure 27-4 *(Continued)* **C.** Angiogram showing obstruction and extensive collateral circulation.

physical signs. For example, the position of the trachea determined by palpation in the suprasternal notch may be helpful in detecting a lateral displacement of the upper mediastinum. Displacement of the apical impulse and of cardiac dullness may be useful indices in detecting shift of the lower mediastinum. Tenderness over a rib may reflect a fracture, metastasis, or underlying pleuritis. Enlargement of the right ventricle can be readily detected by palpation in the subxiphoid region. *Hoover sign* may be useful in disclosing a unilateral lag in motion of one side of the chest due to pleuritis or a pleural effusion. The sign is elicited by comparing the displacement from the midline during a patient's deep inspiration of the examiner's hands, each placed lightly over one hemithorax, with thumbs touching beneath the xiphoid at the start of the breath.

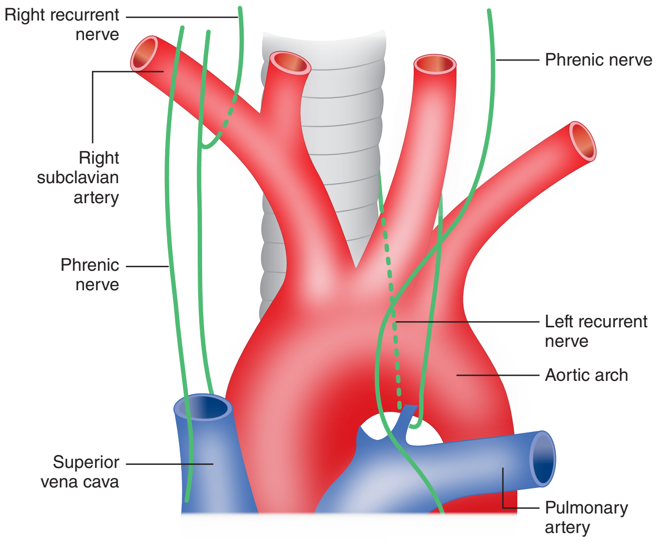

Figure 27-5 Courses of the recurrent laryngeal nerves. Invasion or compression of a nerve by a carcinoma of the lung causes paralysis of the vocal cord.

An abnormal mass or fullness palpated in the supraclavicular space may be a clue to a neoplasm or an involved lymph node and suggests a convenient location to obtain a biopsy for diagnosis.

Consolidation of the lung, which causes increased transmission of sound, can be detected as fremitus (i.e., as a palpable vibration) over the affected area while the patient repeatedly vocalizes the traditional "one, two, three" as the examiner moves his or her palms systematically over the two hemithoraces. Conversely, impairment of sound transmission, as by a pleural effusion, diminishes vocal fremitus. In some instances, a pleural friction rub is palpable.

■ Percussion of the Chest

Percussion as part of the physical examination follows Auenbrugger sounding of beer barrels to determine their fluid levels. The response to percussion is impaired whenever something other than air-filled lung lies directly beneath the chest wall. Common causes of dullness to percussion are consolidation or atelectasis of the lung, fluid in the pleural space, pleural thickening, and a large mass at the surface of the lung. Widespread hyperresonance may be elicited in emphysema, and circumscribed hyperresonance over a pneumothorax or large bulla.

■ Auscultation of Lungs

Ever since the time of Laennec, physicians have applied a stethoscope to the chest in search of sounds of disease.[8] Attention is focused on the intensity and quality of the sounds, as well as on the presence of abnormal (often called "adventitious") lung sounds.[9] Other devices have been used to assess sounds generated by breathing.[10,11] Web sites providing access to audio files demonstrating normal and adventitious breath sounds are available (e.g., www.easyauscultation.com/lung-sounds).[12] The advent of bedside ultrasonography has greatly augmented clinical assessment of patients with respiratory complaints (see Chapter 29).

Changes in the Intensity and Duration of Lung Sounds

The generation of lung sounds requires an ability to move air through patent airways. A global decrease in the intensity of breath sounds over the thorax or a hemithorax may be due to a variety of abnormalities: impaired movement of air due to airways disease (e.g., in emphysema), paralysis of a diaphragm, or complete obstruction of a bronchus. A decrease in audible breath sounds may also occur when the transmission of sounds to the chest wall is impaired (e.g., by a pleural effusion, pleural thickening, or a pneumothorax). A bulla gives rise to a more circumscribed diminution in breath sounds. In a patient with COPD, regional variations in breath sounds correspond to the distribution of ventilation. With adequate pressure of the diaphragm of the stethoscope, it is possible to auscultate the lungs as effectively through thin clothing as over bare skin; of course, this approach hinders inspection and percussion.[13]

An abnormal increase in intensity of breath sounds is accompanied by a change in their character. (The sounds become either harsh or bronchial.) The abnormal sounds are heard over consolidated, atelectatic, or compressed lung as long as the airway to the affected portion of the lung remains patent. Consolidated lung is presumed to act as an acoustic conducting medium that, unlike normal lung, does not attenuate transmission of tracheal sounds to the periphery.

Noting the duration of the inspiratory and expiratory phases of breathing may be useful. Inspiration is normally audible for a longer period, with little, if any, expiratory noise. A prolongation of expiration, often longer than inspiration, is found with obstructed airways.

Changes in the Transmission of Lung Sounds

Changes in voice sounds are often easier to appreciate than changes in breath sounds. Large pleural effusions, pneumothorax, and bronchial occlusion produce distant or inaudible breath sounds. Transmission of voice sounds is enhanced by consolidation, infarction, atelectasis, or compressions of lung tissue. Accompanying the increased transmission is a change in the character of the voice sounds that causes them to be higher pitched and less muffled than normal *(bronchophony)*. When bronchophony is extreme, spoken words assume a nasal or bleating quality *(egophony)* and the sound "ee" is heard through the stethoscope as "ay."[14] Egophony is most common when consolidated lung and pleural fluid coexist; sometimes it is heard over an uncomplicated lobar pneumonia or pulmonary infarction. Transmission of whispered voice sounds with abnormal clarity *(whispered pectoriloquy)* has the same significance as bronchophony.

Changes in the Quality of Lung Sounds

Normal breath sounds have a smooth, soft quality and are described as *vesicular*. Abnormal, or adventitious, lung sounds have traditionally been resistant to meaningful clinical classification. However, a rational, clinically useful set of definitions based on acoustic analysis of tape recordings and the nomenclature introduced by Forgacs is commonly employed (Table 27-2). Using this approach, lung sounds are categorized as continuous (*wheezes*, *rhonchi*, or *stridor*) or discontinuous *(crackles)*.

Wheezes, rhonchi, and stridor are musical adventitious sounds. Wheezes originate in airways narrowed by spasm, thickening of the mucosa, or luminal obstruction. Although wheezes are more apt to occur during forced expiration (which further narrows airways), they may occur during both inspiration and expiration in asthma. Wheezes presumably originate through a combination of limitation to airflow and vibrations in the walls of the airways. Rhonchi are due to the presence of liquid or mucus in the airways; the quality and location may be readily changed by asking the patient to cough, thus moving the secretions. Stridor is predominantly inspiratory and best heard over the neck. Common causes of stridor are a foreign body in the upper intrathoracic airway or esophagus, an acquired lesion of the airway (e.g., carcinoma in adults), or a congenital lesion in children.

TABLE 27-2 Classification of Common Lung Sounds

Acoustic Characteristics	American Thoracic Society Nomenclature	Common Synonyms
Discontinuous, interrupted explosive sounds; loud, low in pitch	Coarse crackle	Coarse rale
Discontinuous, interrupted explosive sounds; less loud than above and of shorter duration; higher in pitch than coarse crackles or rales	Fine crackle	Fine rale, crepitation
Continuous sounds longer than 250 ms, high-pitched; dominant frequency of 400 Hz or more, hissing sound	Wheeze	Sibilant rhonchus
Continuous sounds longer than 250 ms, low-pitched; dominant frequency about 200 Hz or less, snoring sound	Rhonchus	Sonorous rhonchus

Adapted with permission from Loudon R, Murphy RLH. Lung sounds. Am Rev Respir Dis. 1984;130(4):663–673.

Crackles are generally attributed to a rapid succession of explosive openings of small airways that closed prematurely during the previous expiration.[15] Crackles have been subdivided according to their timing during inspiration (early or late) and by differences in their quality ("wet" or "dry"); at times they have been termed "*rales*." Noting differences in timing has been advocated as a way of distinguishing between possible causes (e.g., "dry" crackles in the fibrosis of interstitial lung disease vs. "wet" crackles in pulmonary edema).[16] Unfortunately, wide variation in the interpretation of these sounds generally renders such attempts at classification of little value and often a cause of confusion. Crackles may accompany alterations in the elastic recoil of airways (emphysema), the presence of secretions (bronchitis or pneumonia), inflammation or fibrosis (interstitial lung disease), or fluid (pulmonary edema). Crackles may also be due to atelectasis, as noted in bedridden patients, and may clear with sequential deep breaths.

Pleural Rub

A pleural friction rub is a coarse, grating, or leathery sound that is usually heard late in inspiration and early in expiration; most often a pleural friction rub is audible low in the axilla or over the lung base posteriorly. The rub sounds close to the ear and usually is not altered by coughing.

DYSPNEA

Dyspnea is the medical term for breathlessness or shortness of breath.[17] The American Thoracic Society has published a comprehensive discussion of the topic.[18] For the patient, dyspnea involves an experience of discomfort in breathing. It is alarming to most and may arouse great concern about a potential dire cause, making it one of the most frequent complaints prompting patients to seek medical evaluation.

In the extensive medical, physiologic, and psychological literature, dyspnea is used variously to designate a variety of sensations, ranging from awareness of breathing on the one hand to respiratory distress on the other. The wide range of meanings is understandable on several counts: (1) dyspnea is a subjective complaint without consistency in objective signs such as tachypnea; (2) few physicians have experienced the respiratory discomfort associated with chest disease, so that most interpretations of the complaint represent extrapolations from normal breathlessness (e.g., after strenuous exercise); (3) most experimental observations relating to dyspnea are based on the study of normal subjects or animals under artificial circumstances; and (4) most physicians apply the term loosely, based on their experience with the predominant patient population that they serve (e.g., patients with COPD or asthma). Despite this variability, in clinical medicine, the complaint of dyspnea almost invariably implies respiratory discomfort.

Because of its subjective nature, the sensation of dyspnea is an amalgam of two components. The first is the sensory input to the cerebral cortex, which consists of information from specialized receptors, predominantly mechanoreceptors, at various sites in the respiratory apparatus (predominantly the upper airways) and face (Fig. 27-6). The different sites of stimulation may contribute to disparities in the sensation. Furthermore, no specific area in the central nervous system (CNS) has been identified as the sensory locus for dyspnea. The input—from airways, lungs (via the vagus nerves), respiratory muscles, chest wall, and chemoreceptors—is processed at consecutive levels of the nervous system (i.e., spinal cord and supraspinal regions en route to the sensorimotor cortex). Additional sensory input, triggered by inadequate oxygen delivery or utilization, is poorly understood. The second component is the perception

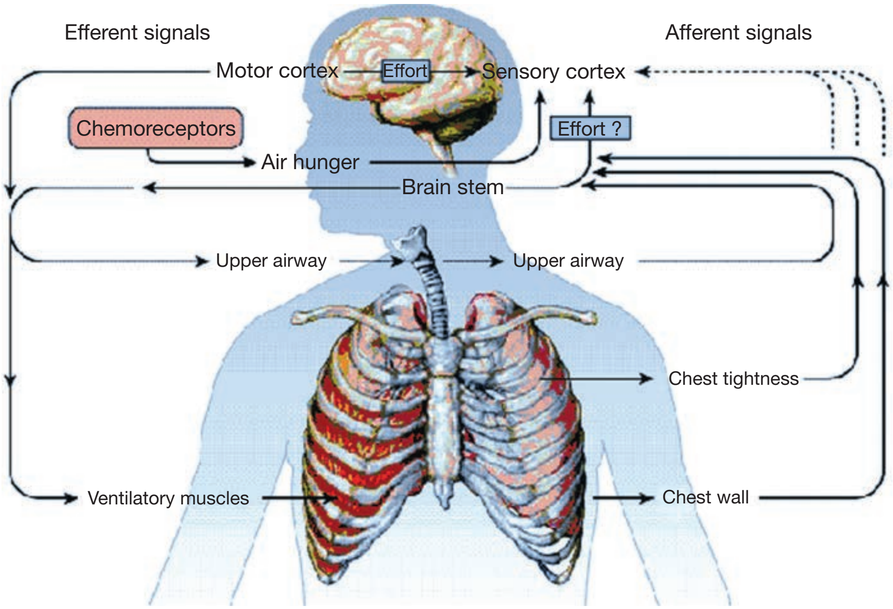

Figure 27-6 Pathways to the sensation of breathlessness. Respiratory effort is believed to originate as a signal transmitted from the motor cortex simultaneously to the sensory cortex and to the motor command to ventilatory muscles. The brain stem may also contribute to the sense of effort. The perception of air hunger is believed to arise, in part, from increased respiratory activity within the brain stem, whereas the sensation of chest tightness probably results from stimulation of vagal irritant receptors. Although afferent information from airway, lung, and chest-wall receptors most likely passes through the brain stem before reaching the sensory cortex, the *dashed lines* indicate uncertainty about whether some afferents bypass the brain stem and project directly to the sensory cortex. *(Reproduced with permission from Manning HL, Schwartzstein RM. Pathophysiology of dyspnea. N Engl J Med. 1995;333(23):1547–1553.)*

of the sensation, which rests heavily on the interpretation of information arriving at the sensorimotor cortex. The interpretation depends greatly on the psychological makeup of the person.

A variety of influences may modify the psychological component of dyspnea. During "Kussmaul breathing" (see below), "air hunger" may seem obvious to the observer, even though the patient does not feel short of breath. In contrast, patients with congestive heart failure or COPD frequently volunteer the complaint of "air hunger." Blunting of the sensorium, as by narcotics or by acute hypercapnia, can eliminate the sensation of breathlessness, even though the abnormal breathing pattern remains. Anxiety may heighten the sense of breathlessness. Indeed, anxiety may be responsible for the clinical syndrome of psychogenic dyspnea, in which the patient experiences "breathing discomfort" that eludes explanation on the basis of a somatic cause. Ill-defined sensations may accompany a full-blown hyperventilation syndrome, consisting of lightheadedness, tingling of the hands and feet, tachycardia, inversion of T waves on the electrocardiogram, and even syncope. Breathing discomfort at rest that decreases with activity is often seen when anxiety or other psychological issues are the cause and is a distinctly unusual pattern for dyspnea due to a cardiopulmonary abnormality.

The quality of dyspnea can vary greatly. In normal persons, as well as in those with chest disease, dyspnea may simply signify the transition from an effortless process that is ordinarily conducted at a subconscious level to the awareness that muscular effort is being expended in breathing.[19] The healthy athlete completing a sprint experiences breathlessness that can be exhilarating, rather than uncomfortable. The asthmatic often interprets breathlessness in terms of "tightness in the chest." The patient with COPD often complains of less severe breathlessness than would be expected from the degree of airway obstruction, possibly reflecting adaptation, either to the chronic obstructive airway disease or to CO_2 retention.

Patients may use different terms to describe breathing discomfort due to various causes.[20–25] In some instances these descriptors may be useful in establishing a differential diagnosis and in assessing the response to therapy.[26] Patients with asthma or myocardial ischemia often refer to "chest tightness."[27] Patients with pulmonary edema may suffer a sensation of "air hunger" or "suffocation."[28] Patients with COPD and hyperinflation of the chest often note an inability to take a deep, satisfying breath. Individuals who are deconditioned may complain of "heavy breathing." Unfortunately, no descriptor has sufficient sensitivity or specificity to be used alone in establishing the cause of a patient's dyspnea. Ethnic and gender differences in the descriptors and perceptions related to dyspnea have been reported.[29,30]

Clinical Presentations

Dyspnea may be acute, chronic, or paroxysmal (Table 27-3).

TABLE 27-3 Common Causes of Acute and Chronic Dyspnea[a]

Acute
Pulmonary edema
Asthma
Injury to chest wall and intrathoracic structures
Spontaneous pneumothorax
Pulmonary embolism
Pneumonia
Adult respiratory distress syndrome
Pleural effusion
Pulmonary hemorrhage
Foreign body aspiration
Vocal cord dysfunction
Chronic, progressive
Chronic obstructive pulmonary disease
Left ventricular failure
Diffuse interstitial fibrosis
Asthma
Pleural effusions
Pulmonary thromboembolic disease
Pulmonary vascular disease
Psychogenic dyspnea
Anemia, severe
Postintubation tracheal stenosis
Hypersensitivity disorders

[a] *Many chronic processes (e.g., left ventricular failure, asthma, and COPD) may have acute exacerbations.*

Acute Dyspnea

The usual causes of acute dyspnea in children differ from those in adults. In children, upper airway infection (e.g., epiglottis, laryngitis, or acute laryngotracheobronchitis) is a common cause. In adults, the causes of acute dyspnea are much more varied (Table 27-3). Among the most common are acute left ventricular failure, pulmonary thromboembolism, pneumonia, and spontaneous pneumothorax. Less common, but not unusual, is massive collapse of one lung due to inability to clear the airways of thick, tenacious secretions (e.g., in chronic bronchitis or asthma) or the first attack of asthma.

Chronic Dyspnea

Chronic dyspnea is almost invariably progressive. As a rule, this type of dyspnea begins with breathlessness on exertion—which, in time, progresses to dyspnea at rest. Pulmonologists encounter dyspnea in patients who have COPD; cardiologists more often deal with dyspnea in patients who are in chronic congestive heart failure. Especially in older patients, distinction between the heart and lungs in the etiology of dyspnea, or the relative contributions of each, can be difficult to establish.

Asthma is a common cause of recurrent bouts of dyspnea, which are usually accompanied by cough and wheezing. Cardiac dysfunction is another cause of acute bouts of bronchospasm, especially in middle-aged or elderly persons.

■ Physiologic Correlates of Dyspnea

Historically, attempts to understand the physiologic basis of dyspnea have evolved along four separate lines: ventilatory performance, the mechanics of breathing, chemoreception, and exercise testing. Exercise testing is presented in Chapter 32.

Ventilatory Performance

Early investigations related the sensation of dyspnea to the level of minute ventilation. Dyspnea was found to correlate with excessive minute ventilation relative to the level of oxygen uptake. Most of the increase in ventilation was accounted for by an increase in respiratory rate, especially in patients with stiff lungs. In patients who continued to ventilate excessively for the level of oxygen uptake (e.g., those with chronic left ventricular failure), the sensation of breathlessness gradually diminished, suggesting adaptation to the continued stimulus.

A second ventilatory measurement that proved to correlate well with dyspnea is the maximum voluntary ventilation (MVV). MVV is decreased by diseases of the lungs, airways, or chest wall. The smaller the MVV, the more likely is dyspnea to occur.

A third time-honored approach to measurement is the "breathing reserve." This value is determined as the difference between the MVV and the actual minute ventilation. In principle, the sensation of breathlessness during the performance of any ventilatory task may be related to the fraction of the maximum breathing capacity (i.e., the MVV) that is used for force generation by the respiratory apparatus. Thus, the closer the minute ventilation is to the maximum breathing capacity, the more likely is the subject to complain of breathlessness. Indeed, when the actual level of ventilation reaches 30% to 40% of the maximum breathing capacity, dyspnea is inevitable. Unfortunately, the breathing reserve correlates better with the dyspnea of normal subjects during exertion than with the dyspnea of chronic bronchitis and COPD or of left ventricular failure. Thus, in COPD the minute ventilation may be a very large fraction of the MVV (>50%) without eliciting dyspnea. In contrast, in acute left ventricular failure, a mild increase in ventilation and a nearly normal MVV may be associated with considerable breathlessness.

Mechanics of Breathing

One teleologic way to regard dyspnea is as a sensation that prompts an unconscious effort to minimize the work, energy cost, or force of breathing. In this light, dyspnea protects the respiratory apparatus from overwork and inefficient operation. This approach has led to exploration of the relationships between dyspnea and the work or oxygen cost of breathing.

Work, Oxygen Cost, and Efficiency of Breathing

It has not been possible to identify a critical level for the work of breathing at which dyspnea will occur. However, a breakdown of the work of breathing into its elastic, resistive, and inertial components has helped to relate physiologic disturbances to particular diseases. For example, in chronic mitral stenosis with pulmonary congestion, the elastic work is greatly increased (Fig. 27-7), whereas in obstructive airway disease, resistive work predominates. Moreover, such observations have reinforced the concept that patterns of breathing are automatically adjusted to minimize the work done by the respiratory muscles in breathing.

The relationship between ventilation and O_2 consumed by the respiratory muscles is curvilinear (Fig. 27-8). This O_2 cost of breathing may increase extraordinarily in patients with COPD or with abnormalities of the chest wall. Indeed, in patients with COPD, the quantity of O_2 delivered to the respiratory muscles during the large ventilatory effort may fail to satisfy their aerobic needs, leading to anaerobic metabolism and lactic acidosis. Although the greater the O_2 cost of breathing the greater the likelihood of dyspnea, the determination of O_2 cost provides no more useful insight into the mechanism of dyspnea than does the work of breathing. Calculation of the efficiency of breathing (i.e., the work of breathing related to energy cost) provides no further clarification.

Length–Tension Inappropriateness

The concept of "length–tension inappropriateness" explains dyspnea as a mismatch between the central motor command to the respiratory muscles (i.e., the motor signal emitted from the brain) and the suboptimal ("inappropriate") shortening of the respiratory muscles elicited by this command (e.g., suboptimal thoracic expansion for any level of central motor command).[31] In essence, this concept pictures a decrease, instead of an increase, in the pressure-generating capacity of the respiratory muscles in the face of the increased need arising from the heightened respiratory drive.

Chemoreception

Chemoreceptors in the medulla respond to changes in pH and Pa_{CO_2} (see Chapter 11). Peripheral receptors in the aortic arch and carotid body also respond to alterations in Pa_{O_2}. Acute hypoxia, hypercapnia, and acidosis are the traditional stimuli for ventilation. For example, upon ascent to altitude, acute hypoxia can stimulate ventilation to the level of awareness that may progress to discomfort during exertion. The effects of these stimuli on breathing decrease if they continue unabated. In addition, side effects, such as blunting of the sensorium during chronic CO_2 retention, diminish the likelihood of dyspnea, even if the level of ventilation is increased. In patients with abnormal pulmonary mechanics, the onset of abnormalities in blood gas composition, as during exercise, may aggravate or contribute to dyspnea. In general, acute hypercapnia is a stronger stimulus for dyspnea than is acute hypoxia.

■ Scaling

A variety of scaling methods have been devised to quantify dyspnea during exercise and various experimental settings. Some, such as the Borg Category Scale (Table 27-4), use numbers and descriptive terms to depict a change in the intensity of the stimulus ("threshold stimulus detection methods"). Others rely on visual analog scales, which are straight lines, usually 10 cm long, that extend from "not breathless" at one end to "extremely breathless" at the other. The

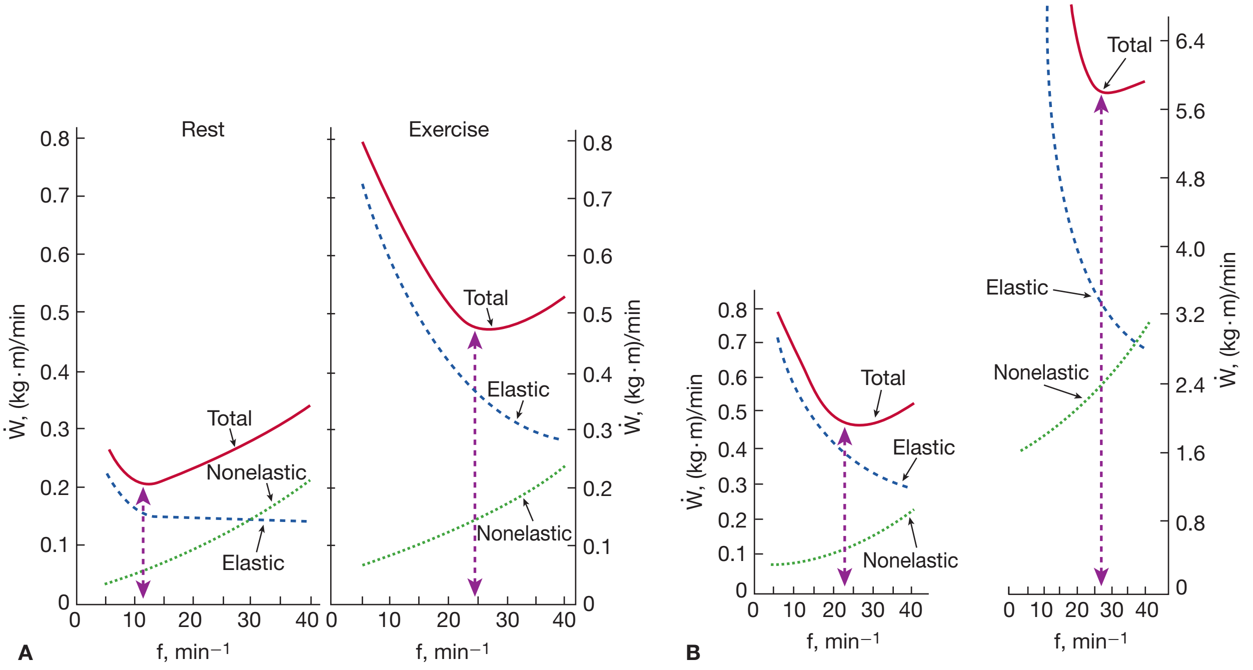

Figure 27-7 Partition of the work of breathing in pulmonary congestion and edema at rest and during exercise. **A.** Normal. The minimal work of breathing at rest was at a respiratory frequency of 12 breaths/min; during exercise, the minimal work was done at a higher frequency (25 breaths/min). **B.** Mitral stenosis. At rest, the frequency for least respiratory work was abnormally high (22 breaths/min); during exercise it increased further (to 28 breaths/min). The *dashed vertical line* (capped by *arrowheads*) in each frame indicates the respiratory frequency at which respiratory work was minimal. f, respiratory frequency. *(Reproduced with permission from Christie RV. Dyspnea in relation to the visco-elastic properties of the lung. Proc R Soc Med. 1953;46(5):381–386.)*

patient marks on the line the intensity of respiratory discomfort elicited by external stimuli, such as resistive loads or exercise testing. The score is measured as the length of the line between "not breathless" and the mark made by the patient. The Shortness of Breath Scale issued by the American Thoracic Society (Table 27-5) and the Medical Research Council (MRC) Dyspnea Scale have also been used in one form or another, particularly in epidemiologic studies. A method of quantifying dyspnea severity that utilizes patient descriptors appears to be applicable and reproducible in a variety of disorders.[32]

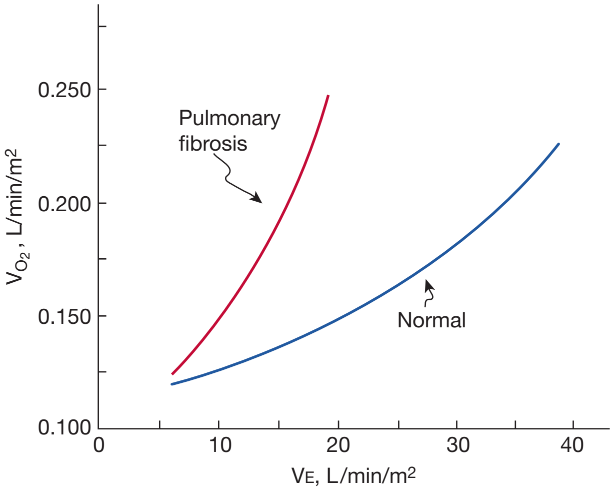

Figure 27-8 Oxygen cost of breathing in restrictive lung disease. Relationship between ventilation and O_2 consumption in pulmonary fibrosis. At each level of ventilation, the patient with pulmonary fibrosis does more work and expends more energy in breathing than does the normal subject.

DYSPNEA IN OBSTRUCTIVE AND RESTRICTIVE PULMONARY DISORDERS

Two common pathophysiologic categories of pulmonary disease in which dyspnea features prominently are chronic obstructive airway disease and restrictive pulmonary disorders.

Chronic Obstructive Airway Diseases

Several chronic obstructive airway diseases associated with dyspnea are well recognized, including COPD and asthma.

COPD

COPD refers to a spectrum of airway diseases in which obstruction to airflow is the common denominator (Chapters 39 and 40). Cigarette

TABLE 27-4 Modified Borg Category Scale

Rating	Intensity of Sensation
0	Nothing at all
0.5	Very, very slight (just noticeable)
1	Very slight
2	Slight
3	Moderate
4	Somewhat severe
5	Severe
6	
7	Very severe
8	
9	Very, very severe (almost maximal)
10	Maximal

TABLE 27-5 American Thoracic Society Shortness of Breath Scale

Descriptions	Grade	Degree
Not troubled by shortness of breath when hurrying on the level or walking up a slight hill	0	None
Troubled by shortness of breath when hurrying on the level or walking up a slight hill	1	Mild
Walks more slowly than people of the same age on the level because of breathlessness or has to stop for breath when walking at own pace on the level	2	Moderate
Stops for breath after walking about 100 yards or after a few minutes on the level	3	Severe
Too breathless to leave the house; breathless on dressing or undressing	4	Very severe

smoking is the leading cause of COPD (Chapter 41). The outer limits of the spectrum are marked by chronic bronchitis at one end and emphysema at the other. Most patients with COPD fall into categories between those limits (i.e., they manifest mixtures of chronic bronchitis and emphysema, which vary in degrees) (Fig. 27-9).

Patients with COPD suffer from disturbances in the mechanics of breathing, abnormal lung volumes, and derangements in gas exchange. The minute ventilation, which may be only slightly increased at rest, constitutes an abnormally large fraction of the maximum breathing capacity (i.e., the "breathing reserve" is low).

Abnormalities in the mechanics of breathing dominate the scene: resistance to airflow is high; the thorax assumes a hyperinflated position, placing the inspiratory muscles at mechanical disadvantage; the work of breathing is greatly increased. The O_2 cost of breathing is correspondingly high. Derangements in dead space ventilation and in alveolar–capillary gas exchange add to the afferent stimuli. As a result of the disturbances in mechanics and gas exchange, swings in pleural pressure (a measure of force applied to the lungs) are large, and a considerable muscular effort is expended in breathing; instead of the normal increase of about 1 mL of O_2 uptake per liter of ventilation per minute, the O_2 uptake increases enormously (up to 25 mL/min). Should O_2 delivery to the overworked respiratory muscles be insufficient, fatigue and exhaustion may send nervous and chemical signals of their own to the brain. Finally, if the patient accumulates excess water in the lungs, the juxtacapillary ("J") receptors provide additional sensory input to the central integrating mechanism. As noted above (see "Length–Tension Inappropriateness"), the convergence of these diverse stimuli upon the sensorimotor cortex may generate an inordinate motor command to the respiratory muscles, which cannot mobilize the thorax sufficiently to generate the pleural pressures needed for adequate ventilation.

One enigma is why patients with COPD maintain different levels of ventilation despite equal abnormalities in conventional pulmonary function tests. The "CO_2 retainer," with respiratory acidosis and arterial hypoxemia, often breathes less than does the non–CO_2 retainer in whom blood gas levels are near normal. One teleologic explanation is that the lower ventilation in the CO_2 retainer causes less dyspnea. However, this explanation affords no insight into the physiologic mechanism.

Treatment of the patient with COPD is directed at diminishing airways resistance and restoring arterial blood gases toward normal. Unfortunately, bronchodilators generally have only modest effects, and the basic abnormalities in the mechanics of the lungs and airways remain. Consequently, the load on the respiratory muscles is not readily alleviated by medical management. Management strategies also include consideration of ways in which the performance of the respiratory muscles can be improved. These have generally taken the form of training exercises to facilitate adaptive changes and to increase both muscle strength and endurance. Exercise reconditioning in patients with COPD has been shown to diminish breathlessness, possibly owing to three interactive mechanisms: (1) increased mechanical efficiency of the exercising muscles, which decrease ventilatory requirements; (2) improved function of the respiratory muscles; and (3) increased tolerance of the "dyspneagenic" sensory input to the brain. Attempts to rest the respiratory muscles have no lasting effect on dyspnea.

Asthma

Asthma constitutes a different entity, not only in its clinical expressions but also because it is usually episodic and is often related to allergic manifestations, and generally affects younger individuals (Chapters 43 to 45).

The mechanisms described previously for COPD apply as well to asthma. However, these mechanisms do not account for the sensation of "tightness in the chest" or the inordinate sense of labored breathing that accompanies the breathlessness in asthma.

■ Restrictive Ventilatory Defects

Restrictive ventilatory defects are due to a variety of causes, ranging from lung disorders to diseases that affect the pleural space, as well as neuromuscular diseases that affect the function of the thorax (Table 27-6). Diffuse interstitial disease has many different etiologies and may be either acute or chronic (Table 27-7). Characteristically, in widespread interstitial disease the diffusing capacity is low and is accompanied by a considerable decrease in total lung capacity and in vital capacity, as well as lesser decrements in functional residual capacity and residual volume (see Chapter 31). Similar findings occur in severe kyphoscoliosis or encasement of the lung by pleural thickening (Fig. 27-10). In contrast, in pulmonary vascular disease, such as idiopathic pulmonary arterial hypertension, a low diffusing capacity may be accompanied by normal lung volumes. Neuromuscular disease that affects the inspiratory muscles sufficiently to diminish maximum inspiratory pressures may decrease vital capacity and total lung capacity, leaving functional residual capacity and residual volume increased.

Patients with widespread pulmonary fibrosis breathe faster and maintain a higher minute ventilation than do normal subjects, both at rest and during exercise. The work and oxygen cost of ventilating the stiff lungs are increased. Dyspnea is attributable to the

TABLE 27-6 Common Causes of Restrictive Ventilatory Defects

Cause	Example
Interstitium	
Interstitial fibrosis and/or infiltration	Usual interstitial pneumonitis/ idiopathic pulmonary fibrosis
Pulmonary edema	Left ventricular failure
Pleura	
Pleural disease	Fibrothorax
Thoracic cage and abdomen	
Neuromuscular disease	Poliomyelitis
Skeletal abnormalities	Severe kyphoscoliosis
Marked obesity	Grossly overweight

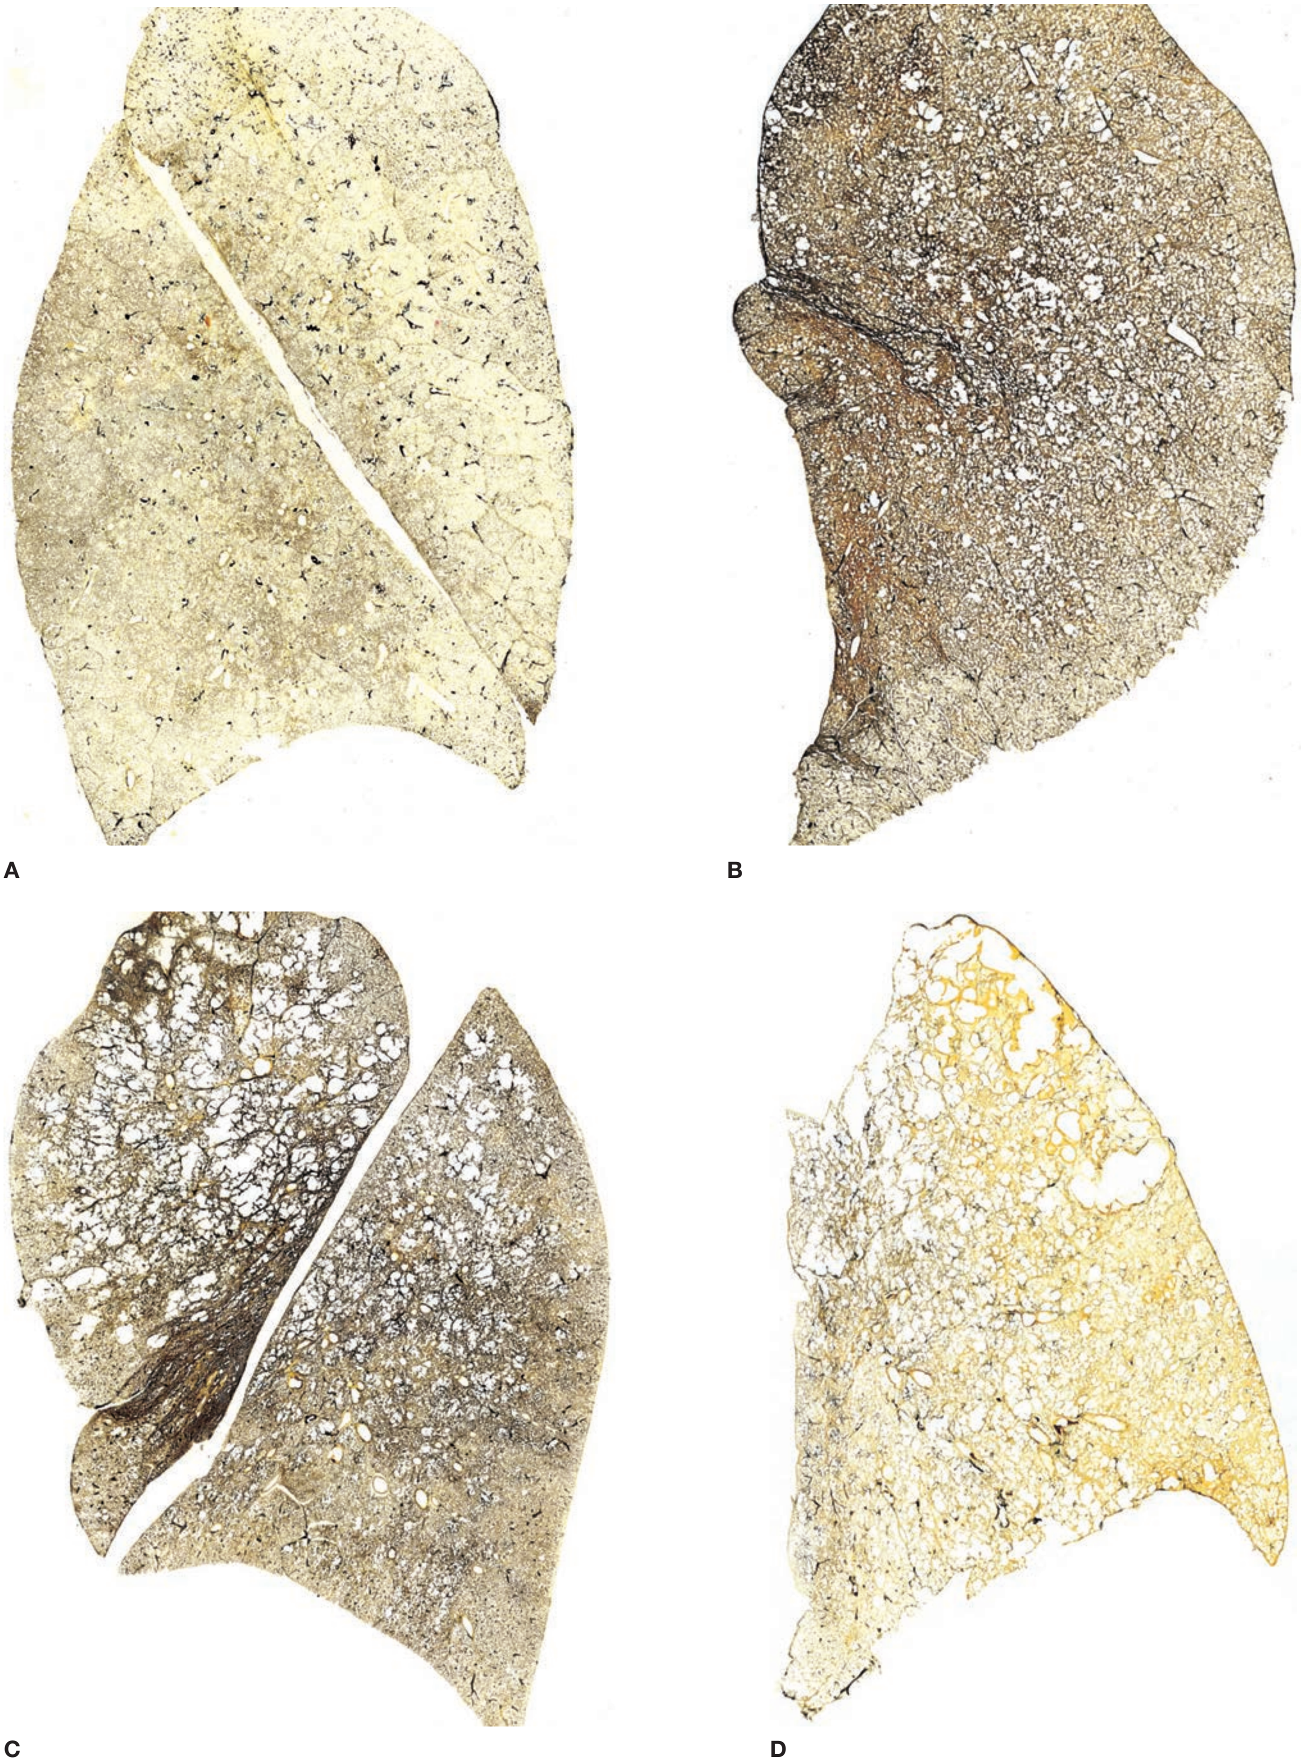

Figure 27-9 Chronic obstructive pulmonary disease (COPD). Sagittal sections showing patterns of emphysema. **A.** Normal lung from a patient who died of unrelated causes. **B.** Predominantly centrilobular emphysema. **C.** Predominantly centrilobular and panlobular emphysema. **D.** Predominantly panlobular emphysema. Centrilobular emphysema is less marked. The three patients with emphysema (**B, C, D**) also had clinical manifestations of chronic bronchitis confirmed by histologic sections.

TABLE 27-7 Some Types of Diffuse Interstitial Diseases

Etiology	Example	Common Features
	Acute	
Infections	Miliary tuberculosis, histoplasmosis *Pneumocystis*, cytomegalic inclusion virus, fungi	Opportunity for exposure to organism Immunosuppression
Pulmonary edema	Narcotic overdosage, nitrogen dioxide (silo-filler's disease), uremia	Distinctive history
Inhalation	Byssinosis	Monday morning asthma and fever
Aspiration	After loss of consciousness	History of alcoholism or epilepsy
Immunologic	Goodpasture syndrome	Renal and pulmonary involvement
Carcinoma of lung	Adenocarcinoma in situ or minimally invasive adenocarcinoma (previously known as alveolar cell carcinoma)	
	Chronic	
Inhalation	Pneumoconioses	History of exposure to inorganic dust
Radiation therapy	After mastectomy	Gradual evolution after treatment
Lymphangitic spread	Carcinoma of breast, lung, stomach, pancreas	Evidence of primary carcinoma
Medications	Bleomycin, busulfan, cyclophosphamide	History, suggestive chest radiograph
Systemic disorders	Sarcoidosis, connective tissue disorders, eosinophilic granuloma, amyloidosis, tuberous sclerosis	Multiorgan involvement; biopsy
Idiopathic	Idiopathic pulmonary fibrosis	Exclusion of known causes

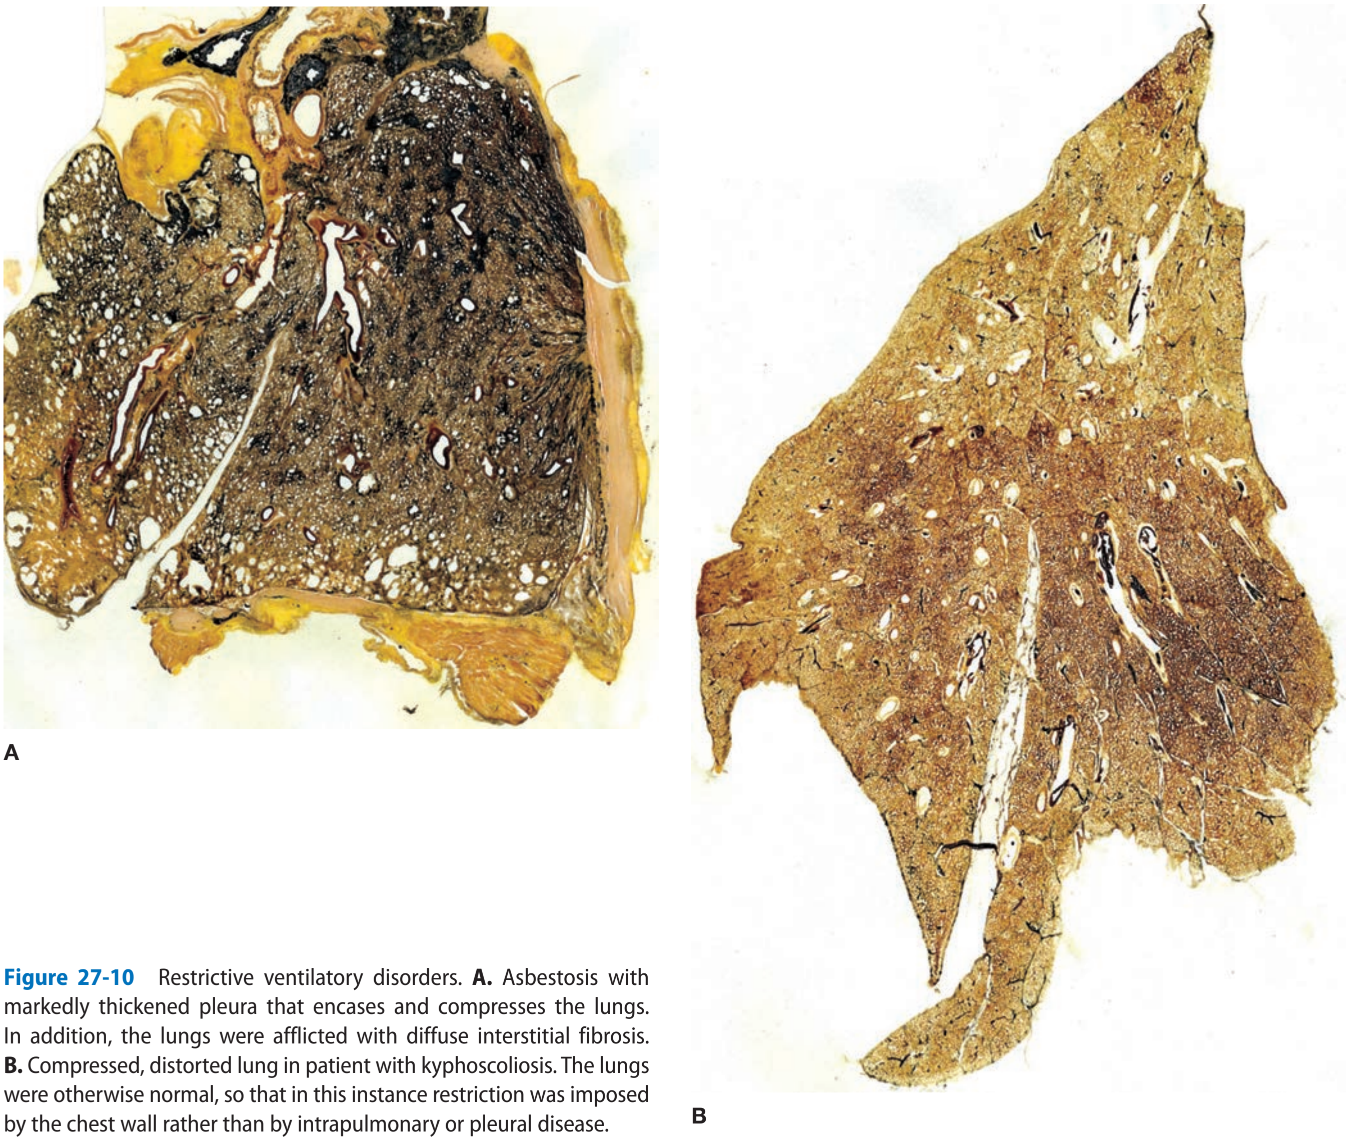

Figure 27-10 Restrictive ventilatory disorders. **A.** Asbestosis with markedly thickened pleura that encases and compresses the lungs. In addition, the lungs were afflicted with diffuse interstitial fibrosis. **B.** Compressed, distorted lung in patient with kyphoscoliosis. The lungs were otherwise normal, so that in this instance restriction was imposed by the chest wall rather than by intrapulmonary or pleural disease.

considerable effort by the respiratory muscles in ventilating the stiff lungs and in sustaining the high ventilatory rate. During exercise, dyspnea may become intolerable.

DYSPNEA IN CHRONIC CARDIAC DISEASE

The mechanisms responsible for dyspnea in cardiac disease vary with the extent to which the lungs are stiffened.

Dyspnea occurs in many forms of heart disease that are not associated with congestion of the lungs. Uncomplicated pulmonic stenosis is an excellent example. The symptom is probably related to an inadequate cardiac output during exercise. In tetralogy of Fallot, dyspnea is sometimes severe and often relieved by assuming a squatting position. In this and other forms of cyanotic heart disease, both dyspnea and fatigue appear during exertion when the arterial oxyhemoglobin saturation decreases appreciably below the resting level.

Cardiac dyspnea is associated with an increase in blood and water content of the lungs. It is a common occurrence in left ventricular failure and mitral stenosis, both of which are accompanied by increases in pulmonary venous and capillary pressures. The engorged pulmonary circulatory bed, coupled with interstitial and alveolar edema, stiffens the lungs (i.e., decreases their compliance) and stimulates the ventilation via "J" receptors. In chronic left ventricular failure, pulmonary fibrosis, consequent to long-standing interstitial edema, contributes to the stiff lungs. Edema of the tracheobronchial mucosa increases airway resistance.

As a result of the stiff lungs and increased airway resistance, swings in pleural pressure during the respiratory cycle are large and the work and energy cost of breathing are increased. Arterial hypoxemia, generally mild, may add to the ventilatory drive. Exercise exaggerates the pulmonary congestion and edema, promotes arterial and mixed venous hypoxemia, and increases the dyspnea.

In patients with pulmonary congestion and edema, tachypnea is a regular feature at rest and increases during exercise. Although tachypnea is consistent, its degree is generally modest and probably not entirely responsible for the dyspnea. Fatigue is a common concomitant of low cardiac output and may stem from diminished O_2 delivery to the respiratory muscles, contributing to respiratory discomfort.

Orthopnea and Other Positional Forms of Breathlessness

Orthopnea signifies dyspnea in the recumbent, but not in the upright or semi-upright, position; it is usually relieved by two or three pillows under the head and back. *Platypnea* signifies dyspnea induced by assuming the upright position and relieved by recumbency.[33]

Platypnea may be seen when, due to gravity, increased blood flow worsens right-to-left shunting of blood through arteriovenous malformations at the lung bases; it may be accompanied by *orthodeoxia*—desaturation of arterial blood when the patient is upright.

Orthopnea is a hallmark of pulmonary congestion that stiffens the lungs (i.e., decreases their compliance). The decrease in compliance on lying flat is attributable to the fact that more of the lung is located at or below the level of the heart. During recumbency, the swings in pleural pressure, the work of breathing, and the respiratory frequency increase. The increase in respiratory frequency appears to be automatically adjusted to minimize the work of ventilating the more rigid lungs.

Some patients with chronic lung disease or asthma are also intolerant of lying flat. Their discomfort is attributed to the greater difficulty of performing vigorous movements of the chest bellows in the recumbent position.

Finally, patients with asymmetric lung disease may experience *trepopnea*—dyspnea when the affected side of the chest is in the dependent position, thereby promoting ventilation–perfusion mismatch (Chapter 14) and resultant hypoxemia.

Paroxysmal Nocturnal Dyspnea

In an episode of paroxysmal nocturnal dyspnea (PND), the patient is aroused from sleep, gasping for air, and must sit up or stand to catch his or her breath; sweating may be profuse. Sometimes the patient opens a room window in an attempt to relieve the oppressive sensation of suffocation. The chest tends to become fixed in the position of forced inspiration. Both inspiratory and expiratory wheezes, often simulating typical asthma, are heard. In some instances, overt pulmonary edema occurs, accompanied by inspiratory crackles. Attacks occasionally recur several times a night, forcing the patient to sleep upright in a chair.

An episode of PND represents precipitous failure of the left ventricle caused by the factors that produce orthopnea (see above), abetted by pulmonary hypervolemia caused by a surge in systemic venous return. Mobilization of peripheral edema from the periphery as the extremities are elevated from the dependent position may contribute to the increase in systemic venous return. The acute increase in pulmonary blood volume increases pulmonary capillary pressures, thereby promoting pulmonary edema, while the surge in venous return imposes an additional burden on the left ventricle.

A variety of factors may trigger an episode of PND: coughing, abdominal distention, the hypercapnic phase of Cheyne–Stokes respiration (see below), a startling noise, or anything that causes a rise in heart rate and further increases the pulmonary capillary and venous pressures. Usually the attack is terminated by assumption of the erect position and a few deep breaths. Cough, an important manifestation of pulmonary congestion, frequently occurs during the attack.

Cardiac Asthma

Asthmatic wheezes, often audible in patients with pulmonary congestion, have given rise to the term *cardiac asthma.* The wheezes are a manifestation of tracheobronchial edema and often are accompanied by overt signs of pulmonary edema. In addition to the reduction in the lumen of the airways and thickening of bronchial walls by edema, the high intrathoracic pressures, which are required to overcome the obstruction during expiration, tend to narrow the airways even further. The resistance to airflow is increased during both inspiration and expiration, and the compliance of the lungs is greatly reduced, reaching values as low as one-tenth of normal. Upon recovery from the acute episode of pulmonary edema, airway resistance and pulmonary compliance return toward normal unless previous episodes have left a residue of pulmonary fibrosis.

DYSPNEA IN ANEMIA

Shortness of breath during exercise or excitement is a common complaint in severe anemia (e.g., hemoglobin concentration under 6–7 g/dL). It is more common in acute than in chronic anemia. Often the dyspnea is associated with dizziness or faintness, and invariably the patient manifests signs of a high cardiac output and low peripheral resistance (i.e., bounding pulse, warm skin, and systolic cardiac murmurs). Although the pathogenesis of the dyspnea is not clear, inadequate oxygen delivery to the respiratory muscles has been proposed.

METABOLIC ABNORMALITIES AND DRUGS

Increases in CO_2 production demand a concomitant rise in ventilation to dispose of the metabolic load and, hence, may result in dyspnea. To prevent acidemia, patients with diabetic ketoacidosis may require an enormous increase in minute ventilation in order to reduce Pa_{CO_2}. Thyrotoxicosis, fever, infection, and pregnancy can also cause an increased minute ventilation, as can drugs, such as aspirin and progesterone.

MISCELLANEOUS DISORDERS

Breathlessness is not uncommon in patients with musculoskeletal disorders. The usual explanation is the heightened motor drive that is needed to activate the weakened respiratory muscles. In the intensive care unit, inadequate ventilator settings for flow and tidal volume may fail to satisfy the intrinsic ventilatory drive of the patient, generating the sensation of breathlessness.

ABNORMAL BREATHING PATTERNS

An important clue to the nature of a clinical problem in pulmonary disease is sometimes provided by bedside observation of a patient's breathing pattern. The pertinent features are the rate, regularity, depth, and apparent effort being expended in breathing. A normal person at rest breathes about 12 to 15 times per minute, with a tidal volume of 400 to 800 mL. As a result, minute ventilation is normally greater than 5 L/min. The pattern is quite regular except for an occasional slow, deep breath, and the respiratory movements appear effortless.

Severe skeletal deformity, as well as massive obesity, can limit chest excursions to cause alveolar hypoventilation (Chapter 83). Neuromuscular weakness, as in myasthenia gravis or Guillain–Barré syndrome, may do the same, not only by diminishing ventilatory excursions as a result of generalized weakness of the respiratory muscles, but also by causing overload of respiratory muscles (e.g., residual effects of poliomyelitis) (Chapters 83 and 84). Unilateral involvement of one pleural space by pneumothorax, effusion, or fibrothorax limits excursions on the affected side. Massive chest trauma may cause flail chest.

In COPD, a slow respiratory rate and large tidal volumes are characteristic. This pattern presumably serves to minimize the work of breathing. Pursed-lip breathing, a self-induced type of positive-pressure breathing, is often part of the picture. In contrast, persons with restrictive ventilator disorders adopt a breathing pattern that is characterized by small tidal volumes and a rapid respiratory rate, often with little apparent effort. This pattern is seen in patients with a decrease in the distensibility of the lung or chest wall or with reduction of the vital capacity from any other cause. During exercise, minute ventilation increases inordinately with respect to the level of O_2 uptake, and respiratory frequency increases more than tidal volume.

Fatigue of the diaphragm and intercostal muscles, sufficient to disturb their coordinated contractions, may give rise to paradoxical breathing, which heralds the onset of respiratory failure.

■ Cheyne–Stokes Respiration

In the fourth century BC, in a preterminally ill person with fever, sweats, and black urine, Hippocrates described a pattern of breathing in which "the respiration throughout [was] like that of a man correcting himself, and rare and large." Presumably he had observed Cheyne–Stokes breathing, which was described more graphically by William Stokes two millennia later (in 1854) as follows:

"The symptom in question (previously described by Dr. Cheyne) consists in the occurrence of a series of inspirating, increasing to a maximum, and then declining in force and length, until a state of apparent apnea is established. In this condition the patient may remain for such a length of time as to make his attendants believe that he is dead, when a low inspiration, followed by one more decided, marks the commencement of a new ascending and descending series of inspirations."

Cheyne–Stokes breathing is characterized by alternating periods of hypoventilation and hyperventilation (Fig. 27-11). In its typical form, an apneic phase, which lasts for 15 to 60 seconds, is followed by a phase during which tidal volume increases with each successive breath to a peak level and then decreases in a progressive fashion to the apneic phase. At the onset of apnea, CO_2 tension in brachial or femoral arterial blood is at its lowest. As apnea persists, CO_2 tension gradually increases, and respiration is stimulated. CO_2 tension continues to increase until maximum hyperventilation is attained, after which ventilation decreases until apnea again occurs. The arterial oxyhemoglobin saturation varies in an inverse manner, being highest at the onset of apnea and lower during mid-hyperpnea. During the cycle, CO_2 tension varies by as much as 14 mm Hg and oxyhemoglobin saturation by as much as 18%.

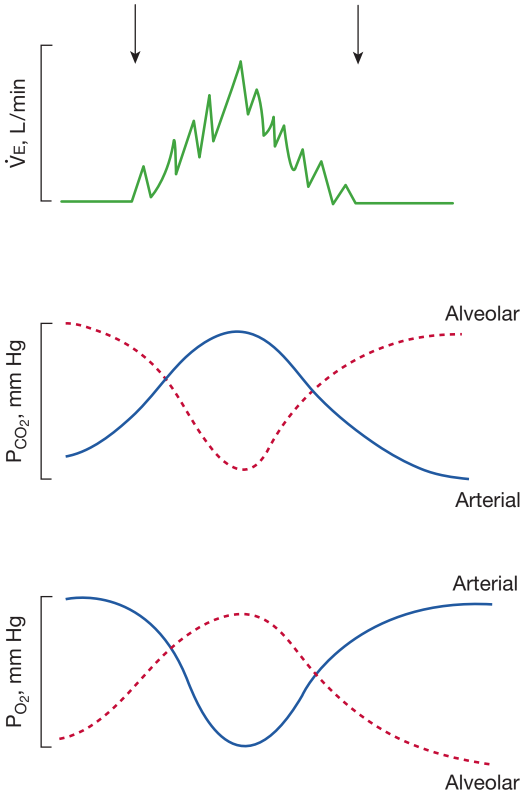

Figure 27-11 Cheyne–Stokes breathing, illustrating the relationship between the ventilation and the blood and alveolar gas tensions during the periods of apnea and hyperpnea. *(Reproduced with permission from Cherniack NS, Fishman AP. Abnormal breathing patterns. Dis Mon. 1975:1–45.)*

In patients with congestive heart failure, the respiratory oscillations are attributable to slowing of the circulation so that the blood gases reaching the respiratory centers in the brain are 180 degrees out of phase with those in pulmonary capillary blood. This mechanism has been verified experimentally by eliciting Cheyne–Stokes breathing in dogs by prolonging the circulation time from heart to brain by way of an extracorporeal circuit.

Fluctuations in mental state and electroencephalographic patterns, and evidence of nervous system dysfunction, may occur during Cheyne–Stokes breathing because of swings in cerebral blood flow. In neurologic disorders, Cheyne–Stokes breathing may be due to supramedullary dysfunction, particularly in patients who have destructive lesions in the tegmentum of the pons.

Less common than in heart failure or neurologic disorders is the occurrence of Cheyne–Stokes respiration in normal infants, in healthy elderly persons, and in normal persons at high altitude. It is also seen occasionally after the administration of respiratory depressants (e.g., morphine), often accompanied by an increase in intracranial pressure, uremia, or coma. At one time, the respiratory center was believed to be depressed in Cheyne–Stokes respiration. This hypothesis has been proved to be in error, since it has been shown that the respiratory response to inhalation of CO_2 is greater than normal in individuals with Cheyne–Stokes respiration. Respiratory alkalosis is common and the arterial P_{CO_2} remains subnormal in both the apneic and hyperpneic phases.

Kussmaul Breathing

In 1874, Kussmaul described three patients with diabetic ketoacidosis who manifested “air hunger”: they were breathing with large tidal volumes and so rapidly that there was virtually no pause between breaths. In essence, they were breathing at rest as though they were exercising; breathing was accomplished with little apparent effort. Since then, this pattern of breathing has been observed in other types of severe metabolic acidoses (e.g., alcoholic ketoacidosis). The usual sequence leading to this type of breathing is renal failure with a progressive decrease in plasma bicarbonate and resultant acidosis. The “compensatory” increase in ventilation that Kussmaul described mitigates the fall in systemic pH caused by the fall in plasma bicarbonate (see Chapter 17).

Other Abnormal Patterns

Gasping respirations are characteristic of severe cerebral hypoxia. The pattern consists of irregular, quick inspirations associated with extensions of the neck and followed by a long expiratory pause. It is commonly seen in shock or in other conditions associated with severe reduction in cardiac output.

Hyperventilation is commonly seen in anxious patients without structural disease of the lungs. In some of these patients, striking deep sighs dominate the ventilatory pattern.

DIAGNOSTIC TESTING IN THE EVALUATION OF DYSPNEA

Attention to the history and physical examination findings, as described in the preceding sections, will help to focus the initial approach to diagnosis.[34] In most cases, the initial diagnostic impression can be confirmed or excluded with only a few tests, and appropriate therapy instituted or the hunt for a cause continued (Table 27-8).

A plain chest radiograph is useful in demonstrating changes suggestive of COPD (chest hyperinflation, bullous changes). Vascular engorgement, an enlarged cardiac silhouette, increased interstitial markings, and pleural effusions may indicate left heart failure.

Spirometry is useful in identifying airways obstruction; improvement in values may be noted following administration of a bronchodilator. The measurement of lung volumes or the diffusing capacity may be reserved for when there is suspicion of an interstitial process or other cause of restriction (e.g., muscle weakness). Measurement of arterial oxyhemoglobin saturation both at rest and with exertion is important. While oxyhemoglobin desaturation will not indicate the etiology of the problem, its presence is always an important indicator of the severity of the disease. An echocardiogram can be used to assess ventricular or valvular cardiac function and to estimate pulmonary arterial pressures.

A complete blood count may reveal anemia or suggest an infection. Measurement of serum electrolytes may indicate the presence of an acidosis or renal dysfunction. Measurement of brain natriuretic peptide (BNP) has been useful in helping to exclude heart failure as an acute cause of dyspnea.[35]

Additional testing is usually not required unless the cause of dyspnea remains unclear following basic studies. Further tests often include CT of the chest, which may reveal changes of emphysema or an interstitial process not suggested by plain radiographs or lung function testing. The CT may additionally help to better

TABLE 27-8 Common Tests in the Evaluation of Dyspnea

Test	Some Possible Abnormalities	Some Possible Diagnoses
Plain Chest Radiograph	Cardiac enlargement	Congestive heart failure
	Vascular enlargement	Pulmonary hypertension
	Abnormal interstitial markings	Pulmonary fibrosis
	Pleural effusions	Malignant pleural effusion
	Hyperinflation	COPD
	Nodules/masses	Neoplastic process
Pulmonary function tests		
Spirometry	Obstructive ventilation defect (decreased FEV$_1$/FVC, %)	Asthma
		COPD
	Restrictive ventilatory defect	Interstitial lung disease
Diffusing capacity	Decreased	Interstitial lung disease
		Pulmonary vascular disease
	Increased	Alveolar hemorrhage
Inspiratory and expiratory pressures	Decreased values	Respiratory muscle weakness
Computed tomography	Abnormal interstitial markings	Interstitial lung disease
	Cystic changes	Bullous lung disease
	Lymphadenopathy	Sarcoidosis
	Vascular filling defects	Pulmonary embolism
	Ground-glass opacities	Neoplastic disease
Blood tests	Elevated white blood cell count	Infection
	Anemia	Anemia
	BNP	Heart failure
	Cr	Renal failure
		Respiratory or metabolic acidosis
	ABG	Acidoses or alkaloses (respiratory or metabolic)

COPD, chronic obstructive pulmonary disease; FEV$_1$/FVC, forced expiratory volume in 1 s/forced vital capacity; BNP, brain natriuretic peptide; Cr, creatine; ABG, arterial blood gas.

characterize an interstitial process identified on plain radiographs. Cardiopulmonary exercise testing (Chapter 32) may be helpful in differentiating between cardiac and respiratory causes of dyspnea, or in excluding a significant abnormality of either system and suggesting deconditioning as the culprit. Arterial blood gas measurements may be necessary to characterize the level of blood oxygenation or to identify hyperventilation or hypercapnia. More invasive testing, including cardiac catheterization or lung biopsy (by either bronchoscopy or surgery), is reserved for situations when the diagnosis remains unsettled and the results will be helpful in guiding therapy or discussions of prognosis.

COUGH

Cough is one of the most frequent causes of visits to the doctor's office.[36,37] Patients are frequently anxious about the possibility of a serious underlying cause. They may also be troubled by the complications of cough, including chest pain from intercostal muscle strain or even a fractured rib. They may be embarrassed by cough-induced urinary or fecal incontinence. Social isolation may also arise from the frequent fear of others that the patient's cough is infectious and communicable.

A cough is an explosive expiration that protects the lungs against aspiration and promotes the movement of secretions and other airway constituents upward toward the mouth. It is a critical element in the self-clearing and protective mechanisms of the lungs—a reflex act that usually, but not invariably, arises from stimulation of the bronchial mucosa somewhere between the larynx and the second-order bronchi. On rare occasions the cause is remote: impacted cerumen in the external auditory canal[38] or an inflammatory process of the pleura (see "Mechanism," below) (Fig. 27-12). The stimuli that may elicit a cough are diverse: inhaled particles, mucus that has been elaborated by the lining of the airways, inflammatory exudate in airways or parenchyma, a new growth or foreign body in an airway, or pressure on the external wall of the bronchus.

A cough may be voluntary, involuntary, or a combination of the two if the subject attempts to control an involuntary cough. Three categories of stimuli are commonly at work in producing an involuntary cough: mechanical, inflammatory, and psychogenic. Mechanical and chemical causes range from inhalation of irritants, such as smoke or dust, to distortions of the airways produced by pulmonary fibrosis or atelectasis. Most often, cough is due to tracheobronchial inflammation. The cigarette smoker is particularly vulnerable to exacerbation of cough by inhaled particles and fumes because of underlying chronic pharyngitis, laryngitis, and tracheobronchitis. As a rule, cough represents organic disease. But on occasion, psychogenic influences are responsible for a dry cough that is related to anxiety. Psychogenic stress can aggravate cough due to organic causes.[39] Cough may also be caused by certain pharmacologic agents, including, most notably, angiotensin-converting enzyme (ACE) inhibitors.

The site of origin and significance of a cough may sometimes be ascertained from telltale signs and symptoms (Table 27-9). For example, the cough of acute tracheitis is often associated with retrosternal "burning." Acute laryngitis is usually associated with hoarseness and sore throat, as well as cough. Tuberculosis of the larynx is associated not only with painful swallowing but also with unequivocal evidence of pulmonary tuberculosis. In asthma, cough is part of a constellation of airway obstruction.

Interpretation of the significance of a cough depends on the clinical features with which it is associated. It has to be viewed in context: Is it acute or chronic? Is it productive or nonproductive? How long has it lasted? What is the general condition of the patient, and what comorbidities are present? For example, the acute onset of a hacking, nonproductive cough accompanied by coryza, sore throat, malaise, sweating, and fever generally heralds a viral upper respiratory infection. An episode of asthma may begin with cough and wheezing. In contrast, a persistent cough, even if virtually ignored by the patient, may be a harbinger of serious disease (e.g., carcinoma of the lung). In a cigarette smoker, a change in the nature of the cough from nonproductive to productive may signify the onset of a serious tracheobronchial infection or pneumonia.

A cough that is productive of purulent sputum is generally a reliable indication of infection in the tracheobronchial tree or lungs. When this symptom is associated with an acute illness, the characteristics of the sputum can be of considerable diagnostic help. Rust-colored sputum, which has a distinctive coloration from the even dispersion of blood in yellow, purulent sputum, was previously seen often in pneumococcal pneumonia; it is less commonly seen today due to the widespread use of antibiotics. The classic description of sputum in *Klebsiella* pneumonia is a resemblance to currant jelly; it also contains blood, but it is bright red and more translucent and viscid than the sputum of pneumococcal pneumonia. Purulent sputum with a foul odor usually indicates an anaerobic infection, commonly due to streptococci or *Bacteroides* in a lung abscess. A persistent cough that is productive of purulent sputum occurs in chronic bronchitis, bronchiectasis, and a variety of other suppurative disorders. Sputum that is mucoid may be a consequence of any long-standing bronchial irritant. Copious sputum production *(bronchorrhea)* may be a sign of adenocarcinoma in situ (AIS) or minimally invasive adenocarcinoma (MIA), previously known as bronchoalveolar carcinoma.

TABLE 27-9 Some Causes and Characteristics of Cough

Cause	Characteristics
Sinusitis or nasopharyngitis	Cough following an upper respiratory syndrome or sinus symptoms; sensation of a need to clear the throat; postnasal drip
Acute infections of lungs	
Tracheobronchitis	Cough associated with sore throat, running nose, and eyes
Lobar pneumonia	Cough often preceded by symptoms of upper respiratory infection; cough dry, painful at first; later becomes productive
Bronchopneumonia	Cough dry or productive, usually begins as acute bronchitis
Mycoplasma and viral pneumonia	Paroxysmal cough, productive of mucoid or blood-stained sputum associated with flulike syndrome
Exacerbation of chronic bronchitis	Cough productive of mucoid sputum becomes purulent
Chronic infections of lungs	
Bronchitis	Cough productive of sputum on most days for more than 3 consecutive months and for more than 2 y Sputum mucoid until acute exacerbation, when it becomes mucopurulent
Bronchiectasis	Cough copious, foul, purulent, often since childhood; forms layers upon standing
Tuberculosis or fungus	Persistent cough for weeks to months, often with blood-tinged sputum
Parenchymal inflammatory processes	
Interstitial fibrosis and infiltrations	Cough nonproductive, persistent, depends on origin
Smoking and inhalation of irritants	Cough usually associated with injected pharynx; persistent, most marked in morning, usually only slightly productive unless succeeded by chronic bronchitis
Tumors	
Bronchogenic carcinoma	Cough nonproductive to productive for weeks to months; recurrent small hemoptysis common
Adenocarcinoma *in situ* or minimally invasive adenocarcinoma	Cough similar to that with bronchogenic carcinoma except in occasional instances, when large quantities of watery, mucoid sputum are produced
Benign tumors in airways	Cough nonproductive; occasionally hemoptysis
Mediastinal tumors	Cough, often with breathlessness, caused by compression of trachea and bronchi
Aortic aneurysm	Brassy cough
Gastrointestinal	
Gastroesophageal reflux disease (GERD)	Nonproductive cough often following meals or with recumbency; may (or may not) be accompanied by other symptoms of GERD (e.g., heartburn, a bitter oral taste, belching)
Foreign body	
Immediate, while still in upper airway	Cough associated with progressive evidence of asphyxiation
Later, when lodged in lower airway	Nonproductive cough, persistent, associated with localizing wheeze
Cardiovascular	
Left ventricular failure	Cough intensifies while supine, along with aggravation of dyspnea
Pulmonary infarction	Cough associated with hemoptysis, usually with pleural effusion
Medication-induced	
Angiotensin-converting enzyme (ACE) inhibitors	Nonproductive cough, more common in women, may occur at any time (following soon after drug initiation or with years of use)

■ Mechanism

A cough begins with a rapid inspiration, followed, in rapid sequence, by closure of the glottis, contraction of the abdominal and thoracic expiratory muscles, abrupt increase in pleural and intrapulmonary pressures, sudden opening of the glottis, and expulsion of a burst of air from the mouth (Fig. 27-13). The high intrathoracic pressures, which often exceed 100 to 200 mm Hg, increase the velocity of airflow through the airways, hastening the propulsion of the offending particles and producing the sound of a cough by setting into vibration airway secretions, the tracheobronchial walls, and the adjacent parenchyma (Fig. 27-14).

Afferent stimuli for a cough originate in irritant receptors and are conveyed centrally by the vagus, glossopharyngeal, trigeminal, and phrenic nerves (Fig. 27-12). In subjects with an idiopathic, persistent, nonproductive cough, increased sensitivity of the afferent nerves of the airways due to neuropeptides stored in them has been proposed.

The vagus nerve carries impulses not only from the larynx, trachea, and bronchi, but also from the pleura and stomach. Receptors in the airways are most concentrated in the larynx, diminish in density in the conducting airways, and are absent from the distal airways, enabling the pooling of secretions in the periphery. The glossopharyngeal nerve carries stimuli from the pharynx; the trigeminal nerve, from the nose and paranasal sinuses; the phrenic nerve, from the pericardium and diaphragm. The motor pathways are even more extensive, comprising not only the cranial and phrenic nerves but also the nerves to the muscles of the rib cage and the accessory muscles. Additional impulses from chemoreceptors are located in the esophagus and carried by the phrenic nerve.

The effectiveness of a cough is strongly influenced by the lung volume at which it occurs. As indicated elsewhere in this volume, cough only removes particles toward the mouth ("downstream" from the "equal pressure points"). In healthy persons at high lung volumes, the equal pressure points are located in the larger airways; they move

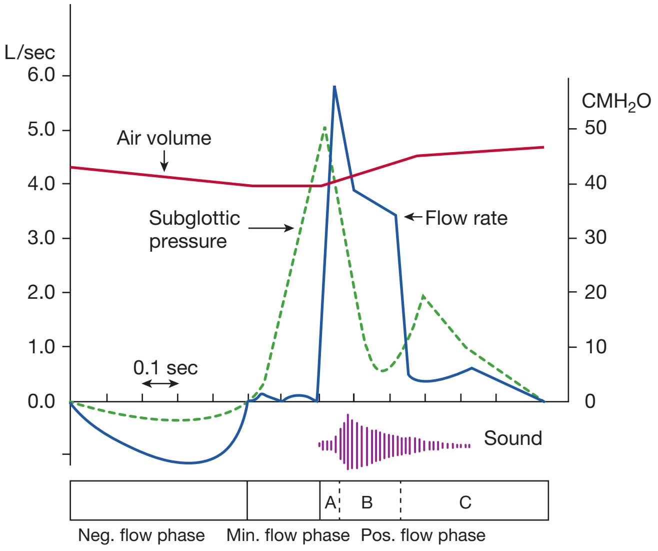

Figure 27-13 Sequence of events during a cough. Simultaneous recordings obtained during a single explosive cough by a normal subject. The three phases of a cough are identified by the boxes at the bottom of the figure. They correspond to (1) a deep initial inspiration, (2) compression of air in the lungs and airways by forceful contraction of the expiratory muscles coupled with tight closure of the glottis and opening of the larynx, and (3) sudden explosive expiration followed by narrowing of the glottis and return of the larynx to its normal inspiratory position. *(Reproduced with permission from Yanagihara N, Von Leden H, Werner-Kukuk E. The physical parameters of cough: the larynx in a normal single cough. Acta Otolaryngol. 1966;61(6):495–510.)*

toward the alveoli ("upstream") as lung volume decreases. A series of coughs without any intervening inspiration moves the equal pressure points even closer to the small airways, helping to clear the depths of the lungs.

The cough reflex may be impaired by interrupting or blunting any step in the sequence. Irritant receptors can be damaged by a local destructive process (e.g., bronchiectasis), or their sensitivity can be diminished by narcotics or anesthetics.

The reflex pathways may be damaged as part of a neurologic disease. Tracheostomy, which eliminates glottic closure, decreases peak intrapulmonary pressures. Contraction of the respiratory muscles may be impaired by weakness due to illness, age, or neuromuscular disease. In general, as long as the patient can achieve maximum expiratory pressures greater than about 60 cm H_2O, the peak flow will suffice to produce effective coughs.

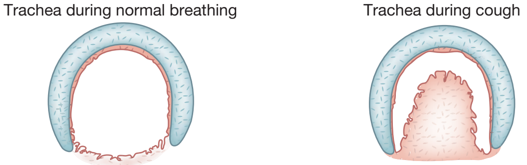
Circulatory Consequences

The increase in intrathoracic pressure that is part of the cough mechanism exerts considerable circulatory effects. However, because the increase in intrathoracic pressure is accompanied by an equal rise in vascular (and cerebrospinal fluid) pressures, distending pressures on the vessels of the heart, lungs, and other vital organs are unaltered, so they are normally spared the ill consequences of marked swings in transmural pressures.

The increase in intrathoracic pressure is accompanied by reflex vasodilation of systemic arteries and veins. Both of these effects contribute to a decrease in cardiac output. In patients with cor pulmonale and right heart failure, cough impedes systemic venous return and may result in syncope.

Posttussive Syncope

Over 100 years ago, Charcot recognized the syndrome of posttussive syncope in individuals without underlying cardiopulmonary disease.



Intrathoracic pressure, cm H_2O	– 4	+ 150
Cross-sectional area, cm^2	1.5	0.25
Volume flow, L/sec	1	7
Linear velocity, cm/sec	667	28,000

Figure 27-14 Effects of tracheal narrowing during a cough. The forced expiratory effort during coughing causes invagination of the noncartilaginous part of the intrathoracic trachea by the high intrathoracic pressure. Air rushing with a high linear velocity through the exceedingly narrow trachea dislodges the material to be dispelled and propels it into the throat. *(Reproduced with permission from Comroe JH: Physiology of Respiration. St. Louis, MO: Mosby-Year Book; 1965.)*

Originally conceived of as a form of epilepsy or a consequence of a laryngeal reflex, it is now attributed to the same circulatory consequences of raised intrathoracic pressures that coughing evokes in a normal person. However, the patient with cough syncope probably coughs more forcefully and longer than does a normal person.

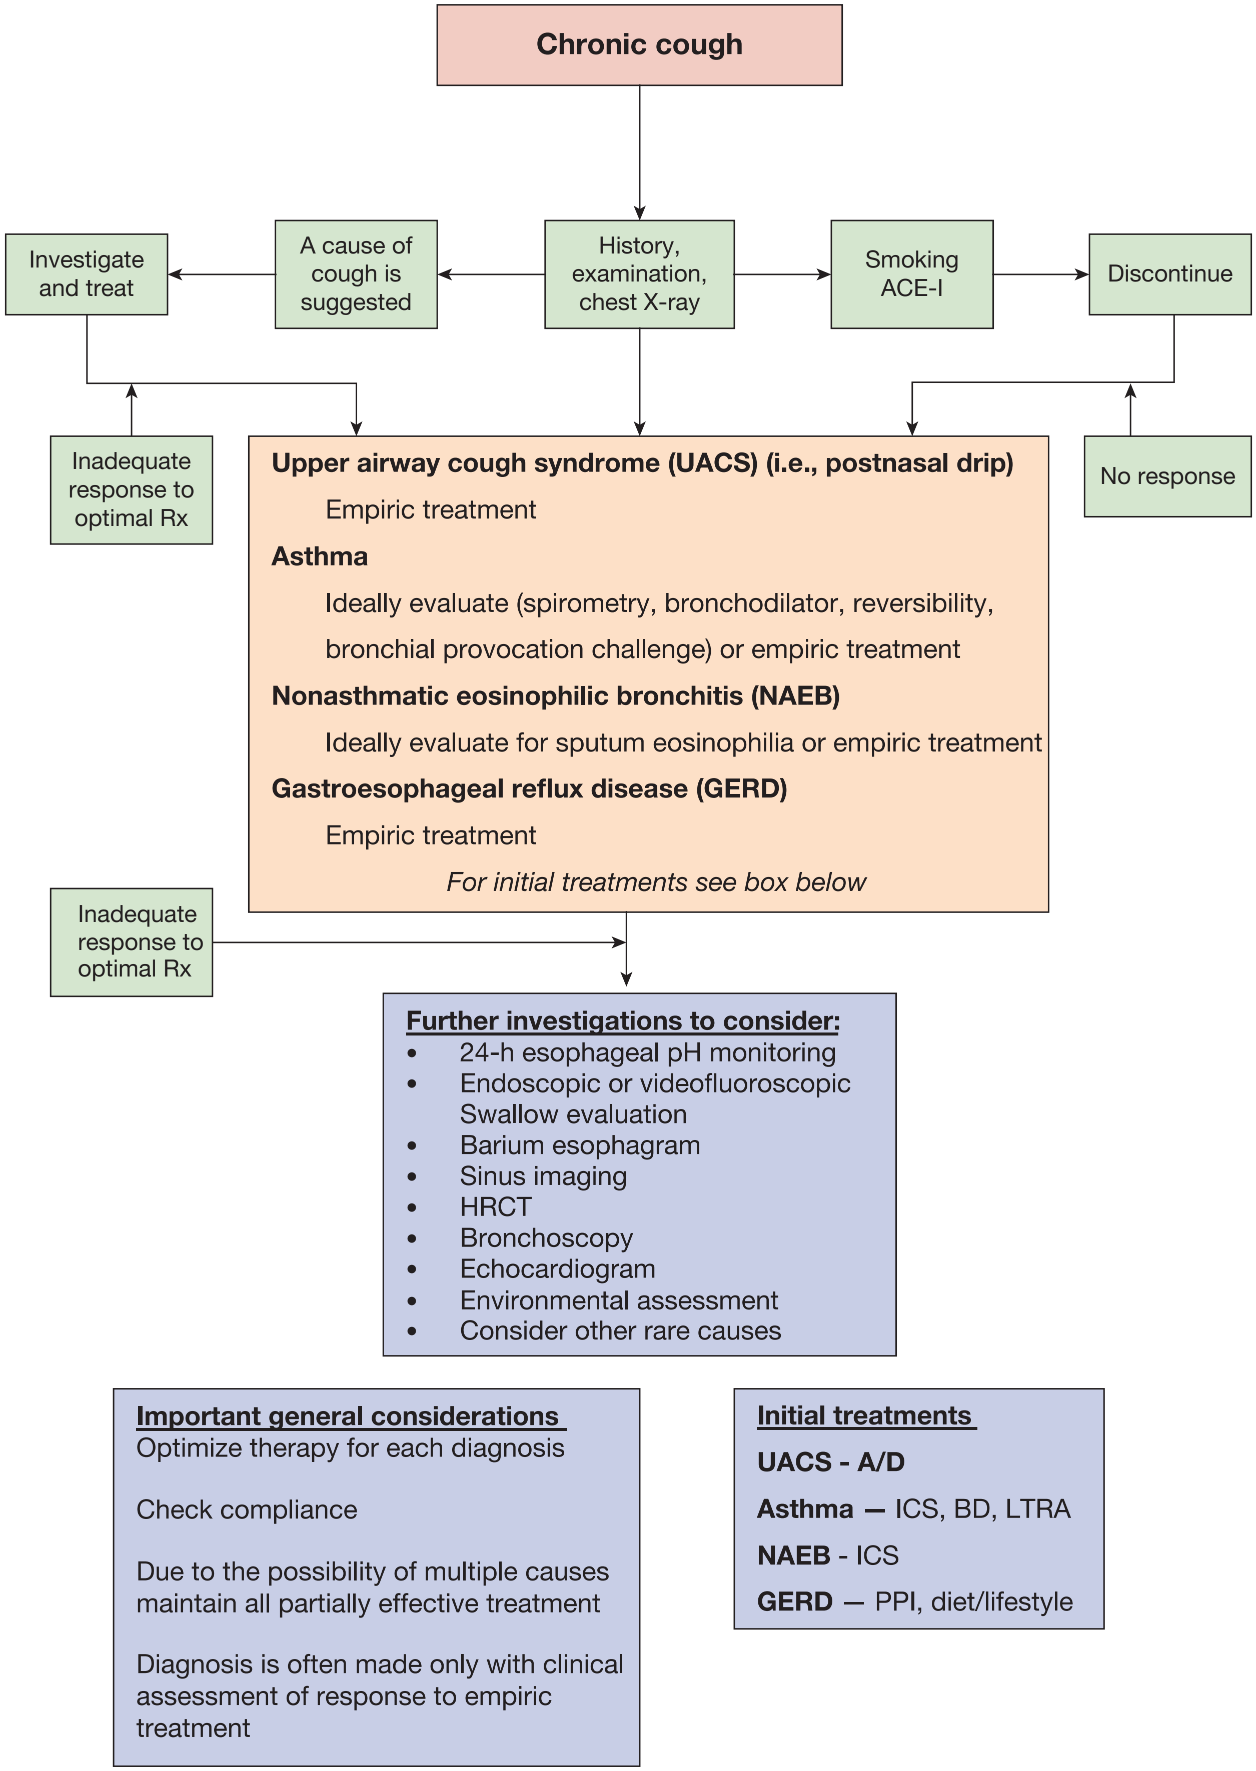
The syncope usually develops within a few seconds after the onset of a paroxysm of coughing and ends quickly once the coughing has stopped. Return to consciousness is without sequelae unless the subject falls and is injured during the faint. Posttussive syncope nearly always occurs in men, probably because they generate a higher intrathoracic pressure and much more profound decrease in cardiac output than do women. It is not clear why this type of fainting occurs in the supine, as well as the upright, position; this occurrence suggests that the reduction in cerebral blood flow during posttussive syncope reflects more than interference with cardiac output. The extent to which intense reflex vasodilation contributes to posttussive syncope is unclear. It is important to distinguish cough syncope from epilepsy and cataplexy.

Etiology

The most common causes of chronic cough and sputum (defined as lasting longer than 8 weeks) are postnasal drip, gastroesophageal reflux disease (GERD), and asthma.[40,41] In most cases, the etiology can be determined, and more than one cause may be present.

In patients treated with angiotensin-converting enzyme (ACE) inhibitors, the drug is very often the cause of a chronic cough (even one developing after years of uncomplicated use). The association of cough and ACE inhibitors may be different among various ethnic groups.[43]

A deliberate evaluation can identify the cause of cough in the vast majority of patients. Usually, the diagnosis is established only by the resolution of the cough following a specific intervention (Fig. 27-15). For example, cough that disappears after antihistamines and inhaled nasal corticosteroid treatment for allergic rhinitis can logically be attributed to postnasal drip. Similarly, cough may disappear after interventions for GERD (e.g., use of H_2-blockers) or asthma (use of inhaled bronchodilators and steroids). A cough that resolves after discontinuation of an ACE inhibitor was presumably caused by the drug. Although the causes of chronic cough are usually benign, a chest radiograph is warranted at the beginning of the evaluation of a chronic cough to assess for serious causes.



Chronic cough
Investigate and treat
A cause of cough is suggested
History, examination, chest X-ray
Smoking ACE-I
Discontinue
Inadequate response to optimal Rx
No response
Upper airway cough syndrome (UACS) (i.e., postnasal drip)
Empiric treatment
Asthma
Ideally evaluate (spirometry, bronchodilator, reversibility, bronchial provocation challenge) or empiric treatment
Nonasthmatic eosinophilic bronchitis (NAEB)
Ideally evaluate for sputum eosinophilia or empiric treatment
Gastroesophageal reflux disease (GERD)
Empiric treatment
For initial treatments see box below
Inadequate response to optimal Rx
Further investigations to consider:
• 24-h esophageal pH monitoring
• Endoscopic or videofluoroscopic Swallow evaluation
• Barium esophagram
• Sinus imaging
• HRCT
• Bronchoscopy
• Echocardiogram
• Environmental assessment
• Consider other rare causes
Important general considerations
Optimize therapy for each diagnosis
Check compliance
Due to the possibility of multiple causes maintain all partially effective treatment
Diagnosis is often made only with clinical assessment of response to empiric treatment
Initial treatments
UACS - A/D
Asthma — ICS, BD, LTRA
NAEB - ICS
GERD — PPI, diet/lifestyle

Figure 27-15 Algorithm for the evaluation of chronic cough lasting 8 weeks in adults. ACE-I, ACE inhibitor; A/D, antihistamine/decongestant; BD, bronchodilator; HRCT, high-resolution computed tomography; ICS, inhaled corticosteroid; LTRA, leukotrienes receptor antagonist; PPI, proton pump inhibitor. *(Reproduced with permission from Irwin RS, Baumann MH, Bolser DC, et al. Diagnosis and management of cough executive summary: ACCP evidence-based clinical practice guidelines. Chest. 2006;129(1 Suppl):1S–23S.)*

HEMOPTYSIS

The coughing up of blood is termed *hemoptysis.*[44] The material and amount produced varies from mere blood streaking of expectorated sputum to massive volumes of pure blood. Massive hemoptysis has been variably defined according to the volume, but its presence implies a potentially life-threatening process requiring immediate evaluation and treatment.

An initial decision faced by the physician who is told that blood has been coughed up is whether to conclude that the blood is coming from the respiratory tract. Any portion of the respiratory tract can be the source of bleeding including a main bronchus, the lungs, or the nose or throat. On occasion, blood from the nose and throat is inhaled and then expectorated. As long as this possibility is kept in mind, bleeding that originates in the nose, throat, or larynx is not apt to be overlooked.

An additional consideration is distinguishing hemoptysis from hematemesis (vomited blood). Even if the blood is aspirated and then coughed up, the patient can usually tell if the blood originated in the respiratory or alimentary tract. The appearance of the bloody material also helps to distinguish between hemoptysis and hematemesis: blood that originates in the airways is usually bright red, is mixed with frothy sputum, has an alkaline pH, and contains alveolar macrophages that are laden with hemosiderin; in contrast, blood from the stomach usually is dark, has an acid pH, contains food particles, and often occurs in patients with a long history of gastric disease.

Blood arising from the bronchial arteries is more often the source of massive hemoptysis, owing to its higher perfusion pressure, than blood from the pulmonary circulation. The bronchial circulation may be the source of life-threatening bleeding, for example, in patients with bronchiectasis in whom the vessels frequently become distorted and easily ruptured. Dieulafoy's disease of the bronchus, in which there is a submucosal fistula between bronchial and pulmonary arteries, is a rare cause of massive hemoptysis.[45]

The differential diagnosis of hemoptysis includes disorders arising within the airways and the pulmonary parenchyma. Inflammatory processes (e.g., bronchitis and bronchiectasis) and neoplasms are the most common causes of blood arising within the airways. Within the pulmonary parenchyma, common causes are infections, such as tuberculosis, pneumonia, *Aspergillus*, or lung abscess. Inflammatory processes that involve the lung, such as granulomatosis with polyangiitis (formerly known as Wegner's granulomatosis) or Goodpasture syndrome, also are important causes of hemoptysis (Fig. 27-16). Bleeding may be iatrogenic, as for example, after a lung biopsy or when chemotherapy for bone marrow transplantation evokes diffuse alveolar hemorrhage. Vascular disorders, including pulmonary embolism, arteriovenous malfunctions, and mitral stenosis, are also to be considered in the differential diagnosis. Unexplained hemoptysis occurs in COPD and usually is not recurrent.[46]

The causes of hemoptysis are numerous and diverse (Table 27-10). The clinical setting is usually helpful in identifying the cause. Hemoptysis before middle age usually brings to mind infections; after 40 to 45 years of age, or if there is a history of smoking, bronchogenic carcinoma heads the list. In patients left with a pulmonary cavity after pulmonary disease that has healed (e.g., tuberculosis), and in regions of the country where pulmonary fungal diseases are prevalent, a bout of hemoptysis is occasionally the first sign of the disease. In patients who have a predisposing cause, such as oral contraceptives or chronic heart failure, pulmonary embolism must be considered.

TABLE 27-10 Some Causes of Hemoptysis

Infections
Bronchitis
Tuberculosis
Fungal infections
Pneumonia
Lung abscess
Bronchiectasis
Neoplasms
Bronchogenic carcinoma
Bronchial adenoma
Cardiovascular disorders
Pulmonary infarction from thromboembolism
Mitral stenosis
Trauma
Foreign body
Hematologic/immunologic
Disorders of hemostasis
Goodpasture syndrome

The evaluation of hemoptysis involves a careful history, physical examination, and a chest radiograph. Initial studies also include a complete blood count. The degree of anemia may influence the rapidity of further testing, and thrombocytopenia may be a contributing factor to hemoptysis. Rapid correction of anemia, thrombocytopenia, or coagulopathy with the transfusion of appropriate blood products may be required promptly depending upon the clinical status and degree of abnormality. Similarly, measurement of coagulation parameters is important. Studies of renal function and a urinalysis may be indicated when a systemic process, which causes a pulmonary-renal syndrome is a possibility. Sputum should be collected and, depending on the circumstance, microbiologic cultures and stains or cytologic examination should be performed. Depending on whether a cause is identified, and the risk factors for a serious cause of bleeding, the evaluation next involves additional studies to search for a source.

Because hunting for the cause and the source of bleeding is generally uncomfortable for the patient and often expensive, the intensity of the search depends on the circumstances. For example, rarely is a search for the bleeding site needed in a patient with acute bronchitis, pneumonia, or bronchopulmonary suppuration. But as a rule, unless the cause is evident, a full-scale investigation is mandatory.

Patients with hemoptysis and a history of tobacco smoking, individuals who are more than 40 years of age, or those who experience hemoptysis that lasts for more than 1 week are at greater risk for a worrisome cause and warrant additional studies. A chest CT scan is usually the next step if the patient has no history of tobacco use or if the plain chest radiograph suggests a parenchymal abnormality, such as bronchiectasis or arteriovenous malformation. Patients with a history of tobacco use or other risk factors for a malignancy warrant fiberoptic bronchoscopy (Chapter 33). In practice, CT scanning and bronchoscopy are often complementary for visualizing abnormalities that are not apparent on plain chest radiographs. Patients with chronic bronchitis and who are at low risk for malignancy, or in whom the chest radiograph is normal or identifies the cause of hemoptysis (e.g., pneumonia) can usually be treated initially for bronchitis with follow-up appraisals to show prompt resolution of hemoptysis. However, should hemoptysis recur, further evaluation is required.

■ Neoplasms

Nonmassive hemoptysis (<500 cc/24 h) is common in bronchogenic carcinoma; less frequently carcinoma is the cause of massive hemoptysis. The likelihood of a neoplastic cause of hemoptysis is greatly increased in a cigarette smoker. Usually a troublesome cough and vague chest pain precede and accompany the hemoptysis. For hemoptysis to occur, the lesion must communicate with the airways. Most often the bleeding is a consequence of ulceration caused by an

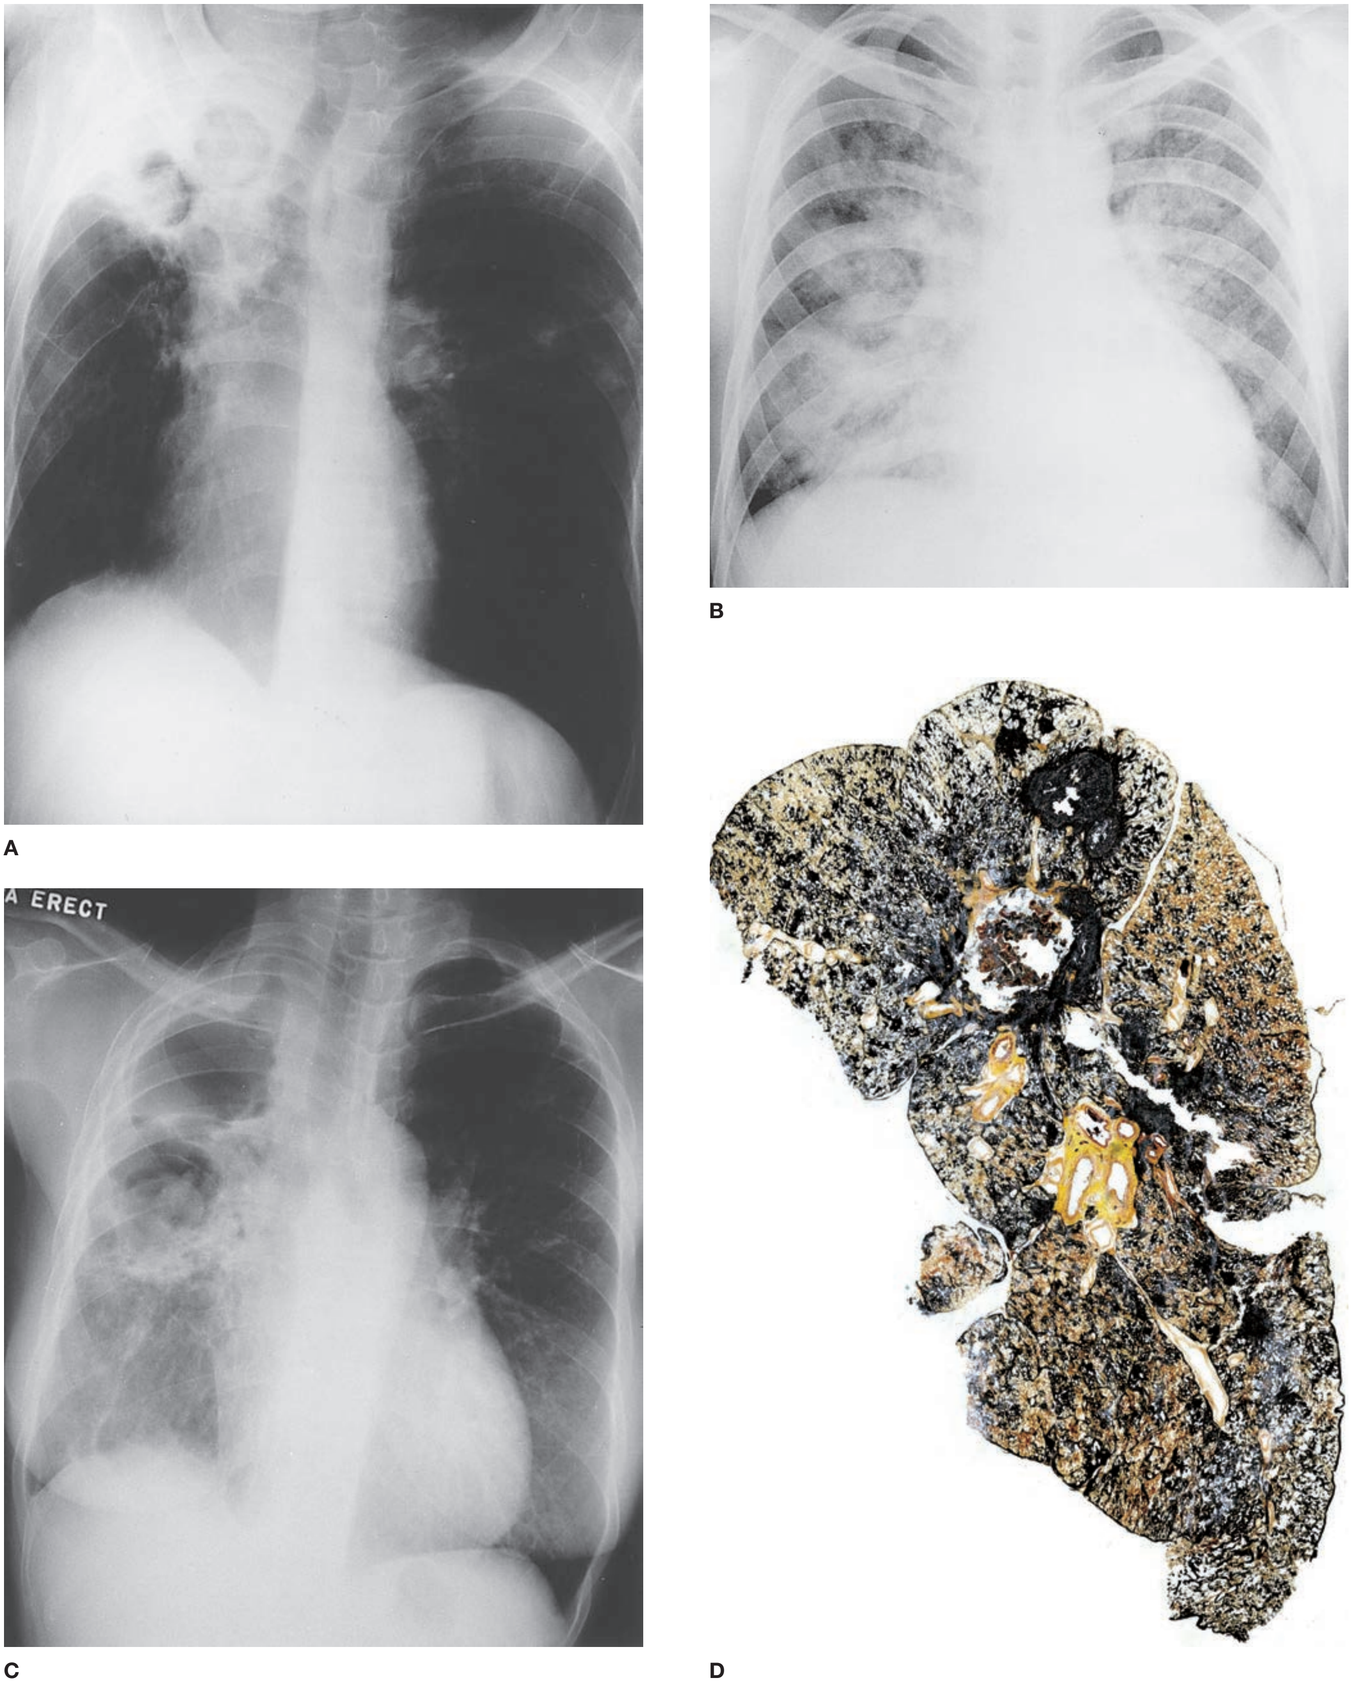


Figure 27-16 Causes of hemoptysis. **A.** Old tuberculosis cavities in right apex. They were removed surgically to control hemoptysis. **B.** Goodpasture syndrome. **C.** Fungus ball in coal miner's pneumoconiosis. **D.** Sagittal section of lung. Fungus ball due to aspergillosis in old tuberculosis cavity. Recurrent hemoptysis was treated with surgical removal of right upper lobe. *(**C.** Reproduced with permission from J. Gough.)*

expanding tumor; sometimes it is due to a pneumonic process or to an abscess in the lung behind an obstructive lesion. Hemoptysis rarely complicates metastatic tumors of the lungs.

Not only malignant, but also benign, tumors of the lung cause bleeding. The classic example is bronchial carcinoid.

Hemoptysis may accompany a severe infection occurring anywhere from the top to the bottom of the respiratory tract. It is uncommon in the usual viral or bacterial pneumonia. Conversely, it is not uncommon in the pneumonia that complicates bronchogenic carcinoma.

The infecting organism determines the appearance and composition of the material that is expectorated with the blood. As indicated previously, in pneumococcal lobar pneumonia, the sputum at the onset is classically described as rusty-looking, but sometimes it is faintly or grossly bloody. In staphylococcal pneumonia, the blood is mixed with pus. In *Klebsiella* pneumonia, the bloody sputum is historically described as resembling currant jelly. Brisk bleeding is common in lung abscess; the blood is mixed with copious amounts of foul-smelling pus. In lung gangrene, blood is associated with necrotic lung tissue.

Bleeding is common in bronchiectasis. Because it usually originates in a bronchial artery, bleeding is often brisk. While most episodes stop spontaneously, the hemoptysis tends to recur and may be life-threatening.

Fungal infections of the lungs may cause hemoptysis (Fig. 27-16). As in tuberculosis, hemoptysis is generally a consequence of a continuing necrotizing and ulcerating inflammatory process or of bronchiectasis. The most common fungal disorder associated with hemoptysis is a "fungus ball" that resides either in a healed tuberculous or bronchiectatic area or in a cystic residue of sarcoidosis. *Aspergillus* is the usual fungal agent; less often another fungus (e.g., *Mucor*) is the cause.

At one time, the most common source of hemoptysis was an active tuberculosis cavity. Despite the increasing frequency of tuberculosis, hemoptysis is uncommon because of effective antituberculous therapy. If tuberculosis is allowed to progress to the point of extensive fibrosis and cavitation, or becomes complicated by bronchiectasis, hemoptysis can be troublesome and persistent. Hemoptysis may arise from a *Rasmussen aneurysm*, which is an erosion of a small- or medium-sized pulmonary artery into an adjacent tuberculosis cavity.

The "right middle lobe syndrome" is frequently associated with hemoptysis. It is due to a partial or complete obstruction of the right middle lobe bronchus, resulting in atelectasis or pneumonitis in the right middle lobe. The obstruction is more often caused by scarring or inflammation than by physical compression of the lumen by an enlarged lymph node. The cause is usually infectious; the infection may be tuberculosis.

In parts of the world where amebiasis is endemic, hemoptysis follows perforation into the airways of an amebic lung abscess. The sputum resembles anchovy sauce.

■ Cardiovascular Disorders

Pulmonary congestion and alveolar edema sometimes produce blood-tinged sputum. In chronic pulmonary congestion secondary to left ventricular failure or to mitral valve disease, alveolar macrophages in the sputum are often laden with hemosiderin ("heart failure cells"). In severe congestion and edema, the sputum is often pink and frothy. Usually there is no difficulty in recognizing that inadequate performance of the left ventricle is the cause of the bloody sputum.

Pulmonary thromboembolism may produce hemoptysis when associated with infarction (Fig. 27-17). The hemoptysis of pulmonary infarction is usually associated with pleuritic pain and, often, with a small pleural effusion because of the peripheral location of the infarct.

Historically, tight mitral stenosis was sometimes first manifested by a bout of brisk, bright-red hemoptysis that is difficult to control. The source of the bleeding is the submucosal bronchial veins, which proliferate considerably in this disorder. Massive hemoptysis due to mitral stenosis is not frequently seen in modern times.

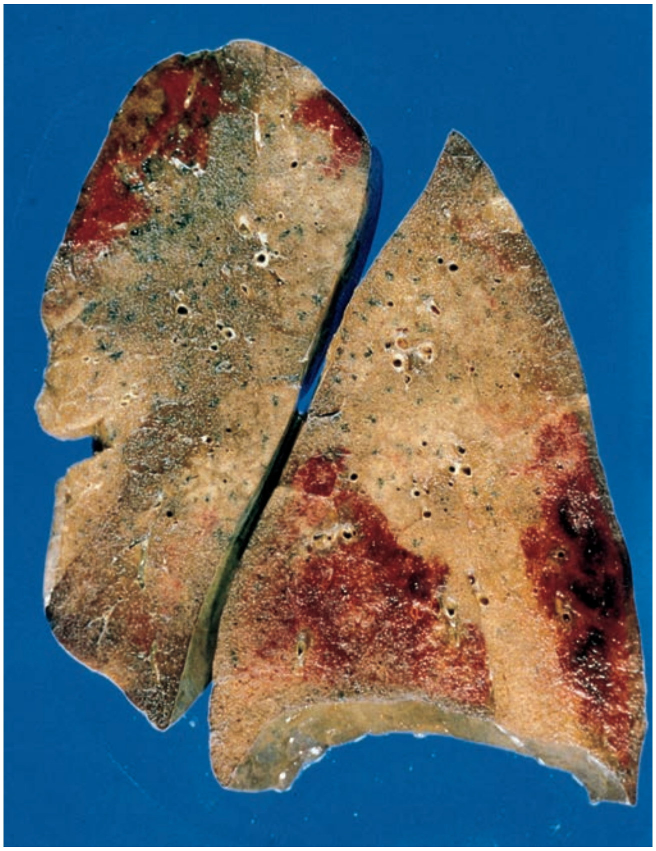

Figure 27-17 Hemorrhagic pulmonary infarcts. Several subpleural areas of infarction are clearly demarcated.

Hemoptysis from other circulatory disorders should be noted. Occasionally, an aortic aneurysm penetrates into the tracheobronchial tree, causing death by exsanguination and asphyxiation. An extraordinary event is the communication of an arteriovenous fistula with a small airway, causing bleeding that is exceedingly difficult to arrest.

■ Trauma

Hemoptysis follows a variety of chest injuries: puncture of a lung by a fractured rib, contusions of a lung by severe blunt trauma to the chest, and necrosis of the lining of the tracheobronchial tree by inhaled fumes or smoke. Blunt trauma from the steering wheel during an automobile collision sometimes lacerates or fractures the tracheobronchial tree. Stab or gunshot wounds often tear the lungs or airways. On occasion, mucosal lacerations in the course of severe coughing evoke hemoptysis.

After lobectomy, or now, much less commonly, pneumonectomy, a large hemothorax occasionally empties into the airways. This is an alarming and ominous event. Its imminent occurrence is often heralded by the expectoration of blood-stained sputum after a paroxysm of coughing. The hemothorax must be promptly evacuated and the bronchus surgically repaired. Hemoptysis within a few weeks to months after lung resection has different implications: recurrence of tumor, granulation tissue, or bronchial sutures. Prompt bronchoscopy is necessary for accurate appraisal of the situation.

■ Miscellaneous

Other causes of hemoptysis are listed in Table 27-10. They vary greatly in severity, urgency, and prognosis. Sometimes the cause is obscure, as in the occasional instance of hemoptysis that accompanies menstruation (*catamenial hemoptysis*). An aspirated foreign body produces bleeding by damaging the mucosa on impact; if allowed to remain in place, it sometimes causes bronchiectasis, which, in turn, may cause bleeding. Pulmonary calcific foci, either in the pulmonary parenchyma or in lymph nodes, sometimes cause hemoptysis by ulcerating into a bronchus.

Thrombocytopenic purpura and hemophilia and the therapeutic use of anticoagulants are occasional causes of hemoptysis.

Hemoptysis in Goodpasture syndrome (Fig. 27-16) or in idiopathic hemosiderosis is life-threatening.

Management of Massive Hemoptysis

The first priority in the care of a patient with life-threatening hemoptysis is to protect the airway and prevent asphyxiation.[47] Intubation should be contemplated and consideration given to selective intubation of one lung in order to protect it from spillage of blood from the other. When the site of bleeding is known, one simple, initial bedside maneuver is to place the involved side in a dependent position in order to protect the uninvolved lung. Bronchoscopy should be performed promptly in order to identify the source (Chapter 33). This may also allow bronchoscopic interventions, such as the placement of a balloon catheter to isolate the involved segment, lavage with iced saline, or the application of topical epinephrine. Bronchoscopic localization may help to guide attempts at arresting the bleeding by angiographic embolization. If these modalities fail to stop the bleeding, surgical exploration may be required. Not surprisingly, emergency procedures are accompanied by a high mortality. None of the approaches has been rigorously studied, and the choice is frequently dictated by the urgency, local experience, and availability of bronchoscopy.

CYANOSIS

Cyanosis refers to a bluish discoloration of the skin that is caused by increased amounts of reduced hemoglobin in the subcapillary venous plexus. The discoloration is most apparent in the lobes of the ears, the cutaneous surfaces of the lips, and the nail beds. In patients with dark skin, the mucus membranes and the retina are important sites to examine for cyanosis. Unless flow through the skin is slowed, as in heart failure, cyanosis implies arterial hypoxemia. Cyanosis does not appear in carbon monoxide poisoning or in severe anemia, even though arterial O_2 content is extremely low. This is because there is an insufficient amount of reduced hemoglobin present for the cyanotic discoloration to be visible. The presence of abnormal pigments in blood, such as methemoglobin or bilirubin, complicates the detection of cyanosis.

Capillary O_2 Content

An increase in the amount of reduced hemoglobin in the capillaries of the skin, as elsewhere, results from inadequate oxygenation of arterial blood, excessive removal of O_2 from capillary blood (as when the circulation through a region is slowed by vasoconstriction or a very low cardiac output), or from a combination of the two. The concentration of reduced hemoglobin in the skin capillaries must reach about 5 g/dL before cyanosis becomes discernible. Thus, in severe anemia, when hemoglobin concentrations are exceedingly low (on the order of 3–4 g/dL), although virtually all the hemoglobin can be reduced in traversing the skin capillaries, an insufficient amount of reduced hemoglobin remains to produce a visible discoloration. On the other hand, the polycythemic patient develops cyanosis at a higher arterial O_2 saturation than does the normal individual.

Causes of Cyanosis

Several types of cyanosis are usually identified according to the underlying mechanism. They include peripheral cyanosis, cyanosis arising from pulmonary disease, cyanosis from venous admixture, and cyanosis due to abnormal pigments in the blood.

Peripheral Cyanosis

This type of cyanosis is secondary to abnormally large extraction of O_2 from blood flowing through peripheral capillaries. The most common cause is a diminished cardiac output associated with peripheral vasoconstriction. Not only the hands and feet, but also the tip of the nose become blue in severe heart failure. Indeed, in patients with intractable heart failure, necrosis occasionally develops at the tip of the nose.

Peripheral vasoconstriction per se, as in Raynaud's disease, also produces cyanosis of the nail beds.

Cyanosis in Pulmonary Disease

Patients with chronic bronchitis and emphysema characteristically manifest derangements in ventilation–perfusion relationships. In some, arterial hypoxemia results. In patients with diffuse interstitial fibrosis, normal arterial oxygenation at rest is succeeded by arterial hypoxemia, and sometimes, by cyanosis, during exercise. Another cause of arterial hypoxemia is the syndrome of alveolar hypoventilation in patients with normal lungs. In any of these situations, cyanosis is intensified if heart failure supervenes and slows blood flow through the skin (i.e., is associated with decreased O_2 delivery).

Cyanosis Due to Venous Admixture

In patients with intracardiac right-to-left shunts, cyanosis arises from a mixture of venous and arterial blood. The effect of venous admixture is particularly striking if the O_2 content of mixed venous blood is inordinately low, as in some types of congenital heart disease and in severe heart failure. Often, secondary polycythemia contributes to the cyanosis. On occasion, regional cyanosis is diagnostic. For example, in patent ductus arteriosus with reversal of blood flow, the lower extremities are deeply cyanotic, whereas the upper extremities are virtually normal in color.

Cyanosis Due to Abnormal Pigments in Blood

Methemoglobinemia is an occasional cause of cyanosis. Methemoglobinemic blood is chocolate brown, and spectrophotometric examination of blood reveals the characteristic pigment. Arterial blood examination discloses a normal P_{O_2}.

The cause of methemoglobinemia may be hereditary (i.e., due to the presence of hemoglobin M or a deficiency in methemoglobin reductase) or, more often, acquired (e.g., by exposure to chemical agents such as aniline dyes, chlorates, nitrates, and nitrites); methemoglobinemia may also result from drugs, such as dapsone, nitroglycerin, phenacetin, or primaquine. Nitrates are a common cause of methemoglobinemia. Nitrates are reduced to nitrites by bacteria in the intestinal tract. Excessive use of nitroglycerin, an organic nitrate, leads to methemoglobinemia.

In methemoglobinemia, the ferrous iron is oxidized to ferric iron, rendering the hemoglobin molecule incapable of binding O_2 or CO_2. Methemoglobin is formed continuously in the normal erythrocyte, but its level within the cell is kept low (<2%) by intracellular reductive mechanisms. High levels of methemoglobin result from hereditary abnormalities (e.g., a deficiency in methemoglobin reductase) or from exposure to drugs or chemicals that increase the rate of oxidation beyond the reductive capacity of the erythrocytes. Clinical manifestations of methemoglobinemia vary with the blood levels. Concentrations of methemoglobin between 10% and 25% usually cause asymptomatic cyanosis. When these levels are exceeded, dizziness, fatigue, and headache appear.

CLUBBING

Clubbing of the digits is a classic finding in medicine that dates back to Hippocrates' awareness of the association between characteristic changes in the fingertips and empyema. Occasionally, it constitutes a valuable clue to clinically inapparent disease of the lungs and pleura.

Clubbing of the fingers designates the selective bulbous enlargement of the distal segments of the digits due to an increase in soft tissue (Fig. 27-18). Although most often it is painless, clubbing remains an important finding, as its presence should signal an evaluation for potential serious causes.

When full-blown, clubbing is easy to recognize: (1) the nails, particularly the index finger, become abnormally curved in the longitudinal and coronal planes; (2) the hyponychial angle, viewed in profile, becomes blunted, often in conjunction with softening and sponginess of the base of the nail; and (3) the undersurface of the

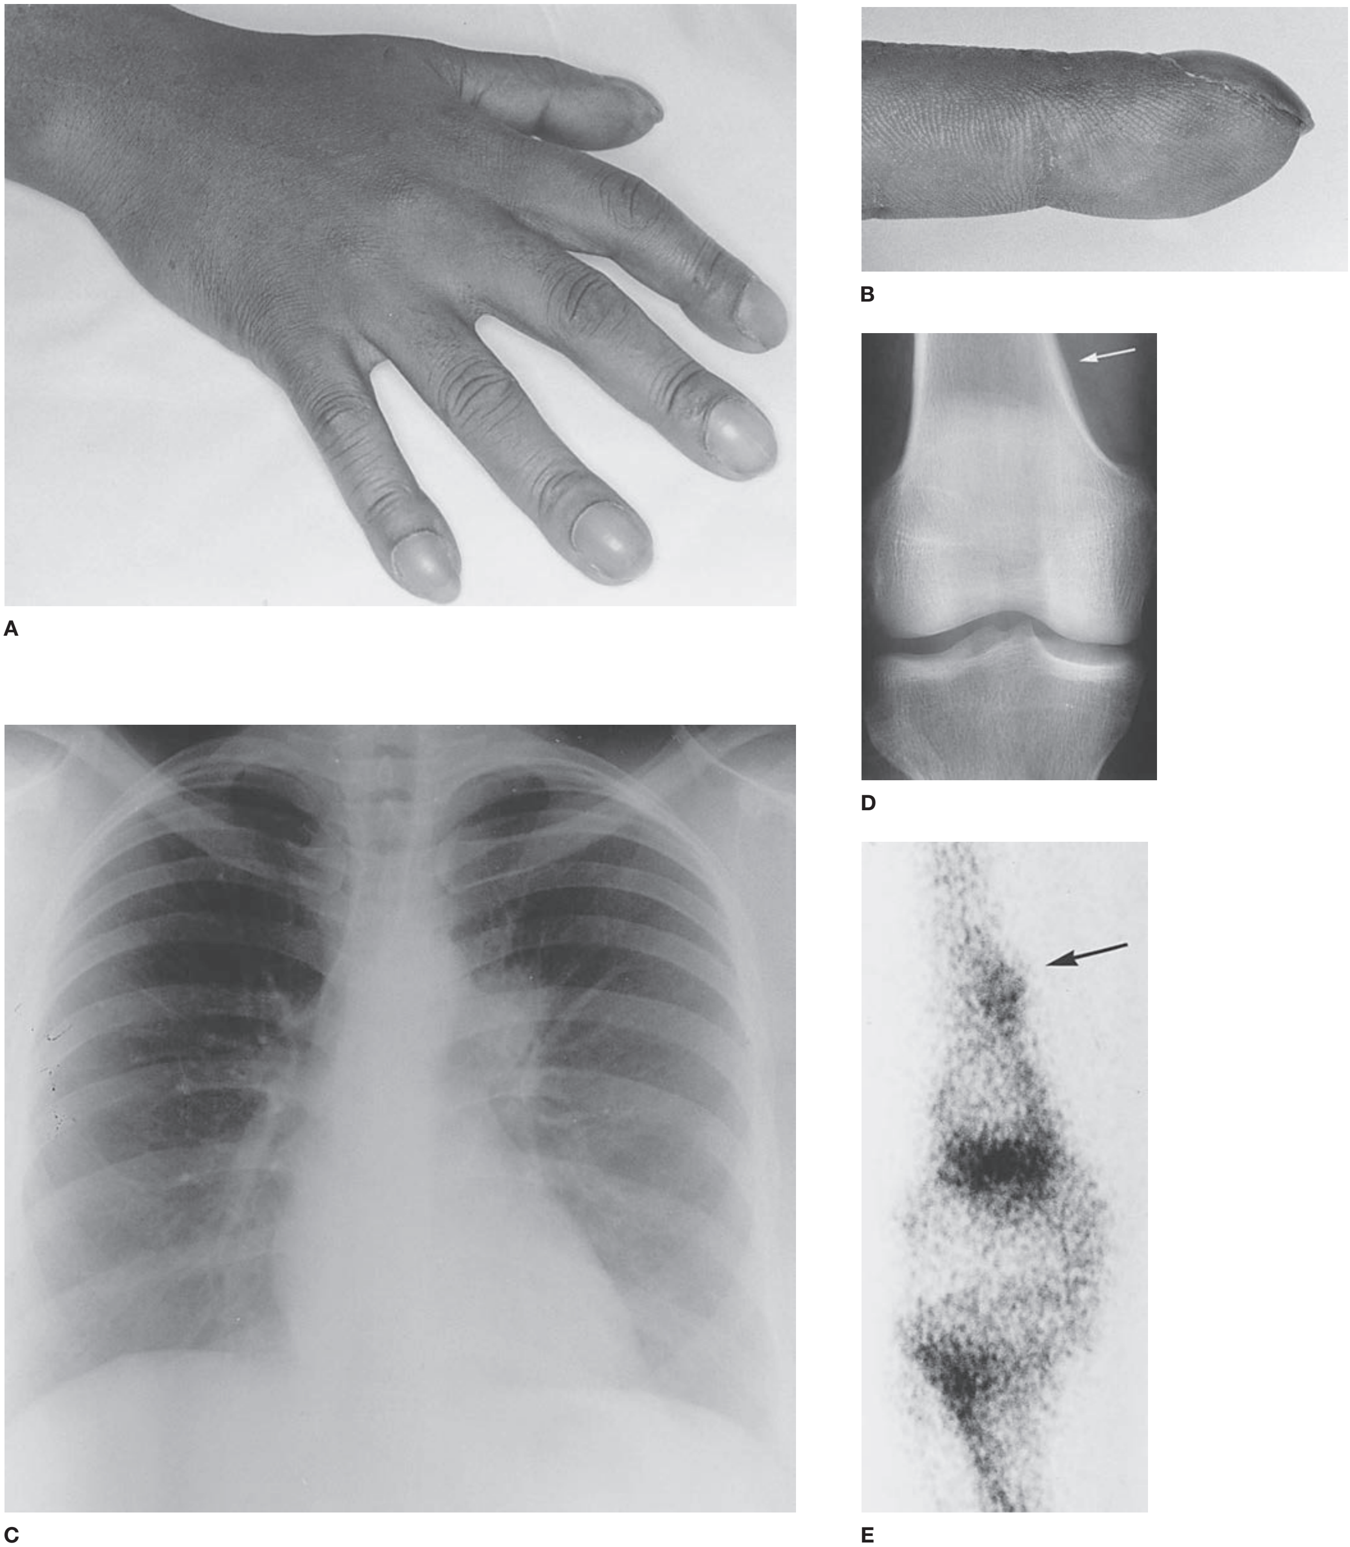

Figure 27-18 Clubbing of the digits and hypertrophic osteoarthropathy. A 40-year-old woman developed swelling and tingling of the fingertips in association with painful swelling of both knees. She was a heavy smoker (36 pack-years) and had an 8-month history of a dry cough. **A.** Clubbing of all fingers. **B.** Index finger. **C.** Left hilar mass that proved to be a primary adenocarcinoma of the lung. **D.** Subperiosteal formation of new bone on the medial aspect of the diaphysis of the femur. **E.** Bone scan, using ^{99m}Tc methylene diphosphonate. An abnormal accumulation of isotope is seen in the area of new bone *(arrow)*.

terminal digit becomes large and bulbous. Early stages of clubbing are subtle and generally difficult to diagnose. Clubbing often has to be distinguished from simple curvature of the nails and, occasionally, from chronic paronychia and Heberden nodes. A variety of methods have been proposed for quantifying clubbing (e.g., measuring casts of the fingertips), but none has become popular.

Clubbing is generally acquired, but it may be hereditary. Acquired clubbing is seen in a wide variety of disorders, both extrathoracic and thoracic (Table 27-1).

It is important to recognize that clubbing is not caused by all forms of chronic lung disease. COPD, for example, does not cause clubbing. The presence of clubbing in a patient with COPD should alert the clinician to the possibility of a second process, commonly lung cancer. As a rule, clubbing is bilaterally symmetrical, affecting hands and feet; on occasion, local factors, such as injury of a finger or of the median nerve, may cause clubbing that is confined to a single finger. Rarely, clubbing may be confined to the digits of one hand (e.g., in an ipsilateral pulmonary sulcus tumor that has invaded the brachial plexus or following hemiplegia). In certain types of congenital heart disease, a telltale distribution of clubbing is of considerable diagnostic value. For example, in patent ductus arteriosus associated with reversal of shunt through the ductus, clubbing affects only the toes.

■ Pathogenesis

The pathogenesis of clubbing is unknown, and no suitable animal model of clubbed fingers has yet been developed, largely because so few species other than primates have fingers. A common denominator in the pathogenesis of clubbing appears to be vasodilation of vessels in the fingertip, including formation of the arteriovenous connections. As a result, hydrostatic pressures increase in the capillaries and venules, promoting the transduction of fluid into the interstitium. The reason for this preferential vasodilation is unclear. A popular notion is that a humoral substance escapes normal deactivation by pulmonary capillaries. This theory could account for clubbing in cyanotic congenital heart disease, in various pulmonary diseases in which proliferation of the bronchial circulation occurs, and in hepatic cirrhosis in which pulmonary arteriovenous anastomoses and right-to-left shunts are common. However, it is difficult to relate this theory to the high incidence of clubbing in subacute bacterial endocarditis.

At present, a single hypothesis that would account for the clubbing that occurs in such diverse disorders as subacute bacterial endocarditis, carcinoma of the lung, hemiplegia, chronic mountain sickness, and purgative abuse is not possible. Indeed, it seems likely that clubbing of the digits is a stereotyped consequence of diverse influences that have in common the capacity to induce marked digital vasodilation and interstitial edema of the soft tissue.

HYPERTROPHIC OSTEOARTHROPATHY

Occasionally, clubbing of the digits is accompanied by hypertrophic osteoarthropathy (HOA), a separate clinical and radiographic entity. Clinically, HOA is manifested by pain and swelling of the soft tissues over the distal ends of the long and tubular bones. Radiographically, the distinctive feature of HOA is the formation of new bone beneath the periosteum of the distal diaphyses of the long bones of the extremities (Fig. 27-18).

The most common disorder associated with HOA is carcinoma of the lung. The incidence is about 5% and is unrelated to the cell type of the cancer, except that small-cell carcinoma is rarely implicated; a peripheral carcinoma of the lung is slightly more common than a central one. Joint symptoms precede the local signs of tumor in about one-third of the cases; the interval is sometimes as long as 2 years. Pulmonary metastases rarely cause HOA. Pulmonary tuberculosis is seldom, if ever, associated with HOA. CF and idiopathic pulmonary fibrosis may be accompanied by HOA. Pregnancy may rarely be a cause of HOA, with symptoms resolving promptly with delivery.

As in the case of clubbing of the digits, theories about pathogenesis tend to focus on humoral factors generated elsewhere. However, a neurogenic theory has also been advanced on the basis of two types of observations: (1) in a few patients, vagotomy has relieved the symptoms of inoperable carcinoma of the lung and led to regression of the bony lesions; and (2) in keeping with the observations on the few patients, vagotomy in dogs is usually followed by a decrease in blood flow to the limbs.

In contrast to clubbing of the digits, which is rarely painful, HOA associated with carcinoma of the lung often causes severe rheumatic symptoms. These symptoms vanish after resection of the carcinoma, even though clubbing usually remains. In patients who are treated with radiotherapy for unresectable carcinoma, pain in the vicinity of the joints usually decreases greatly and usually does not recur even if metastases develop in the lungs or elsewhere.

CHEST PAIN

Pain in the chest is a common clinical problem. It may arise from within the thorax (the heart, pericardium, lungs, pleura, chest wall) or be referred from elsewhere (e.g., from below the diaphragm). Characteristic patterns and associations may help to clarify the source of the pain.

First thoughts about chest pain almost invariably turn to the pain of myocardial ischemia. However, cardiac pain is often distinguishable from other types of chest pain because of its viselike nature; its characteristic radiation to the left arm, shoulder, or neck; and its lack of relation to breathing. Extracardiac painful sensations can arise from various sites within the thorax, most often from the pleura, the lungs, or the chest wall. Pain may also be referred to the thorax as a result of GERD.[48–50] In the primary care setting, in stable patients it is usually possible to exclude as the basis for pain cardiac, gastrointestinal, or pulmonary diseases.[51,52]

■ Pleuritic Pain

The most characteristic pain associated with the respiratory apparatus is pleural pain. It originates in the parietal pleura and endothoracic fascia; the visceral pleura is insensitive to pain. In contrast to the deep, oppressive substernal pain of myocardial infarction, pleuritic pain is identified by the patient as being close to the thoracic cage. It is predominantly an inspiratory pain, reflecting the stretching of inflamed parietal pleura during movement of the thorax; coughing or laughing is distressing; the patient often clutches the chest to minimize its excursion. The pain is usually local, but sometimes it spreads along the course of the intercostal nerves that supply the affected area. Irritation of the diaphragmatic pleura by an inflammatory process either below or above the diaphragm often causes ipsilateral shoulder pain when the central portion of the diaphragm is involved; sometimes the pain is referred to the abdomen when the outer diaphragmatic pleura is irritated.

As a rule, pleural pain is part of a syndrome of pleural inflammation that includes malaise and fever; an important exception to this generalization is the pleural pain of pulmonary infarction, which is often unassociated with any premonitory signs. In addition to inflammation and malignant etiologies, pleuritic pain occurs with pneumothorax.

■ Pulmonary Pain

A second distinctive type of respiratory chest pain accompanies a tracheitis or tracheobronchitis. The pain is searing and is most pronounced after cough. Invariably, this central chest pain is associated with evidence of upper respiratory infection. It is aggravated by cough. Cold air may be intolerable.

An uncommon type of chest pain is associated with pulmonary hypertension. It is usually absent at rest and appears during exertion. The pain is substernal and is associated with dyspnea; it subsides

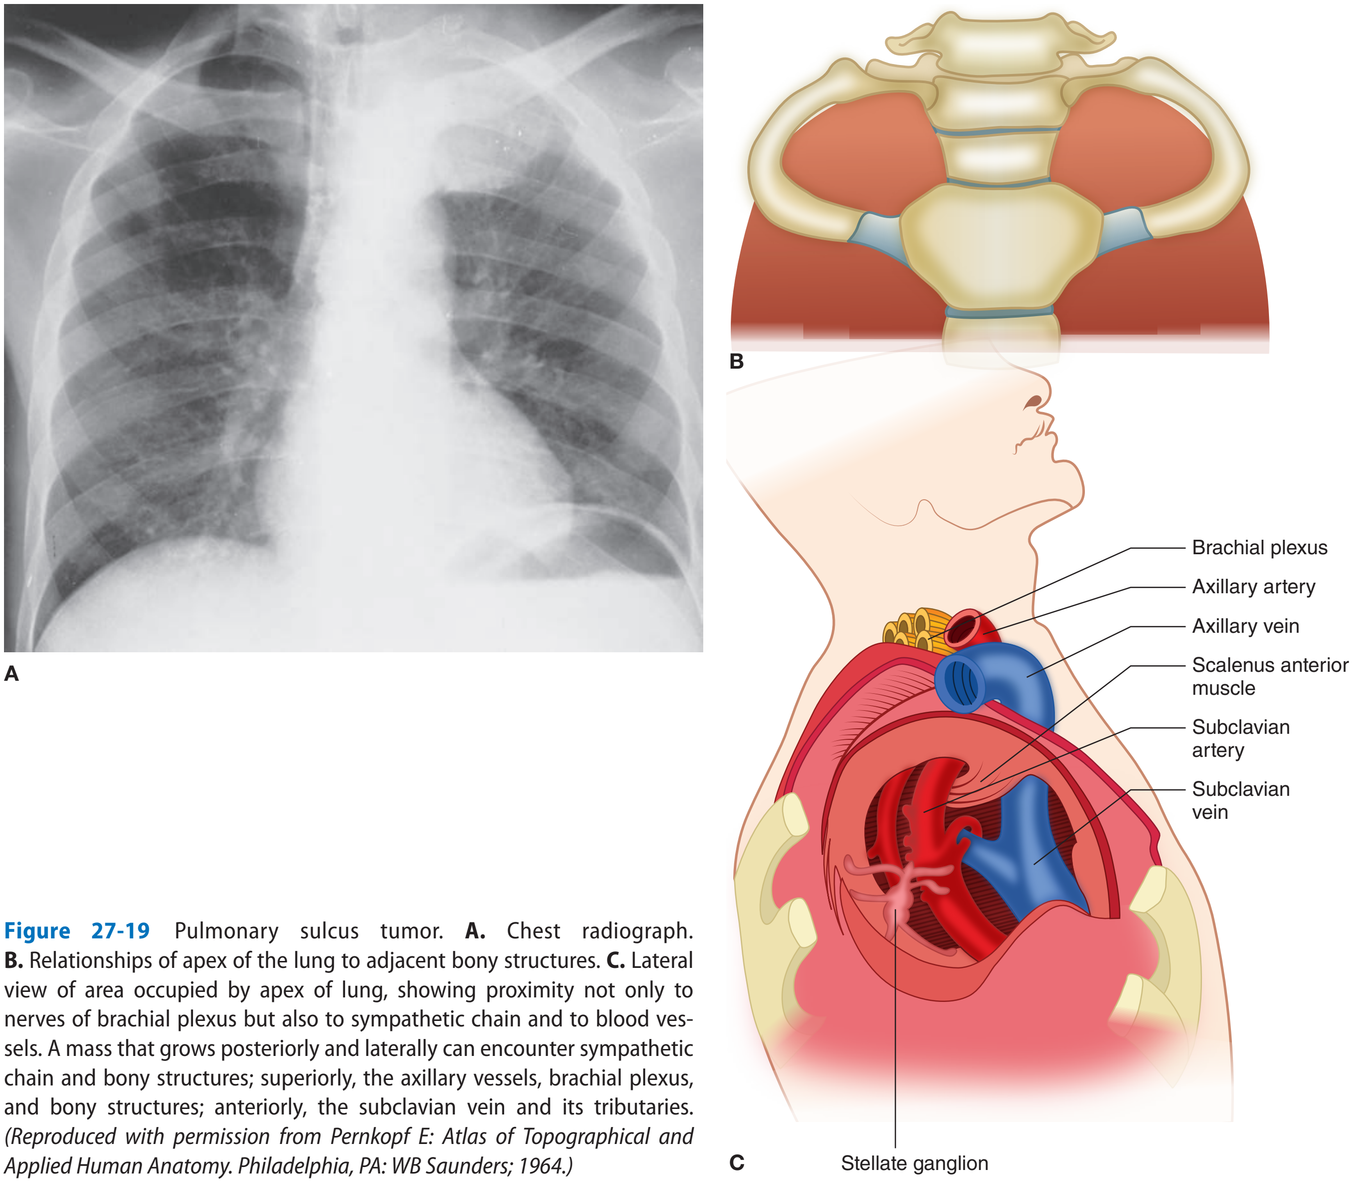

Figure 27-19 Pulmonary sulcus tumor. **A.** Chest radiograph. **B.** Relationships of apex of the lung to adjacent bony structures. **C.** Lateral view of area occupied by apex of lung, showing proximity not only to nerves of brachial plexus but also to sympathetic chain and to blood vessels. A mass that grows posteriorly and laterally can encounter sympathetic chain and bony structures; superiorly, the axillary vessels, brachial plexus, and bony structures; anteriorly, the subclavian vein and its tributaries. *(Reproduced with permission from Pernkopf E: Atlas of Topographical and Applied Human Anatomy. Philadelphia, PA: WB Saunders; 1964.)*

promptly when exercise stops. It is often mistaken for classic angina until the presence of pulmonary hypertension is uncovered. It may be due to right ventricular strain and ischemia.

■ Chest-Wall Pain

Musculoskeletal pain arising in the chest that is also aggravated by breathing may be confused with pleuritic pain. It is rarely severe and incapacitating, is often bilateral, and generally is intensified by changes in body position or flexing the thorax. The affected muscles are often tender to gentle pressure. A fractured rib is often identified as the source of pain by a history of a fall, injury, or trauma. Additional clues are point tenderness and crepitus of the affected area, reproduction of the pain upon manual compression of the chest, or radiographic evidence of a broken rib.

The pain of a pulmonary sulcus tumor, or "Pancoast tumor," (Fig. 27-19) is quite distinctive. This unusual location of a carcinoma of the lung was originally described by Pancoast in 1932. Pain due to the tumor occurs along the distribution of the eighth cervical and first and second thoracic nerves. In addition, Horner syndrome, local destruction of bone by the tumor, and atrophy of hand muscles may be observed. The chest radiograph is distinctive in showing a small, sharply defined shadow at one apex. Destruction of one or more of the upper three ribs posteriorly and of their adjacent transverse processes may also be seen.

■ Cardiac Pain

Attention was called above to the pain of myocardial ischemia. Another type of cardiac pain is that of pericarditis. Pericardial pain is often aggravated by deep breathing and, almost invariably, is accompanied by a telltale rub that is synchronous with the heartbeat. The discomfort may be relieved by leaning forward.

The *postcommissurotomy* or *postpericardiotomy syndrome* is characterized by chest pain that develops within a few days to weeks after cardiac surgery or pericardiotomy. The pain is usually sudden in onset and substernal, with radiation to the left side of the neck; often it is aggravated by deep breathing. Low-grade fever and a high erythrocyte sedimentation rate are regular concomitants.

Chest pain may also be troublesome in patients who have undergone cardiac transplantation. The diagnosis is usually self-evident when account is taken of the antecedent history of cardiac surgery. Indeed, confusion is more apt to arise with the pain of myocardial infarction than with respiratory causes of chest pain.

Miscellaneous Causes of Pain

Other structures in the mediastinum may be the source of chest pain. Noteworthy are the types of pain arising from the esophagus (peptic esophagitis) and dissection of the aorta. Their patterns and intensity help to distinguish them from respiratory pain. Esophageal disease is typically accompanied by a burning pain, frequently after eating. Acid reflux may worsen with recumbency. Aortic dissection is often described with a sharp, tearing sensation of acute onset, with radiation to the shoulder; these are often signs of impending cardiovascular collapse.

Arthritis of the cervical spine is a common cause of thoracic pain. Usually the cause is quite clear because of the characteristic distribution of the pain. Cervical spondylosis occasionally causes severe pain in the chest and arms, but it is more apt to mimic myocardial infarction than is respiratory pain. A metastatic tumor to the thoracic spine often causes bilateral symmetric pain; there is often discomfort to palpation over the affected area. Unilateral pain, along the distribution of an intercostal nerve, is characteristic of herpes zoster before the appearance of the skin eruption and is often described as an intense burning sensation.

Anxiety may produce or intensify chest pain. Usually, pain related to anxiety is accompanied by dyspnea and hyperventilation. Manifestations of vasomotor instability, such as excessive palmar sweating, flushing, and tachycardia, may accompany the complaint of chest pain due to anxiety. Rarely does the pain conform to a characteristic or consistent pattern. Anxiety also interferes with the quantification of pain originating in a somatic lesion and with its management.

FEVER

In the patient with lung disease, fever usually, but not invariably, signifies infection. When the lung disease is chronic, as in bronchitis and emphysema, a bout of acute bronchitis usually elicits only a modest fever, even though the sputum turns purulent. In contrast, an acute pneumonia or lung abscess may be associated with high fever.

The possibility that fever is due to infection lends urgency to the situation. The wide range of pulmonary infections is considered elsewhere in this book.

Neoplasms are also associated with fever. In certain neoplasms, such as carcinoma within a bronchus, the fever is generally a secondary effect attributable to infection distal to obstruction; necrosis within the tumor is a less common cause. In others, such as hypernephroma, fever and chills are striking, even though evidence of infection is absent. A mesothelioma of the pleura is often associated with fever. Presumably, in patients with neoplasms who have no evidence of infection, necrosis within the tumor leads to the elaboration of fever-producing factors within and around the tumor.

Acute hypersensitivity pneumonitis (extrinsic allergic alveolitis) is sometimes accompanied by fever.

In contrast to the pulmonary disorders in which fever is a characteristic feature, pulmonary sarcoidosis is uncommonly associated with fever unless there is extrapulmonary involvement, such as lymphadenopathy or erythema nodosum. Pneumoconiosis is usually not associated with fever unless complicated by necrosis in the midst of conglomerate fibrosis or by superimposed tuberculosis. Among the other many disorders of the lungs that cause no fever (and few systemic complaints) are idiopathic pulmonary fibrosis, lymphangitic carcinomatosis, multiple pulmonary metastases, alveolar proteinosis, idiopathic pulmonary hemosiderosis, and alveolar microlithiasis.

PULMONARY-CUTANEOUS SYNDROMES

Examination of the skin may provide important clues in the diagnosis and treatment of patients with pulmonary disease. Some skin lesions either accompany pulmonary disease or complicate its treatment; occasionally, systemic diseases that affect both skin and lung present first with cutaneous manifestations.

This section focuses on processes in which there are prominent cutaneous manifestations that might impact the care of the patient with pulmonary disease. The diagnosis and development of a differential diagnosis of cutaneous lesions is beyond the scope of this chapter and can be found in general dermatology textbooks.[53–55]

Atopic Dermatitis

Atopy refers to a group of disorders, including asthma, allergic rhinitis, and atopic dermatitis, in which immune and pharmacologic responses are abnormal. The atopic person usually has a family history of one or more of these disorders. Atopic dermatitis is a common disorder, affecting 1% to 3% of the population in the United States. In 85% of affected subjects, the skin lesions appear before 5 years of age.[56] The dermatitis may resolve as the patient reaches adulthood; in the adult, either the skin lesions or respiratory systems may predominate although there is a wide range of individual variability.

In infants, the skin lesions often begin as dry, erythematous plaques on the cheeks; excoriations and scaling may be prominent. In older children, the lesions localize in flexures; lichenification and excoriated papules are prominent features (Fig. 27-20). In adults, the lesions favor the hands and extremities. Atopic subjects also manifest prominent folds of the lower eyelids, periorbital hyperpigmentation with facial pallor, generalized dry skin, and white dermatographism. At any age, pruritus may be prominent, leading to secondary bacterial infection (bacterial impetigo) within the lesions.

The cause of atopic dermatitis is unknown. In all likelihood, the pathogenesis is multifactorial, probably including disordered immune regulation as a causative factor. Patients with atopic dermatitis often have elevated levels of IgE; may have abnormalities of CD30, macrophage-derived chemoattractant, interleukins (IL)-12, -16, -18, and -31, and thymus and activation-regulated chemokine; and have mutations of the filaggrin gene. The use of any of these biomarkers has not yet been demonstrated to be diagnostic or of prognostic value.[56] In persons with atopic dermatitis, abnormalities in cell-mediated immunity and lymphocyte function increase the risk of disseminated viral disease, particularly herpes simplex. The role of food or environmental antigenic challenge in flares of atopic dermatitis is unsettled, but it is known that asthma can be precipitated by such challenges.

The relationship between atopic dermatitis and lung disease is imperfect. Although hyposensitization is useful for asthma, it is either not helpful or is detrimental in atopic dermatitis. In addition, the use of omalizumab, while beneficial for asthma, has

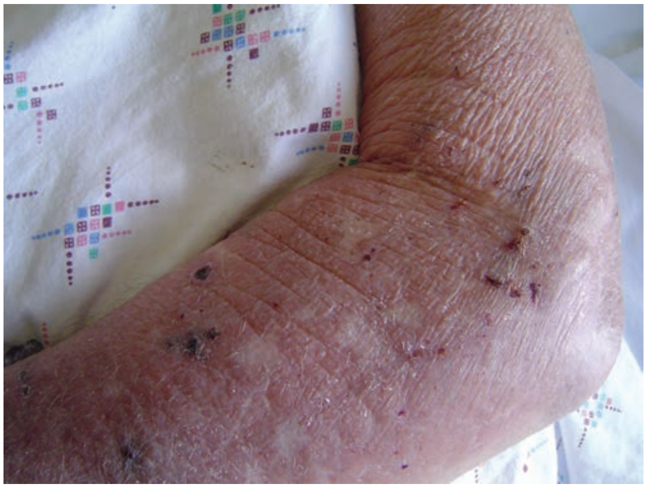

Figure 27-20 Atopic dermatitis is characterized by lichenification, excoriations, and slight scale.

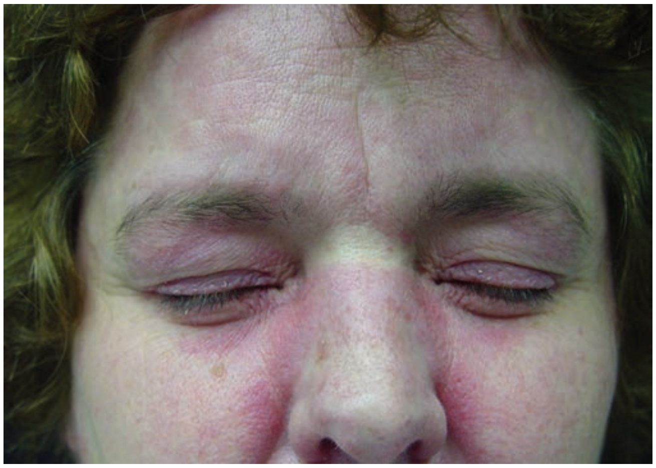

Figure 27-21 Heliotrope eruption of dermatomyositis.

demonstrated mixed results for patients with atopic dermatitis. Recent evidence suggests that the use of dupilumab, an IL-4, IL-13 antagonist, might be useful for atopic dermatitis, as well as for the associated asthma.[57] In addition, there is active clinical investigation using JAK inhibitors and other biologic agents for atopic dermatitis (ClinicalTrials.gov accessed December 29, 2021).

Collagen Vascular Disorders

Common collagen vascular disorders warrant discussion in relation to possible coexisting pulmonary manifestations, especially dermatomyositis (DM) and scleroderma.

Dermatomyositis (DM)

DM is one of the idiopathic inflammatory myopathies. DM characterized by proximal, symmetrical, progressive muscle weakness, and characteristic cutaneous lesions.[58,59] The pathognomonic skin lesions include a heliotrope eruption, which consists of erythematous to violaceous periorbital changes that may be accompanied by edema (Fig. 27-21), and Gottron papules, which consist of erythematous papules over the bony prominences on the dorsal hands (Fig. 27-22). Patients may also manifest a photodistributed poikiloderma (Fig. 27-23), nail-fold changes, and an erythematous to violaceous scaly alopecia. Patients with DM frequently complain of marked itching.

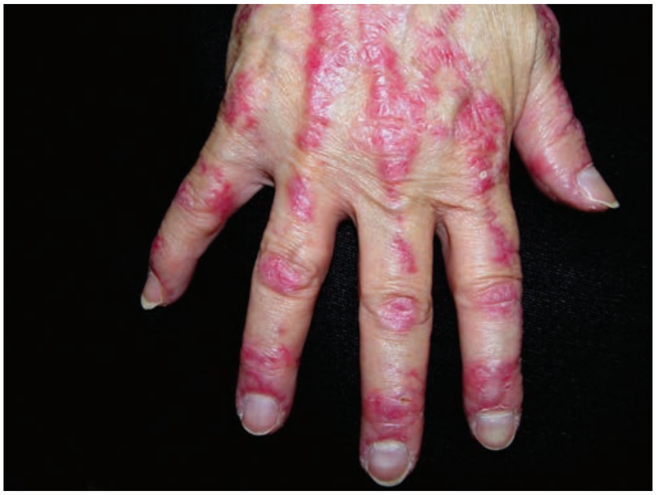

Figure 27-22 Gottron papules in dermatomyositis: Erythematous to violaceous lesions are most prominent over the joints. In addition, this patient demonstrates cuticular and periungual changes that are frequent in dermatomyositis.

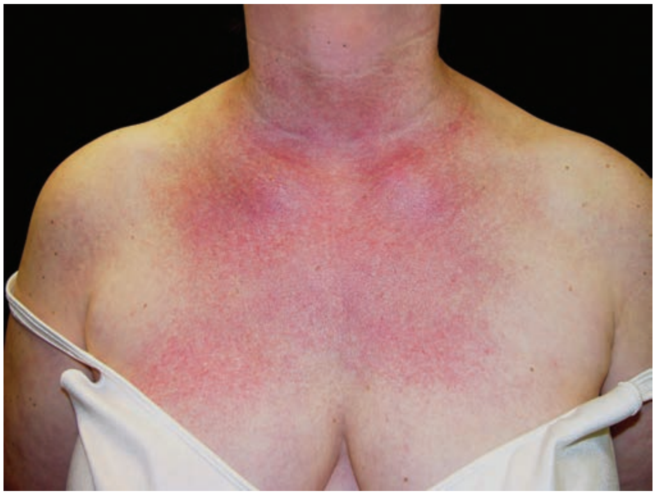

Figure 27-23 Photodistributed poikiloderma in a patient with dermatomyositis.

Patients with DM may also have other systemic manifestations, including arthritis, esophageal disease, and cardiopulmonary disease; some have a malignancy. A variant of DM is known as clinically amyopathic dermatomyositis (CADM). CADM is manifest by skin lesions in the absence of muscle weakness; muscle-derived enzymes are not elevated.

Pulmonary disease occurs in classic DM and in CADM in approximately 15% to 65% of patients. Interstitial pneumonitis is a primary process in DM/polymyositis.

Pulmonary involvement is more frequent in patients with esophageal dysfunction. Lung disease may also occur as a direct complication of the muscle disease, for example, hypoventilation or aspiration in patients with dysphagia, or may be a result of treatment, such as opportunistic infections or drug-induced hypersensitivity pneumonitis.

Pulmonary disease appears to be more prominent in patients in southeast Asia, China, and Japan; however, there are many reports of patients in the United States with varying ethnicities who have developed pulmonary disease, particularly interstitial fibrosis, as well as rapidly progressive and, at times, fatal disease.[60] Patients with polymyositis and lung disease tend to have antisynthetase antibodies, particularly the Jo-1 antibody. However, Jo-1 is rarely found in patients with dermatomyositis. In addition, some of the patients with CADM, specifically those with the myositis-specific antibody, melanoma differentiating antibody 5 (MDA5), are associated with an elevated risk of interstitial lung disease. Further, many of the MDA5+ CADM patients with lung disease have a rapidly progressive course and a high mortality rate. These patients are best treated aggressively, beginning with pulsed intravenous corticosteroids and with intravenous cyclophosphamide and either a calcineurin inhibitor or mycophenolate mofetil. Those who respond may be transitioned to corticosteroids with a traditional immunosuppressive, such as mycophenolate mofetil or azathioprine. Those without a good response might be treated with rituximab and, eventually, lung transplantation.[61]

Scleroderma

Scleroderma refers to hard skin. This process may be localized to the skin or may be part of a systemic disease.[62,63] Localized cutaneous scleroderma may occur as limited plaques of morphea, generalized morphea, deep morphea, or linear scleroderma. Interstitial pneumonitis is an extremely rare complication of morphea or linear scleroderma.

Two principal forms of progressive systemic sclerosis (PSS) have been described: limited scleroderma (acrosclerosis) and diffuse

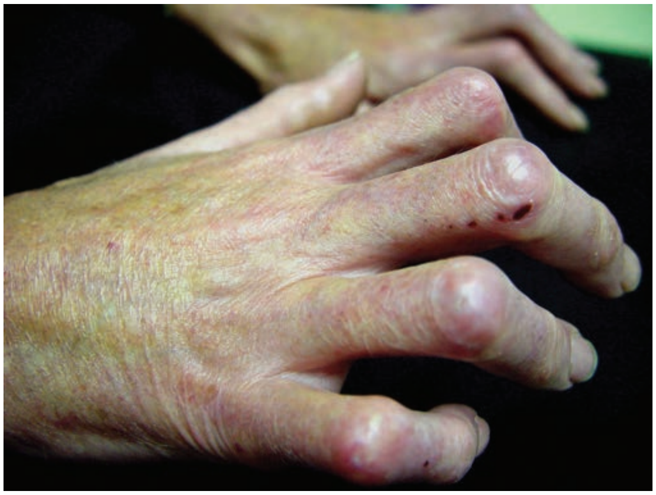

Figure 27-24 Acrosclerosis characterized by marked contractures and sclerodactyly.

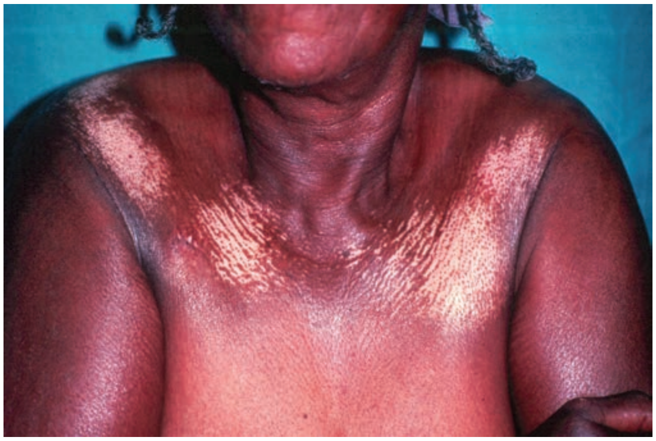

Figure 27-26 Vitiligo-like dyspigmentation associated with progressive systemic sclerosis.

scleroderma. Acrosclerosis is the more common of the two and is characterized by sclerosis of the skin of the fingers (sclerodactyly) (Fig. 27-24) and Raynaud's phenomenon (Fig. 27-25). A variant (CREST syndrome) includes calcinosis, Raynaud's syndrome, esophageal dysmotility, sclerodactyly, and telangiectasia.

In contrast, patients with diffuse scleroderma have widespread sclerosis beyond the acral areas of sclerodactyly. The prognosis for patients with diffuse scleroderma is poorer than those with acrosclerosis. Both types of scleroderma are often preceded by Raynaud's phenomenon, diffuse arthralgias, or arthritis. The skin manifestations begin with transient, recurrent swelling of the hands, and progress to tapered fingers with shiny, hidebound skin (sclerodactyly). The feet, chest, face, and scalp are often involved in the sclerotic process. In time, the skin becomes taut, leading to contractures of the large and small joints that culminate in a claw-like deformity of the hand.

A variety of pigmentary disturbances may occur in scleroderma, including generalized hyperpigmentation that resembles adrenal insufficiency, focal hyperpigmentation or hypopigmentation, and areas of perifollicular pigmentation that resemble vitiligo (Fig. 27-26). Raynaud's phenomenon leads to small pitted scars at the fingertips or frank ulceration, with or without gangrene of the fingertips, toes, knuckles, and ankles, especially the malleoli.

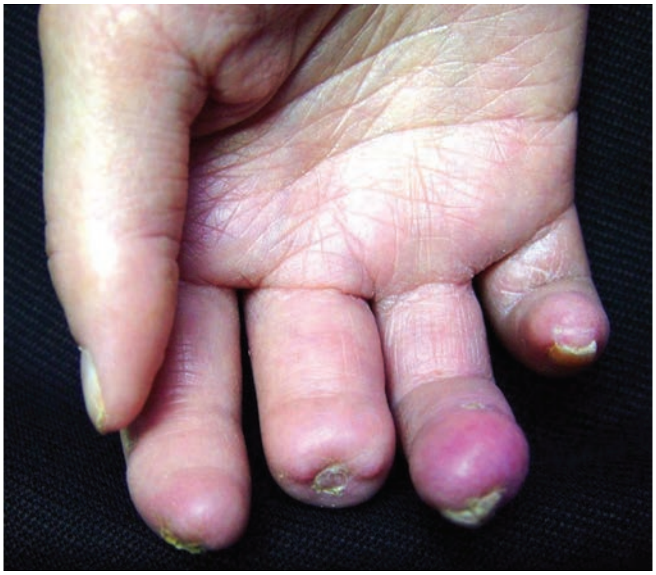

Figure 27-25 Raynaud's phenomenon in this patient was so severe that autoamputation of the distal digits occurred.

The face often undergoes distinctive changes, leading to a fixed stare and inability to wrinkle the forehead. As the facial tissues shrink, the nose becomes pinched, the cheeks sunken, the mouth narrowed, and the lips thinned. In diffuse scleroderma, cutaneous sclerosis, accompanied by a yellowish-brown hue, spreads from the chest to the head and extremities. Sharply delineated, broad telangiectatic macules appear on the face, buccal mucosa, lips, and hands.

PSS is associated with interstitial pneumonitis. This is more common in patients with diffuse disease than in patients with limited disease. Pulmonary hypertension has been reported to occur in patients with CREST syndrome (see Chapter 72).

Treatment of ILD associated with scleroderma is potentially difficult and includes the use of immunosuppressive medications, as well as antifibrotic agents, including nintedanib. Management recommendations are an evolving process, and combinations of therapies might prove effective in the near future.

■ Infections

A variety of infections involving the lungs may have cutaneous involvement.[64] Prototypical examples are described below.

Blastomycosis

Skin lesions are as common as pulmonary lesions in patients with blastomycosis. Cutaneous disease usually represents dissemination from a pulmonary focus that is often small and may be inapparent. The typical presentation is as a solitary nodule or multiple papules or nodules on the face, wrists, hands, or feet, which subsequently ulcerate and discharge pus (Fig. 27-27). The lesions grow eccentrically at the periphery and atrophy centrally over a period of months, eventually forming an arciform or serpiginous contour with sharply elevated and verrucous borders. Miliary abscesses occur along the borders of the lesions. In addition to the cutaneous involvement, osteolytic lesions may occur.

Coccidioidomycosis

Coccidioidomycosis is usually manifest as a pulmonary infection. In its acute form, it is often associated with cutaneous symptoms; roughly 20% of patients develop erythema nodosum (EN). EN is often accompanied by fever, arthritis, and eosinophilia. In patients with progressive pulmonary disease and eventual disseminated disease, the skin may be affected; subcutaneous granulomatous eruptions

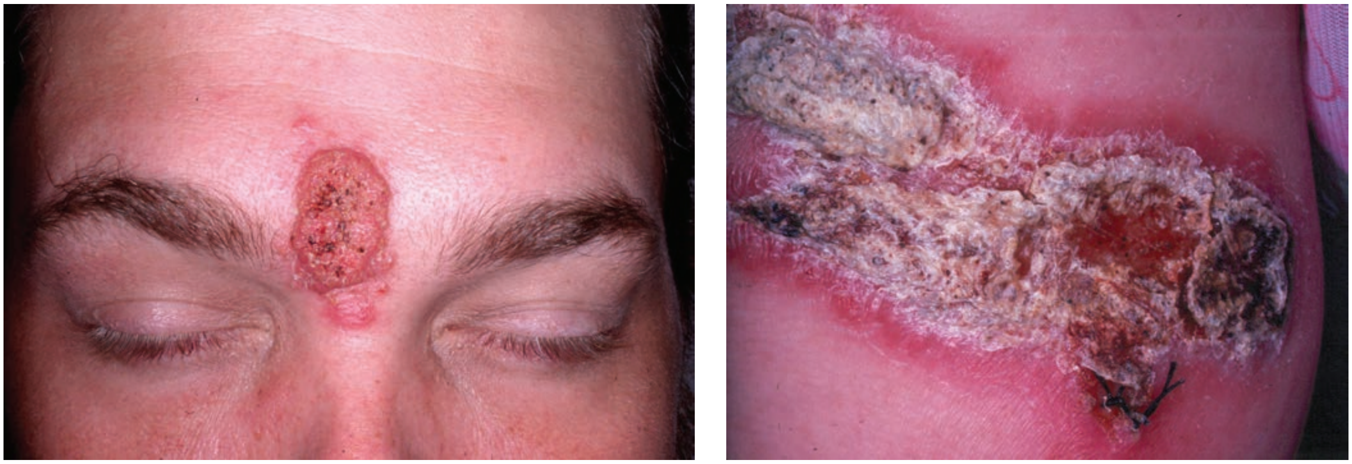

Figure 27-27 **A, B.** Blastomycosis: verrucous lesions on the face (**A**) and trunk (**B**).

form and undergo necrosis and ulceration. After several months, the lesions tend to become verrucous. A third form is primary cutaneous disease, which occurs in farmers and laboratory workers as a chancriform lesion with sporotrichotic spread. This variant is extremely rare.

Actinomycosis

The thoracic form of this disease presents as a pulmonary parenchymal process that sometimes forms multiple draining sinus tracts.[65] Diagnosis is often difficult, but identification of sulfur granules in the draining exudates is helpful.

Tuberculosis

Cutaneous involvement results from direct inoculation with the tubercle bacillus via either the skin or mucus membranes, or as a consequence of widespread organ involvement that begins in the respiratory tract.

When the tubercle is introduced via the skin or mucus membranes by a contaminated syringe or a wound in a previously unexposed host, a nodule usually develops at the site of injury. Within several weeks, the nodule evolves into a chancre, a well-circumscribed ulcer. Particularly if host defenses are impaired, these chancriform lesions, which are typically located on the extremities, develop associated regional lymphadenitis, followed by systemic dissemination of the organism.

A person who was previously infected with *Mycobacterium tuberculosis* is apt to develop *tuberculosis verrucosa cutis* after receiving a cutaneous inoculation. The characteristic lesion in a sensitized person is a papule or a pustule, which becomes verrucous. On occasion, this disorder produces plaque-like lesions of the extremities, consisting of verrucoid-indurated papules surrounded by an erythematous halo.

Lupus vulgaris is the most common form of cutaneous postprimary tuberculosis that follows inoculation or lymphatic or hematogenous spread of *M. tuberculosis.*[66] Patients with this disorder typically present with reddish-brown plaques surrounded peripherally by yellowish nodules, especially on the neck or extremities. The skin lesions tend to spread centrifugally as the center becomes atrophic. Papillary growths also occur in the nasal, buccal, and conjunctival mucosa. Histologically, lupus vulgaris generally shows epithelioid tubercles with caseation necrosis. Chronic cutaneous eruptions tend to involute, leaving considerable scarring. Treatment with antituberculosis drugs is effective in treating these skin manifestations.

Disseminated miliary tuberculosis may result in macules, papules, or vesicles. In children, especially those who are debilitated, subcutaneous nodules or gummas appear, ulcerate, and eventually develop draining sinus tracts, especially in the extremities and trunk. *Scrofuloderma,* which occurs following the necrosis of cervical nodules, is associated with fistula and sinus tract formation in the overlying cutaneous tissues.

Tuberculids are skin lesions that are considered to represent either a hypersensitivity reaction to *M. tuberculosis* or an embolic response to atypical *Mycobacteria.* EN also occurs in association with primary tuberculosis.

HIV Infection

Early in the epidemic of HIV infection, the incidence of Kaposi's sarcoma (KS) increased. However, since the advent of HAART therapy, KS has become less common.[67,68] KS can occur in any immune-suppressed individual, whether the immune dysfunction is due to HIV infection, age, or iatrogenic immunosuppression in transplant recipients.

Human herpesvirus 8 (HHV-8) has been identified and linked to all forms of KS. In addition, HHV-8 viremia is associated with progression on KS in both classic and endemic forms. In the elderly population, KS has an indolent course and occurs primarily on the lower extremities. At the outset, the lesions are dark-blue, purplish, or reddish papules, macules, and nodules (Fig. 27-28). After months to years, plaques evolve in association with thickening of the skin from mid-tibia to ankle and lymphedema. In patients with immune dysfunction, including AIDS, KS is more aggressive and is often widespread in its cutaneous manifestations.

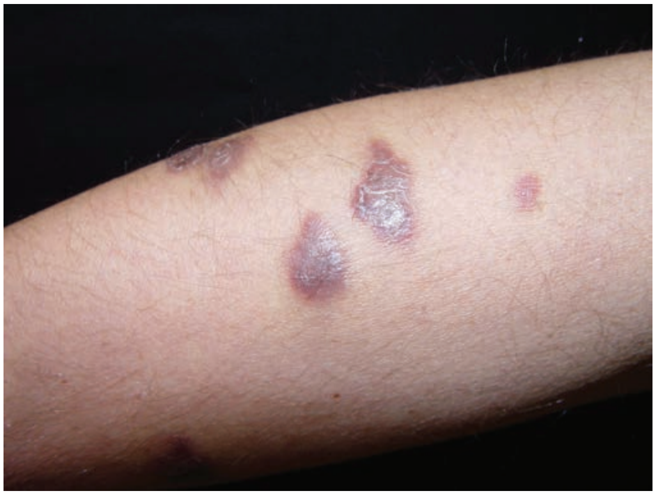

Figure 27-28 Kaposi's sarcoma in an HIV-positive patient.

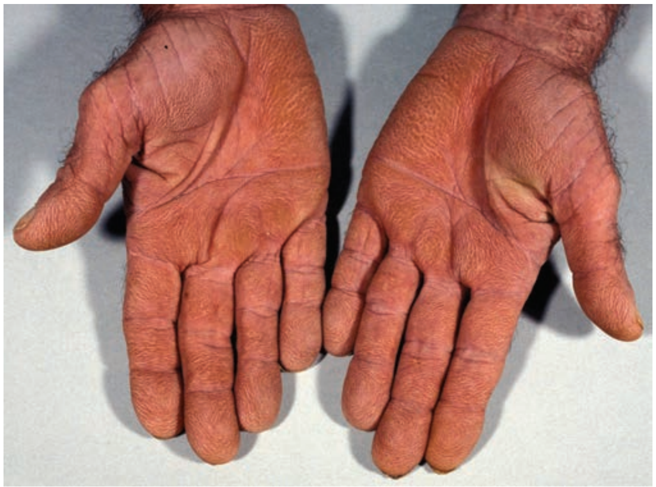

Figure 27-29 Tripe palms. *(Reproduced with permission from Dr. Jon Dyer.)*

The respiratory tract is second only to the gastrointestinal tract in frequency of systemic involvement. Tumors may involve the larynx, trachea, bronchi, pulmonary parenchyma, and pleura. Accordingly, local manifestations of respiratory tract involvement range from hoarseness, signs of airway obstruction, cough, and hemoptysis, to dyspnea. When the parenchyma of the lung is affected, chest radiographs usually show many small nodules; occasionally, parenchymal infiltration of the lung is massive. On bronchoscopic examination, bronchial and tracheal lesions appear as small bluish nodules. Bloody pleural effusions are rare.

■ Lung Cancer

Several paraneoplastic syndromes may occur in patients with lung cancer.[69] In most instances the dermatosis is not specific for lung cancer; other sites may be involved. The following are some of the more ominous manifestations of potential pulmonary malignancy.

Tripe palms is a paraneoplastic condition that is manifest as rugose thickening of the palms and, occasionally, the soles (Fig. 27-29).[70] Patients often have coexistent acanthosis nigricans (AN). Patients with tripe palms and AN usually have adenocarcinomas of the gastrointestinal tract; however, when tripe palms occur in the absence of AN, patients often have squamous cell carcinoma of the lung.

Patients with *Bazex syndrome (acrokeratosis paraneoplastica)* develop an erythematous to violaceous psoriasiform eruption primarily on acral surfaces[71] (Fig. 27-30). The ears, nose, cheeks, hands, feet, and knees are most often affected, but the nails may become dystrophic, and the palms and soles may develop a keratoderma in later stages of the disease. The disorder may develop in stages and is associated primarily with carcinomas of the upper respiratory and digestive tracts (larynx, pharynx, trachea, bronchus, and/or upper esophagus); the malignancy is often detected concurrently. If the tumor is effectively treated the eruption may resolve, but it may return with tumor recurrence.

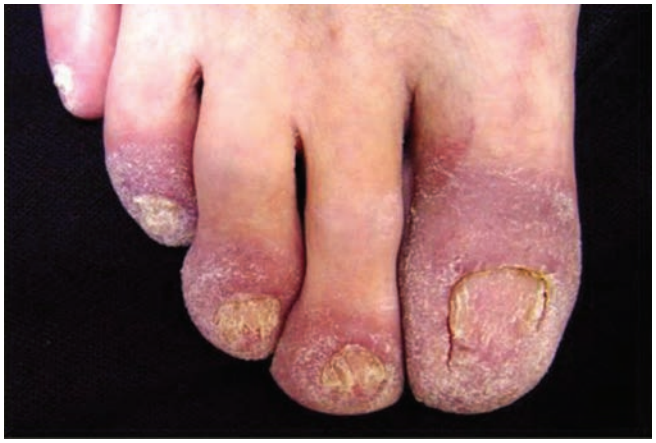

Figure 27-30 Acrokeratosis paraneoplastica (Bazex syndrome). This patient was thought to have psoriasis prior to the diagnosis of a squamous cell carcinoma of the tonsillar pillar.

Ectopic ACTH-producing tumors cause many of the typical signs and symptoms of Cushing syndrome. Intense hyperpigmentation, present in only 6% to 10% of patients with Cushing disease, is especially common in association with ectopic ACTH production and should alert the clinician to the possibility of a hormone-secreting tumor. Although the cause of the hyperpigmentation is unclear, it may be related to tumor production of the peptide β-lipotropin, which contains within its sequence of 91 amino acids the 22-amino-acid sequence of β-MSH. A myasthenia gravis–like syndrome, including profound proximal muscle weakness, may be a striking clinical feature and may reflect either underlying hypokalemia or polymyositis. Small-cell carcinoma of the lung is the tumor most often associated with ectopic ACTH production, although other malignancies have been reported.

The *carcinoid syndrome* is another example of a hormonal syndrome associated with a nonendocrine tumor. The disorder is probably most often caused by the release of the enzyme kallikrein from tumor cells, with subsequent conversion of kininogen to vasoactive kinin peptides, including bradykinin; in addition, increased blood levels of histamine may be important in the rare metastatic gastric carcinoid. The most striking cutaneous manifestations are episodes of flushing, initially lasting 10 to 30 minutes and involving only the upper half of the body; as the flush resolves, gyrate and serpiginous patterns may be noted. With successive attacks more extensive areas may be affected and the redness takes on a cyanotic quality, eventually leading to a more permanent facial cyanotic flush with associated telangiectasia, resembling rosacea. Persistent edema and erythema of the face may result in leonine facies. A pellagra-like picture, which has been noted in some patients, may be due to abnormal tryptophan metabolism. Systemic symptoms associated with the cutaneous flushing include abdominal pain with explosive watery diarrhea, shortness of breath, and hypertension.

Carcinoid tumors are usually found in the appendix or small intestine; extraintestinal carcinoid tumors may arise in the bile ducts, pancreas, stomach, ovaries, or bronchi.[72] The carcinoid syndrome occurs primarily when an intestinal carcinoid tumor metastasizes to the liver or with extraintestinal tumors; flushing attacks can be provoked by palpation of hepatic or abdominal metastases or by alcohol ingestion, enemas, emotional stress, or sudden changes in body temperature. When the syndrome is associated with bronchial adenomas of the carcinoid variety, the flushing is more prolonged and often associated with fever, marked anxiety, disorientation, sweating, salivation, and lacrimation.

Migratory superficial thrombophlebitis and multiple deep venous thromboses have been noted in patients with cancer, especially those with tumors arising in the pancreas, lung, stomach, prostate, or hematopoietic system. The neck, chest, abdominal wall, pelvis, and limbs are most frequently affected.

■ Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis (LYG) is a rare Epstein-Barr virus–associated B cell lymphoproliferative disorder. LYG universally involves the lungs with other common sites, including the skin, the central nervous system, the liver, and the kidneys. It may occur more frequently in patients with immunologic diseases undergoing therapy with immunosuppressive agents, particularly thiopurines and methotrexate. The skin is the most commonly affected extrapulmonary site, occurring in 40% to 50% of patients.[73,74]

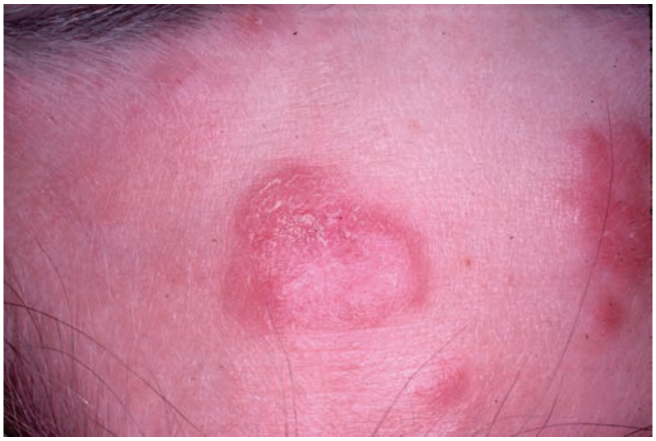

Figure 27-31 Lymphomatoid granulomatosis. This young woman developed the acute onset of multiple erythematous plaques on her face, accompanied by dyspnea and fever. She died within a month from pulmonary disease.

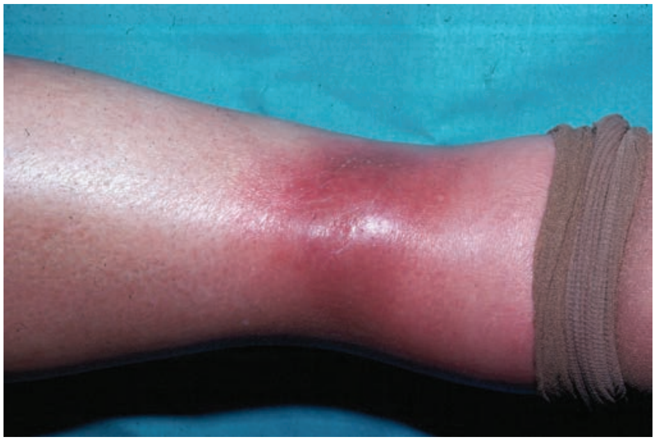

Figure 27-32 Erythema nodosum. Red tender subcutaneous nodule on the leg.

In 10% to 25% of patients, the skin lesions are the first clinical evidence of the disorder; the skin lesions precede involvement of the lungs by 2 weeks to 9 years. Because of the frequent occurrence of skin lesions, ease of performing a skin biopsy, and characteristic histology of the disease, careful dermatologic examination should be carried out in patients suspected of having lymphomatoid granulomatosis.

The characteristic cutaneous lesions are 1- to 4-cm erythematous to purplish dermal papules, or subcutaneous nodules, with or without ulceration.[75]

The lesions generally occur over the buttocks, thighs, and lower extremities (Fig. 27-31), but they may occur anywhere. Healing is often accompanied by scarring and hyperpigmentation.

The skin histopathology is similar to that observed in the lungs and is characterized by a marked angiocentric and angiodestructive lymphohistiocytic infiltrate composed predominantly of CD4-positive T cells. EBV-positive B cells are often present.

Reactive Dermatoses

Two disorders in this category warrant mention: pachydermoperiostosis and EN.

Pachydermoperiostosis is a syndrome in which hypertrophic osteoarthropathy (HOA) is associated with cutaneous changes of the face and extremities that are similar to those that occur in patients with acromegaly. Although this disorder is generally benign, it is occasionally associated with bronchogenic carcinoma.

EN is a relatively common process and is usually acute and self-limited.[76] The typical clinical presentation is the sudden onset of one or more, tender, erythematous nodules on the anterior legs, which are more easily palpated than visualized (Fig. 27-32). The eruption is often preceded by a prodrome of fever, malaise, or arthralgias. As the lesions age, they may develop an ecchymotic appearance. They heal over a 4- to 6-week period, usually without scar formation. Ulceration of the primary process is rare. Although EN is usually acute, patients with chronic or recurrent disease have been described using such terms as "chronic EN," "EN migrans," "subacute nodular migratory panniculitis" (Vilanova's disease), or "septal granulomatous panniculitis." Chronic or recurrent EN most commonly occurs in middle-aged women. The disease is often present for several years and is most common on the legs.

Etiologic or associated conditions are present in about 50% of patients with EN. The associated conditions can be divided into three broad categories: infections, drugs, or systemic diseases (usually inflammatory disorders). The infectious agents associated with EN tend to primarily affect the respiratory or gastrointestinal tract and are most often bacterial or fungal in origin. The most common drugs are antibiotics and oral contraceptives. Pregnancy, particularly in its second trimester, is a known association, and the EN will recur with subsequent pregnancies or with the administration of oral contraceptives. EN-like lesions may occur in Behçet disease and are accompanied by oral and genital ulcerations, pathergy, uveitis, or CNS disease or other systemic manifestations.

A specific variant of sarcoidosis associated with EN is known as Löfgren syndrome.[77] This is an acute, self-resolving process in which EN occurs with bilateral hilar lymphadenopathy, polyarthritis, and anterior uveitis. Granulomatous colitis (Crohn disease), regional enteritis, and ulcerative colitis have been associated with EN. In patients with inflammatory bowel disease, it appears that the EN parallels the activity of the bowel disease. At least half of the cases of EN are not found to have an associated or underlying process.

Neutrophilic Dermatoses: Sweet Syndrome and Pyoderma Gangrenosum

Sweet syndrome (Fig. 27-33) and pyoderma gangrenosum (Fig. 27-34) are distinct dermatoses, but they share common associations and are often managed using similar therapies.[78,79] In addition, a condition

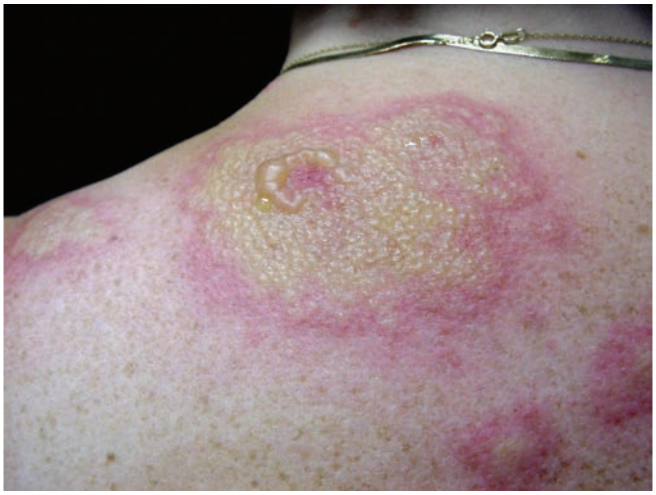

Figure 27-33 Acute febrile neutrophilic dermatosis (Sweet syndrome): erythematous plaque with what appears to be vesiculation on the surface.

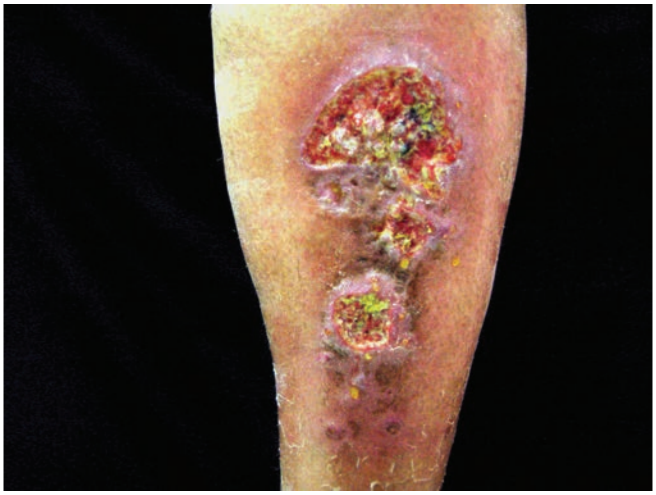

Figure 27-34 Pyoderma gangrenosum: large ulceration on the leg with a violaceous, undermined border. This patient had active Crohn's disease.

known as neutrophilic dermatosis of the dorsal hands (Fig. 27-35) often has characteristics that overlap between a superficial variant of pyoderma gangrenosum (also termed atypical pyoderma gangrenosum) and Sweet syndrome.[79] The associated diseases include inflammatory bowel disease, rheumatoid arthritis, and myelogenous malignancy and premalignancy. Extracutaneous neutrophilic inflammation has been reported in multiple organs, but the lungs are most frequently involved. The inflammatory reaction may cause pulmonary infiltrates, including cavitary disease. It is critical that infectious diseases be excluded with appropriate cultures before initiating therapy with corticosteroids or other immunosuppressive therapy.

■ Pruritus

Pruritus is a symptom that accompanies many dermatoses, but it may also accompany systemic diseases.[80] Patients without an obvious cause for their itching require a systemic evaluation, which usually includes a chest x-ray. Causes for pruritus are not commonly found, but Hodgkin disease and other malignancies might be uncovered during the evaluation. Effective treatment of an underlying malignancy will result in a disappearance of the pruritus.

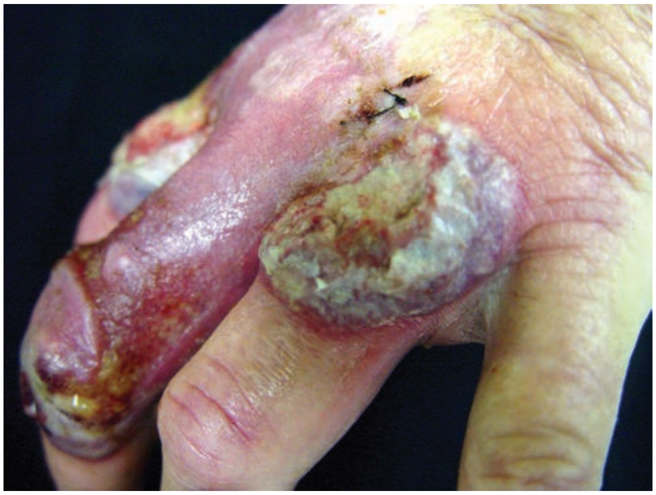

Figure 27-35 Neutrophilic dermatosis of the dorsal hands (also known as atypical pyoderma gangrenosum). Such patients often have a hematologic malignancy or premalignant process.

■ Urticaria

Urticaria is a reactive cutaneous disease manifested by transient urticarial skin lesions. Acute urticaria is almost always due to the ingestion of a food or medication and usually subsides within several days. The presence of chronic urticaria requires a thorough evaluation and, at times, pulmonary evaluation may reveal an infectious, inflammatory, or neoplastic cause (<25% of patients).

■ Vasculitic Syndromes

Important vasculitic syndromes with cutaneous and pulmonary (Chapter 58) involvement are discussed below: granulomatous polyangiitis with eosinophilia (formerly known as Churg–Strauss syndrome), granulomatous polyangiitis (formerly known as Wegener granulomatosis), polyarteritis nodosa, and urticarial vasculitis.

Granulomatous Polyangiitis with Eosinophilia

The clinical picture of allergic rhinitis, asthma, peripheral eosinophilia, and pulmonary infiltrates occurring with systemic vasculitis has been designated the granulomatous polyangiitis with eosinophilia.[81] However, the histologic finding of necrotizing granulomas and tissue eosinophilia is not unique to this clinical syndrome. Indeed, the same histologic appearance may be seen in a wide variety of systemic diseases, including allergic granulomatosis, granulomatosis polyangiitis (see below), rheumatoid arthritis, and lymphoproliferative disease.

One or more types of skin lesions develop in 70% of patients with granulomatous polyangiitis with eosinophilia. Most common is palpable purpura of the extremities; histologically, the lesions show necrotizing vasculitis without granuloma formation. In one-third of patients, the cutaneous lesions are nonspecific—that is, erythematous and urticarial. In another one-third, however, the skin lesions are distinctive—that is, tender, red to violaceous, indurated nodules, measuring 0.5 to 2 cm, which develop central crusting or become infarcted. These nodules occur most often over the scalp or symmetrically over the extensor surfaces of the extremities. These nodules are the ones most likely to have the histologic picture of necrotizing granulomatous vasculitis and eosinophilic infiltration; immunofluorescence staining may show vascular deposition of fibrin and complement.

Granulomatous Polyangiitis

About 45% of patients with granulomatous polyangiitis have cutaneous manifestations, most often small vessel vasculitis manifest as palpable purpura or livedo reticularis.[82] Occasionally, biopsy of the skin lesions reveals usually reveals a small vessel vasculitis and only rarely is a granulomatous process observed. In addition, the presence of cutaneous disease is usually indicative of active systemic involvement; therefore, such patients should be carefully evaluated and aggressively treated.

Polyarteritis Nodosa

Patients with polyarteritis nodosa frequently have cutaneous lesions. The skin disease may represent small vessel vasculitis as in granulomatosis with polyangiitis or may represent medium-sized vessel involvement. In the latter case, the manifestation is livedo reticularis or ulceration.

Urticarial Vasculitis

Urticarial lesions may occur in patients as a manifestation of small vessel vasculitis. Urticarial vasculitis was first described in four patients with recurrent attacks of erythematous urticarial and hemorrhagic skin lesions associated with synovitis and, sometimes, abdominal distress. The patients did not have systemic lupus erythematosus or paraproteinemia, but they did have hypocomplementemia; two had nephritis.

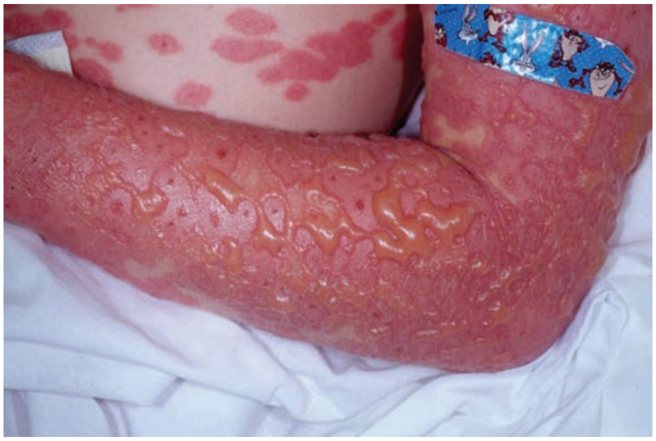

Figure 27-36 Stevens–Johnson syndrome/toxic epidermal necrolysis.

Urticarial lesions may also be an early clinical manifestation of lesions that become typical palpable purpura. The spectrum of urticarial vasculitis has also grown in recent years to include the presence of lung disease, characterized by asthma or obstructive lung disease. Patients with hypocomplementemic urticarial vasculitis often have or develop obstructive pulmonary disease, whereas most patients with normal complement levels, chronic urticarial, and vasculitis have little or no systemic involvement.[83]

Patients are often treated with corticosteroids or other immunosuppressive drugs. Although these agents are useful in controlling the cutaneous lesions, they do not appear to have any impact on progression of the pulmonary disease.

■ Toxic Epidermal Necrolysis

Toxic epidermal necrolysis (TEN) is one of the true dermatologic emergencies.[84] This disorder is most often due to drug administration and develops acutely. Patients often have a prodrome followed shortly by widespread skin involvement with a superficial blistering (Fig. 27-36). Multiple mucosal surfaces are affected (Fig. 27-37). Prognosis is dependent upon the extent of the blistering, age, and the presence of comorbid diseases.

Lung involvement in TEN is unusual, but affected patients often are treated in an intensive care unit or burn unit and frequently become ventilator-dependent. Infections, particularly pneumonia, are a frequent complication and may result in death.

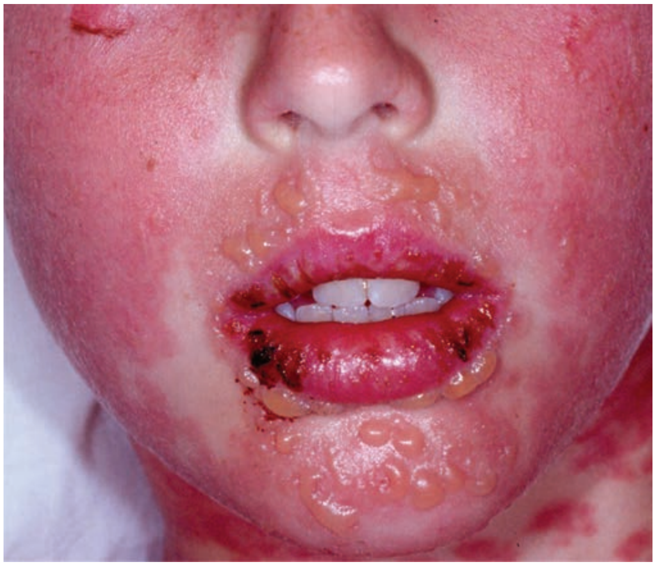

Figure 27-37 Mucosal lesions of Stevens–Johnson syndrome/toxic epidermal necrolysis.

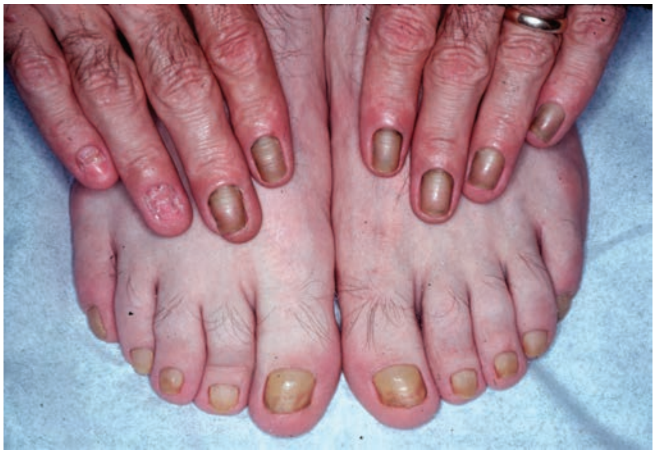

Figure 27-38 Yellow nail syndrome. All 20 nails were affected in this patient.

■ Yellow Nail Syndrome

Thick, yellow discoloration of all 20 nails occurs in the yellow nail syndrome[85] (Fig. 27-38). The nails are thick, but there is no onycholysis and no subungual debris, allowing clinical differentiation from onychomycosis. The nails are not clubbed, and there are no underlying bony abnormalities. This disorder is almost always associated with pulmonary abnormalities, including pleural effusions, lymphoma, and sleep apnea. There is no known therapy for the nail changes in this disorder, but improvement of the associated pulmonary disease may result in improvement of the nails.

■ Miscellaneous Disorders

Pulmonary-cutaneous syndromes include a number of inherited congenital and developmental disorders.

α_1-Antitrypsin Deficiency

α_1-Antitrypsin deficiency is regularly associated with pulmonary (Chapters 39 and 40) or hepatic disease. Cutaneous manifestations may also occur in some patients with this inherited disorder and most commonly manifest as panniculitis or, rarely, as a cutaneous vasculitis.[86,87] Although the panniculitis is a lobular panniculitis, in contrast to the septal panniculitis that is found in EN, the clinical disease is similar except that these patients' lesions may ulcerate.

Cutis Laxa

Cutis laxa is caused by a disorder in the formation of elastin that is transmitted as a dominant hereditary trait.[88] In children with this disorder, skinfolds of the abdomen and face are large and pendulous. The pulmonary manifestations of cutis laxa include emphysema and pulmonary artery stenosis.

Cystic Fibrosis and the Skin

CF is an inherited disorder that frequently affects the lungs and results in premature death (Chapter 48). Some patients with CF have skin disease.[89] Specifically, cutaneous vasculitis seems to be more frequent in CF patients, probably due to the frequent formation of circulating immune complexes.

Ehlers–Danlos Syndrome

The most important disorder of collagen affecting the skin and lungs is Ehlers–Danlos syndrome (cutis hyperelastica), a hereditary

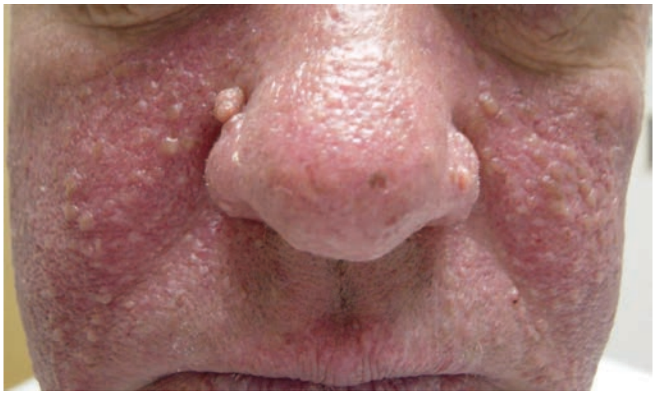

Figure 27-39 Flesh-colored central facial papules in a patient with Birt–Hogg–Dubé syndrome.

disorder of collagen in which the skin and blood vessels are unduly elastic and fragile and the joints are hyperextensible. The skin is smooth, rubbery, and bruisable; the joints are hypermobile. Associated systemic abnormalities include megaesophagus, megacolon, dissecting aortic aneurysm, and diaphragmatic and inguinal hernias. Among the pulmonary disorders are spontaneous pneumothorax, arteriovenous fistulas, megatrachea, and bronchial ectasia.[90]

Birt–Hogg–Dubé Syndrome

Birt, Hogg, and Dubé described an autosomal dominant condition that is manifested by multiple facial flesh-colored papules characterized histologically as trichodiscomas.[91] BHD is due to heterozygous mutations in the folliculin (FLCN) gene located on chromosome 17, which encodes a highly conserved tumor suppressor protein (Fig. 27-39). Affected patients frequently develop renal cell carcinomas, particularly oncocytomas. In addition, multiple lung cysts and development of spontaneous pneumothorax at a young age are common. Although there is no known therapy, recognition of affected patients may lead to discovery of renal tumors prior to metastasis and assessment of family members.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT), also known as Osler–Rendu–Weber syndrome, is an autosomal dominant disorder that is manifested by vascular ectasia in various organs, including the skin and mucus membranes (Fig. 27-40). HHT often is first manifested as nosebleeds. Eventually lesions affect the lips, tongue, nasal mucosa, palate, and palms. Patients with HHT may have arteriovenous malformations in the lungs or CNS. Epistaxis, melena, and hemoptysis are common in adults.

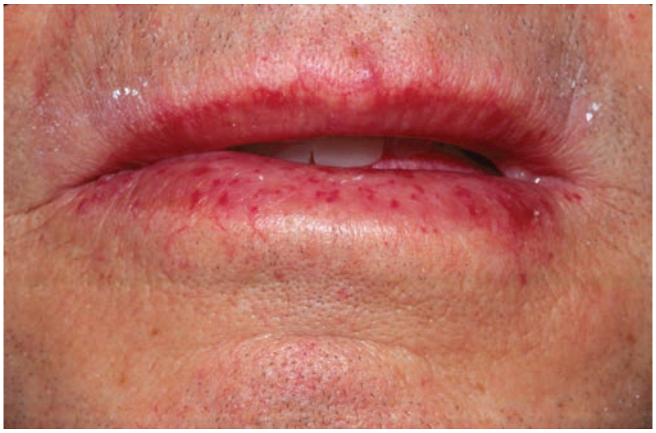

Figure 27-40 Mucosal telangiectasia in a patient with hereditary hemorrhagic telangiectasia.

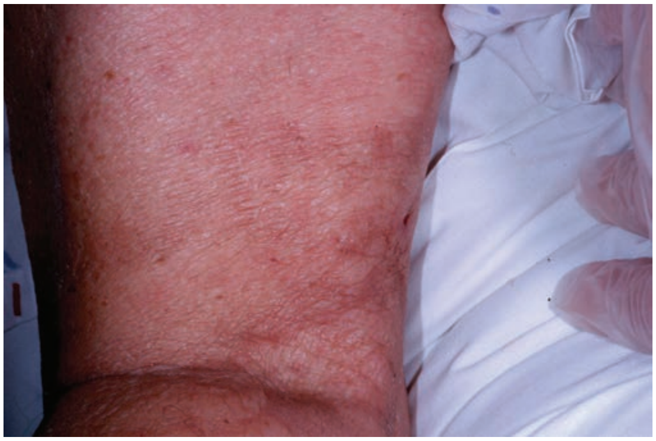

Figure 27-41 Peau d'orange changes in a patient with nephrogenic systemic fibrosis.

Nephrogenic Systemic Fibrosis

Nephrogenic systemic fibrosis is a disorder of the skin in which a rapid onset of skin hardening (Fig. 27-41) occurs in patients with some form of renal disease.[92] Often the onset of the fibrosis is preceded by anasarca. The disease has been linked to gadolinium deposition in tissue following its use for MRI or MRA. Initial descriptions of the disease focused on the cutaneous findings, but it has become evident that patients may also have systemic fibrosis, including pulmonary fibrosis. There is no known effective therapy for these patients, but with time the fibrosis does seem to lessen.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus (PNP) is a severe mucocutaneous disease with a specific pattern of immunofluorescence. It is a rare vesiculobullous disorder. Patients with PNP often present with severe oral erosions and polymorphous cutaneous lesions, including targetoid lesions, bullae, and erosions (Fig. 27-42). Patients with PNP often have a lymphoproliferative disorder with a high prevalence of Castleman disease. In addition to the mucocutaneous disease, these patients frequently have bronchiolitis obliterans.[69]

Sarcoidosis

Sarcoidosis is a multisystem disorder with protean manifestations (Chapter 53). Skin lesions occur in about 25% of patients and may

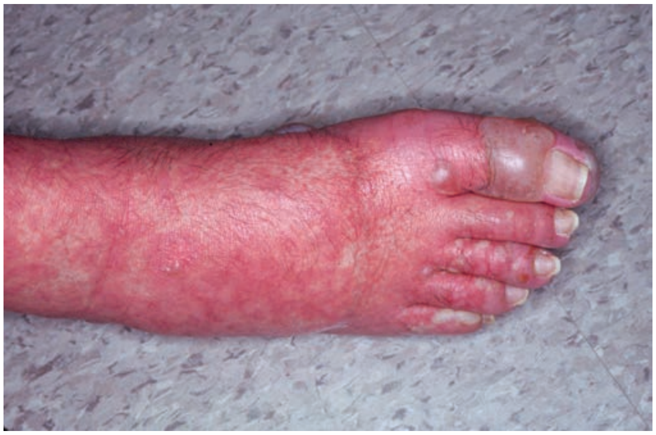

Figure 27-42 Paraneoplastic pemphigus.

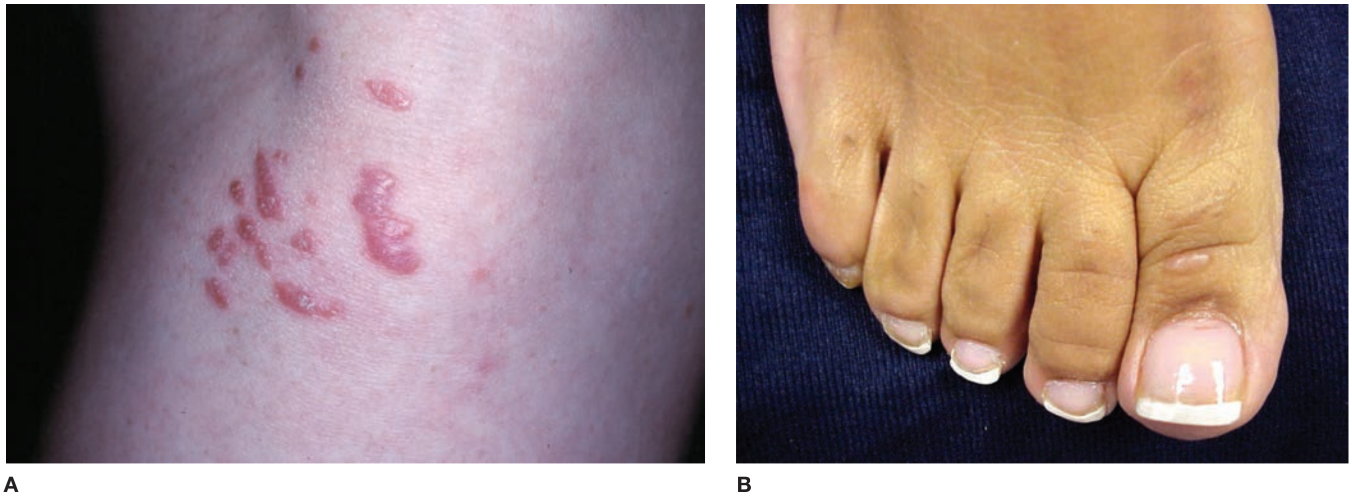

Figure 27-43 **A, B.** Sarcoidosis: acute onset of papular lesions (**A**) on the knees and feet (**B**) were associated with a self-limited course in these patients.

be "histopathologically specific" or "nonspecific." The most common nonspecific manifestation is EN (see above). Histopathologically specific lesions are manifestations of granulomatous inflammation in the skin. Although associated with chronic disease in the past, it now appears that there are many patients with self-limiting granulomatous disease of the skin. Skin lesions are most commonly papules, plaques, or nodules. Rarely is there a great deal of surface change, and ulceration is uncommon.

Several clinical variants are worth noting. Papular lesions on the knees (Fig. 27-43) are commonly associated with EN and are self-limiting. Lesions on the nasal ala (Fig. 27-44) are frequently associated with sarcoidosis of the upper respiratory tract (SURT), and a thorough otolaryngologic evaluation is indicated. Erythematous to violaceous plaques on the face are known as lupus pernio (Fig. 27-45); residual scarring in this disorder is possible. In addition, patients tend to have accompanying chronic disease in the lungs. Finally, lesions of sarcoidosis frequently occur within scars or tattoos (Fig. 27-46). In this circumstance it may be difficult to distinguish sarcoidosis from foreign body granulomas.

Tuberous Sclerosis

Tuberous sclerosis is a hereditary disorder characterized by mental retardation, epilepsy, and skin lesions, including adenoma sebaceum (Fig. 27-47), periungual and subungual fibromas (Fig. 27-48), Shagreen patches, and ash leaf macules. Also seen as part of this disorder are retinal phakomas, calcification of basal ganglia, and ungual fibromas. Approximately 9% of patients with visceral tuberous sclerosis have pulmonary manifestations; some of the pulmonary lesions are cystic and may be associated with recurrent spontaneous pneumothorax and hamartomas. Certain, poorly understood diseases, such as fibrocystic pulmonary dysplasia, may represent a forme fruste of tuberous sclerosis.

MEDICATION TOXICITY

Cutaneous toxicity may arise from therapy given for pulmonary disease. In addition, pulmonary toxicity may develop in the setting of treatment of dermatologic disorders.

■ Dermatologic Toxicity from Agents Used to Treat Pulmonary Disease

Two examples of dermatologic injury from agents used to treat lung disease are described below: epidermal growth factor receptor inhibitors and immunosuppressive agents.

Epidermal Growth Factor Receptor Inhibitors

Epidermal growth factor receptor inhibitors are now being used for the treatment of solid tumors, including lung cancers. These agents

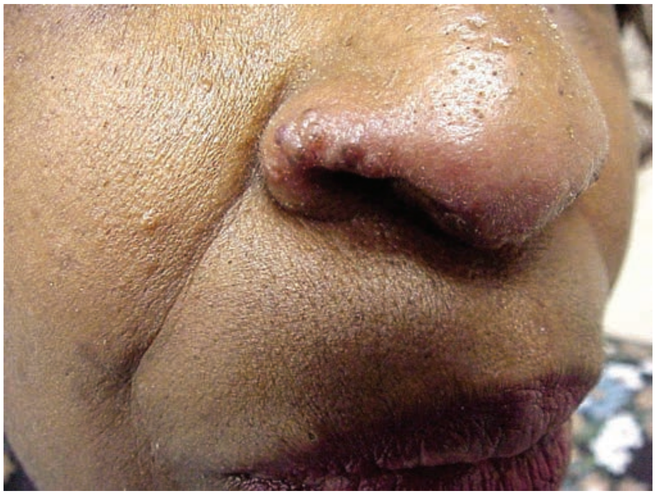

Figure 27-44 Sarcoidosis affecting the nasal ala is regularly associated with granulomatous disease in the upper respiratory tract (SURT).

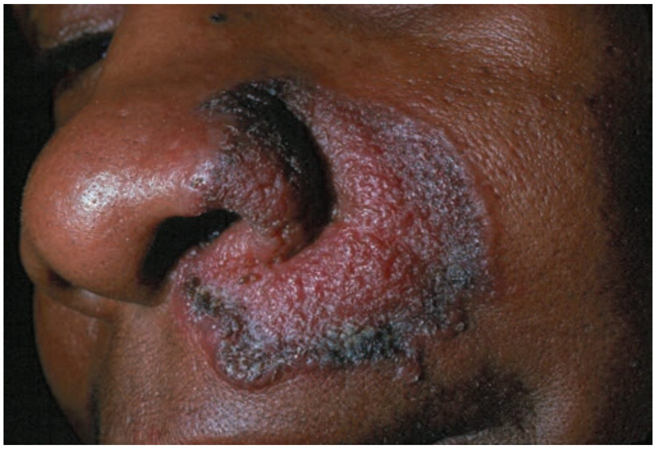

FIGURE 27-45 Lupus pernio (sarcoidosis).

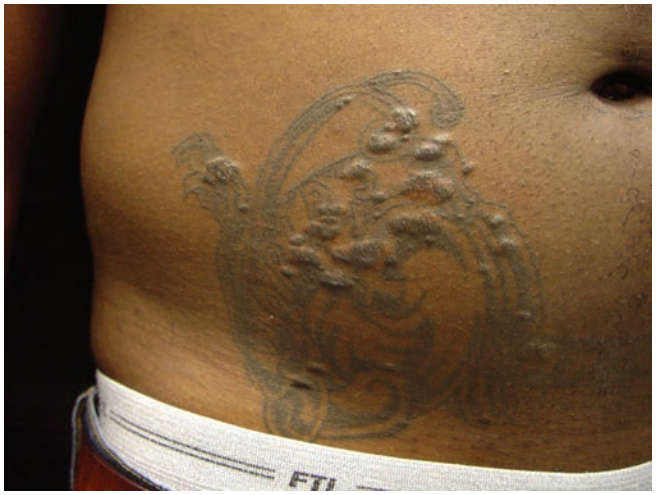

Figure 27-46 Sarcoidosis within tattoos.

are regularly associated with development of an acneiform eruption on the face.[93] The presence and severity of the eruption appear to correlate with survival.

Immunosuppressive Therapy in Lung Transplant Recipients

Patients who are organ recipients are regularly treated with corticosteroids in combination with various immunosuppressive agents. Therapy with corticosteroids has well-known dermatologic consequences, including striae, steroid-acne, or folliculitis, and an increased risk of superficial fungal infections. The intensity of the immunosuppression and duration of therapy are associated with increasing risk of cutaneous malignancy, specifically nonmelanoma skin cancer (NMSC) and KS. Squamous cell carcinoma is overrepresented in comparison with basal cell carcinoma; in addition, the tumors appear to be more aggressive in the presence of immunosuppressive therapy. Therefore, in patients who develop multiple squamous cell carcinomas immunosuppressive therapy should be less intense, if possible, or substitution of cyclosporin and azathioprine by other “less” toxic agents should be considered.

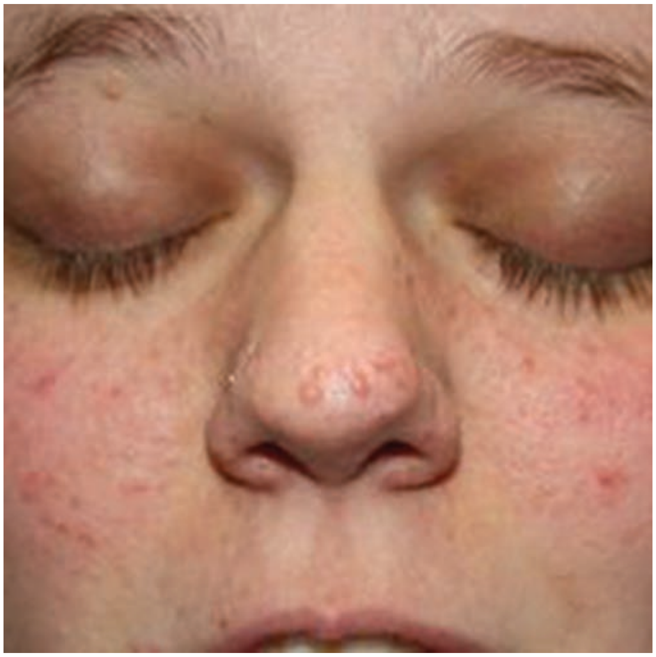

Figure 27-47 Tuberous sclerosis. Fibrous papules on the nasal tip and central face.

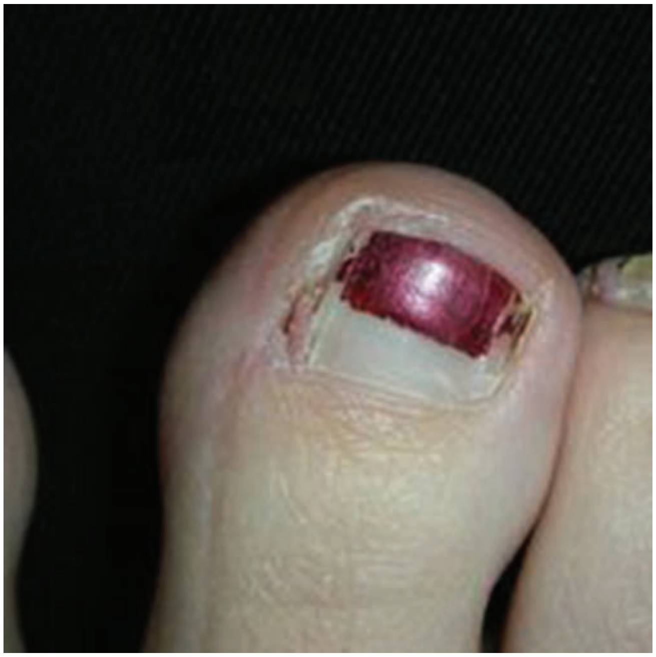

Figure 27-48 Tuberous sclerosis. Periungual fibromas.

■ Pulmonary Toxicity from Dermatologic Therapies

Two examples of pulmonary toxicity arising from agents used to treat dermatologic disorders are described below: methotrexate and tumor necrosis factor-α inhibitors.

Methotrexate

Methotrexate is a common systemic therapy for patients with psoriasis. In addition, it is regularly used for cutaneous dermatomyositis, cutaneous sarcoidosis, and cutaneous lymphomas. Pulmonary toxicity is not common and is believed to be idiosyncratic. Most of the dermatologic use is for psoriasis vulgaris and psoriatic arthritis; fortunately, pulmonary disease appears to be quite rare in these patients. No specific monitoring is recommended.

Biologics and Small Molecules

A growing number of tumor necrosis factor (TNF) antagonists are available, including infliximab, etanercept, adalimumab, golimumab, and certolizumab. In addition, IL 12/23, IL 23, IL 17, and JAK inhibitors are additional therapeutic considerations. These therapies have revolutionized our approach to psoriasis, psoriatic arthritis, inflammatory bowel disease, and rheumatoid arthritis. All have been associated with an increased risk of infection, particularly pneumonia and tuberculosis.

SUMMARY

The diagnostic approach to a patient with suspected pulmonary disease begins with a thorough history and physical examination. Elements of the family history, along with determination of work and other environmental exposures, are important components of the history. Many times, characteristic cutaneous findings shed light on an underlying pulmonary diagnosis. The clinical examination is complemented by radiographic studies, assessment of pulmonary and cardiac function, and routine and specialized laboratory studies, as warranted.

CHAPTER 28

Modern Approach to Thoracic Imaging Diagnosis

Eduardo J. Mortani Barbosa Jr.
Leonid Roshkovan

INTRODUCTION

This chapter is not intended to provide a comprehensive review of the entire scope of thoracic imaging; dedicated textbooks in radiology serve this purpose well. Moreover, the chapter does not provide a comprehensive guide to the interpretation of thoracic imaging studies. Rather, the focus is on what modern thoracic imaging can provide to empower clinicians to diagnose and manage common clinical scenarios in the third decade of the 21st century. The goal is to present a strategic approach to thoracic imaging, which starts with broad clinical categories of disease and addresses the following central clinical questions: What is the differential diagnosis and how can a specific diagnosis be confirmed? What is the prognosis and how can disease progression and therapeutic effectiveness best be monitored?

In each subsection, organized initially by imaging technique, and subsequently, by broad diagnostic categories, the authors aim to answer these questions by providing a practical, logical, and evidence-based approach that emphasizes which imaging tests to order and what to expect from each test. Often, imaging findings are either pathognomonic or highly characteristic of a diagnosis in the appropriate clinical context and, therefore, will suffice for clinical diagnosis and management. However, when this is not the case, tissue sampling or additional laboratory tests may be required for diagnostic confirmation; these scenarios are outlined and options discussed for tissue sampling, including image-guided percutaneous biopsy, bronchoscopy, and surgical biopsy. In addition, the ways in which modern functional and quantitative radiographic techniques may impact the field of thoracic imaging in the near future will be considered, and validated clinical applications differentiated from promising research applications that may evolve into useful clinical tools in the next several decades.

Finally, since radiology and, in particular, thoracic imaging, play such a major and central role in modern medicine, our ultimate goal is to enable the practicing pulmonologist to use imaging resources consistently, wisely, efficiently, and effectively.

SUMMARY OF TECHNIQUES: DIAGNOSTIC AND INTERVENTIONAL

The inception of the field of radiology dates back to 1895 with Wilhelm Röentgen's serendipitous discovery of x-rays and subsequent production of the first radiograph. Within only a few years, radiology became established as a new medical field. Chest radiography, although one of the first clinical applications and currently over 100 years old, is still the most frequently performed imaging test worldwide and the cornerstone of initial imaging assessment of most patients with thoracic diseases. Nonetheless, over the last four decades we have witnessed an explosion of technical innovation and developments, with the introduction of ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and hybrid scanners (PET/CT and PET/MRI), which have greatly expanded the ability of modern imaging to accurately diagnose even the smallest or earliest disease processes and revolutionized the practice of medicine.

More recently, the widespread impact that computers have made on the acquisition, distribution, visualization, and post-acquisition processing of medical images has consolidated the central role of radiology. In the future, we hypothesize that major trends will include quantitative and functional imaging, molecular diagnosis, clinical utilization of radiomic and artificial intelligence tools, and value assessment with regard to generating better patient outcomes. In the following sections we present current clinical applications, advantages, and disadvantages of each modality, as well as appropriateness criteria for ordering each test, according to the clinical scenario.

CHEST RADIOGRAPHY

Two basic types of chest radiographic examinations are available—bedside portable AP (anteroposterior) and the combination of PA (posteroanterior) and lateral projections. Supplementary views include oblique, lordotic, lateral decubitus, and expiratory radiographs. For most clinical scenarios, the evaluation should begin with a chest radiograph, as this study remains the most cost-effective imaging test for diagnosing a variety of common clinical conditions (Figs. 28-1 and 28-2). Moreover, chest radiographs are universally available and can be obtained even in patients who cannot be moved to an advanced scanner (e.g., patients in the ICU setting). Nonetheless, in many clinical scenarios, additional advanced imaging will be required to clarify radiographic findings or obtain more

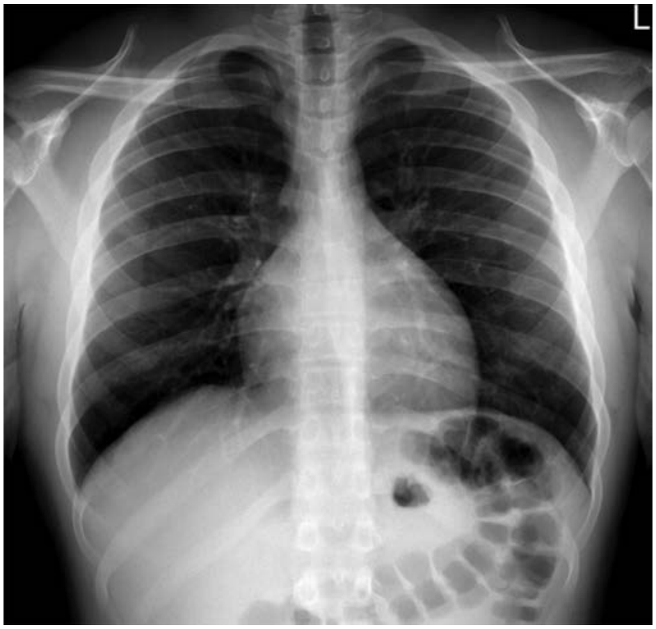

Figure 28-1 Normal PA radiograph.

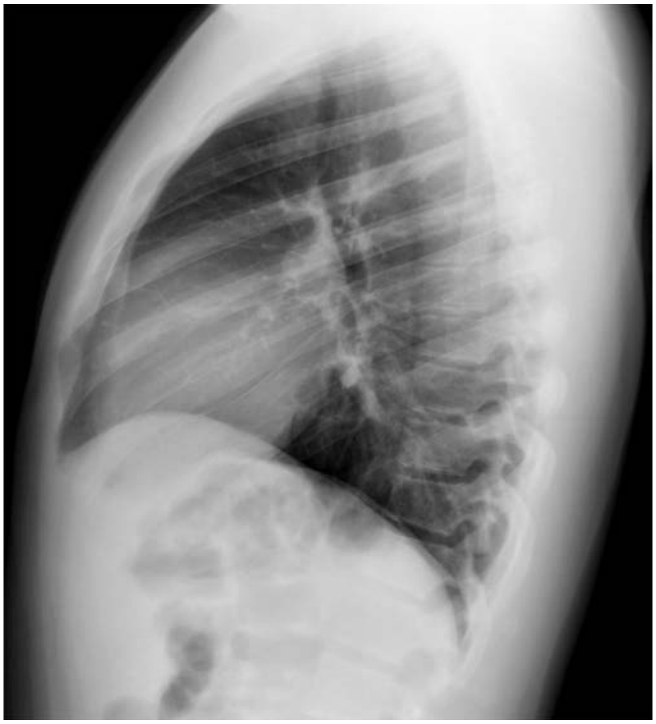

Figure 28-2 Normal lateral radiograph.

accurate characterization of disease pattern and severity (Figs. 28-3 to 28-6).

Whereas the basic physical principles of radiography have not changed in over a century, the quality and clinical availability of chest radiographs have been greatly enhanced in recent decades due to the transition from analog to digital technology. Digital imaging provides better image contrast, reduces the number of suboptimal or nondiagnostic examinations, and permits more immediate examination availability using image transfer and display software.

Currently, two standards for digital radiography exist: computed radiography (CR) and digital radiography (DR), which differ in the process of imaging acquisition. CR utilizes a photostimulable phosphor cassette, just as does the film-screen analog technique; however, the latent image is read by a laser and converted from an analog to digital signal, rather than being transferred to film. DR bypasses this step and utilizes flat panel detectors that directly transform the x-ray signal to a digital image via integrated, thin-film, transistor readout systems. From a practical perspective, DR images are often sharper, with better spatial resolution and, consequently, better visualization of detail. In addition, DR streamlines workflow for routine images and offers the possibility of tailoring the radiation dose.

Most modern facilities use a combination of CR and DR units, due to cost considerations. The principal benefit of CR and DR technology is the ability to process the acquired images to emphasize specific anatomic areas (e.g., lung parenchyma, soft tissues, bones), thereby greatly reducing the need to repeat examinations due to over- or under-penetration by the x-ray beam.[1] Digital methods to "remove" the ribs from the image are now available using either post-processing bone-suppression software or dual-energy acquisition techniques (Figs. 28-7 and 28-8). These approaches can provide an unobstructed view of the lungs for improved detection of nodules and other pulmonary findings. In addition, computer-aided diagnostic techniques and use of artificial intelligence[2] may now assist the radiologist in the detection of subtle lung lesions.

The PA view obtained in the erect position is the standard radiographic examination and demonstrates the anatomy and most thoracic pathologic processes. In particular, the PA view allows evaluation of pulmonary masses and consolidation, diffuse lung disease, pleural effusion, pneumothorax, mediastinal abnormalities, and disorders of the rib cage and scapular girdle.

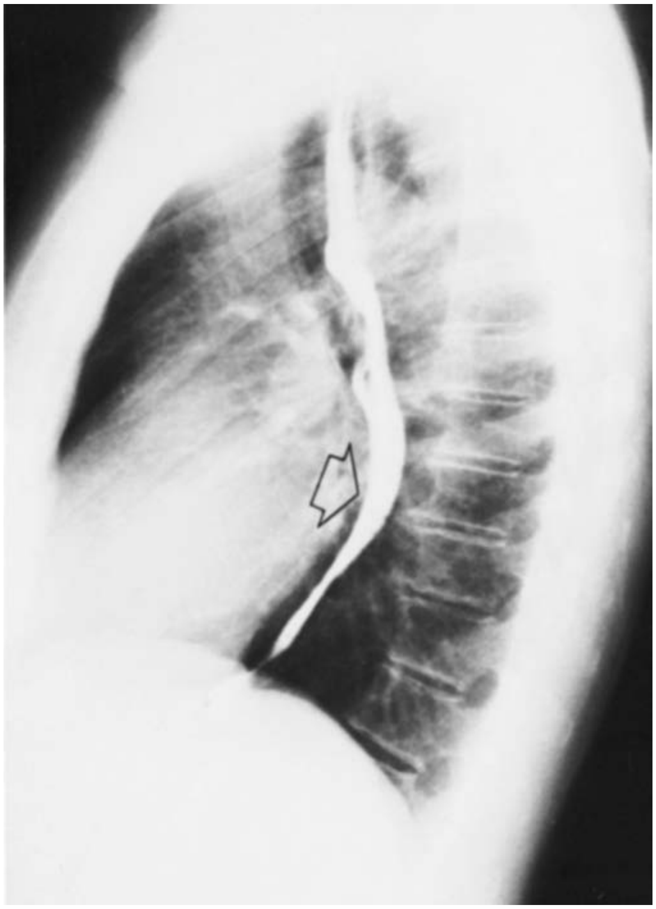

Figure 28-3 Lateral chest radiograph following barium contrast swallow. Not only is this technique very useful for evaluating the esophagus, it is also able to demonstrate left atrial enlargement, with consequent posterior displacement of the contrast column *(arrow)*.

The lateral view provides additional information by better depicting the posterior diaphragms and posterior lung bases, retrocardiac left lung base, anterior mediastinum, and thoracic spine.

The AP view provides similar information to the PA view, but it is limited by lower spatial and contrast resolution and by magnification of the mediastinal structures. In addition, it is less sensitive for detection of small pneumothoraces and pleural effusions. The AP view is often performed in the supine position in bedridden patients, particularly those who are postoperative or in the ICU. AP portable chest radiographs can be very helpful in assessing the position of support lines, tubes, and medical devices. Medical devices can also be enhanced using newer digital image-processing algorithms.

Supplementary views are not routinely performed, unless there is a specific clinical question. In the past, lordotic views were obtained to better visualize the lung apices by displacing the clavicle and first rib shadows superiorly. However, their role has been largely replaced by CT. Expiratory views may be more sensitive in detecting small pneumothoraces, particularly in the setting of recent lung interventional procedures. Lateral decubitus views, although used less frequently than in the past, may be helpful in determining if a pleural opacity seen on standard views is a freely mobile effusion or a loculated effusion or pleural mass. When the patient is imaged with the pleural opacity on the dependent side, a freely mobile pleural effusion conforms to the most dependent region of the

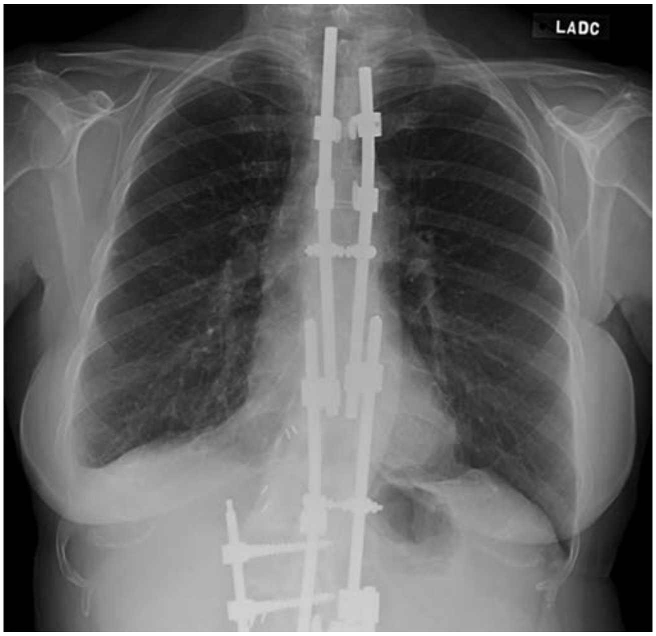

Figure 28-7 Dual-energy PA radiograph without post processing.

hemithorax and a sharp horizontal level demonstrated due to gravity. If a nondependent lucency is seen in the chest or abdomen, in conjunction with a sharp horizontal level delineating it from normal anatomical structures, the diagnosis of a small pneumothorax or pneumoperitoneum may be made. Finally, oblique views are helpful in determining if a questionable radiographic abnormality seen on the frontal view is real or artifactual, as well as in determining its location in the thorax. Performed properly, supplementary views can increase the diagnostic accuracy and clinical utility of chest radiography, sometimes obviating the need for chest CT with its attendant higher cost and radiation exposure.

Many radiographic techniques that were widely used in the past (e.g., laminography, bronchography, air contrast studies, fluoroscopy) have been made obsolete by other techniques and are of historic interest only. The exception is focused fluoroscopy for evaluation of diaphragmatic motion ("sniff test"), in which the patient is imaged during quiet breathing, deep breathing, and forceful inspiration ("sniff"). A paralyzed hemidiaphragm moves paradoxically upward with forceful inspiration. Fluoroscopy in conjunction with barium swallow may also be used to assess esophageal diseases, assessing for both structural and, to a lesser degree, functional abnormalities.[3]

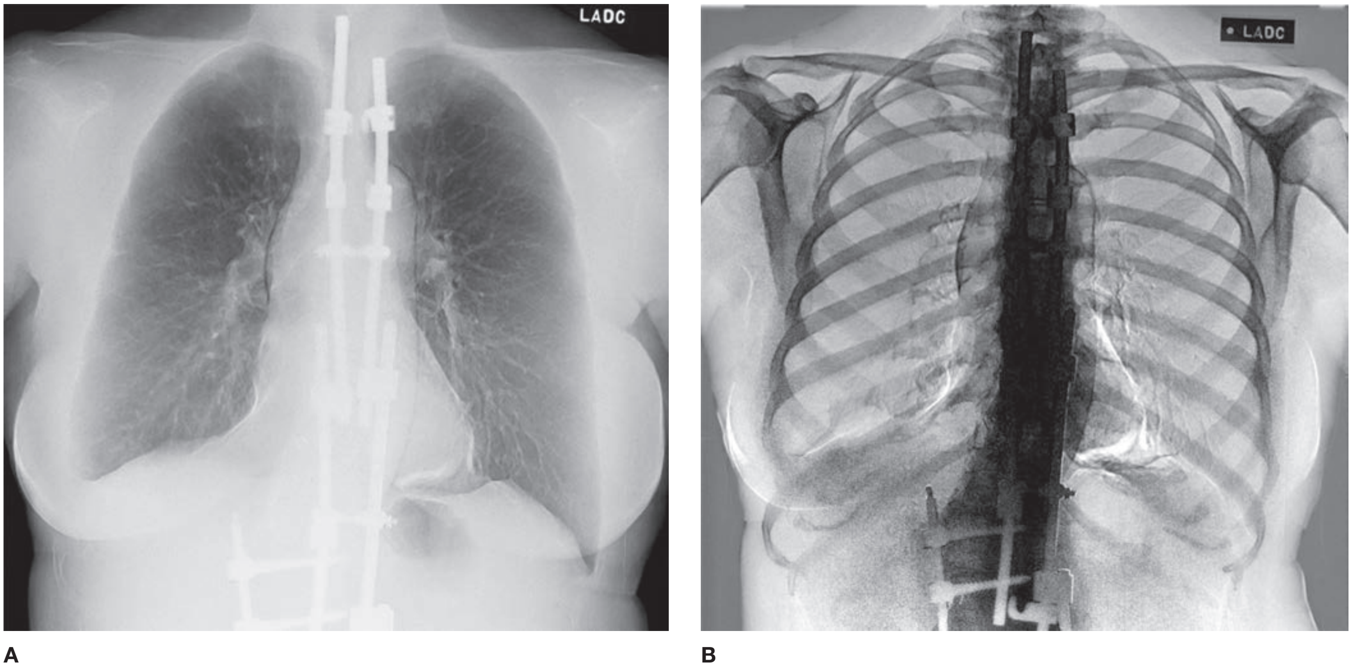

Figure 28-8 **A.** PA radiograph with bone subtraction. **B.** PA radiograph with lung and soft tissue subtraction. This technique may allow detection of subtle disease patterns otherwise obscured on a regular radiographic image.

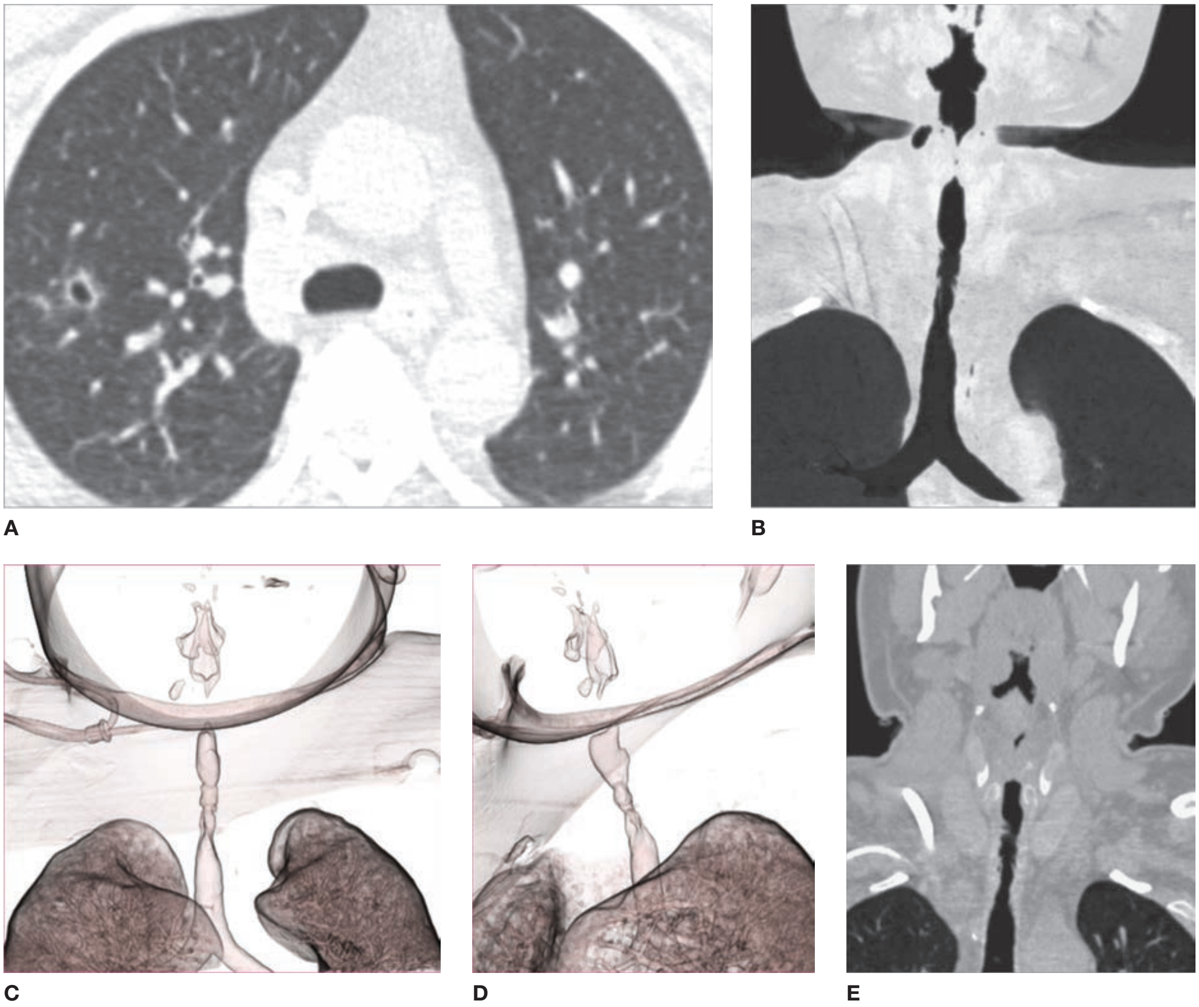

Figure 28-9 CT offers the best imaging evaluation of the pulmonary parenchyma and airways, and advanced postprocessing techniques can provide exquisite views of disease distribution and extension. Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) affecting the lung and airways. **A.** Cavitary nodule in the right upper lobe; (**B**) minimum intensity projection image demonstrating irregular, long segment narrowing of the upper and middle trachea; (**C**) and (**D**) two different projections of a 3D volume rendering airway reconstruction demonstrating the complex configuration of the stenotic tracheal segment; (**E**) coronal reformatted image depicting tracheal wall thickening associated with stenosis.

CHEST CT

CT is the current cornerstone of advanced thoracic imaging. It is a digital cross-sectional imaging technique that utilizes a rotating x-ray source around the patient, coupled to diametrically positioned sodium iodide detectors in a circular configuration. As the scanner gantry rotates, multiple projections are generated at different angles with different x-ray beam attenuations, depending on which part of the patient's anatomy was traversed. Following scan acquisition, through a mathematical procedure (filtered back projection or, more recently, iterative reconstruction), the sum of projections is transformed into an image in which the relative density of each small volume of the patient's anatomy (voxel) is proportional to its x-ray absorption coefficient and normalized from a scale of –1000 to >+1000 HU (Hounsfield units, zero representing the absorption coefficient of water, –1000 of air). Because it eliminates the main drawback of radiographic techniques, that is, the projection of a three-dimensional (3D) structure into a two-dimensional image, CT allows very accurate localization of pathologic processes. Moreover, the superior contrast resolution of CT allows detailed evaluation of mediastinal and chest wall soft tissue attenuation structures, which are poorly assessed radiographically. CT is also superior to chest radiographs for detection of small pulmonary lesions, as well as for their characterization (Figs. 28-9 and 28-10).

Early CT scanners had a single row of detectors and a single x-ray source, acquiring one axial image at a time before the scanner table was moved to acquire the next image. This process could take more than 30 minutes for a single thoracic CT examination. Most modern scanners have between 64 and 320 rows of detectors, one or two x-ray tubes (dual-source CT scanners), extremely fast and continuous gantry rotation, and simultaneous table translation, resulting in helical image acquisition and the ability to scan the entire chest in less than 1 second. Modern CT scanners are able to produce high-quality, submillimeter, isotropic resolution images that can be reconstructed in any arbitrary plane without loss of detail. Postprocessing techniques utilizing computational algorithms also allow 3D reconstructions, such as volume rendering and maximal-intensity projection images, which can be utilized to demonstrate complex 3D vascular or airway anatomy and pathology. A new generation of commercially available CT scanners called dual-energy scanners (utilizing both high- and low-energy kV settings while scanning) offer additional advantages compared to routine CT scanners based on their ability to perform advanced material decomposition—e.g.,

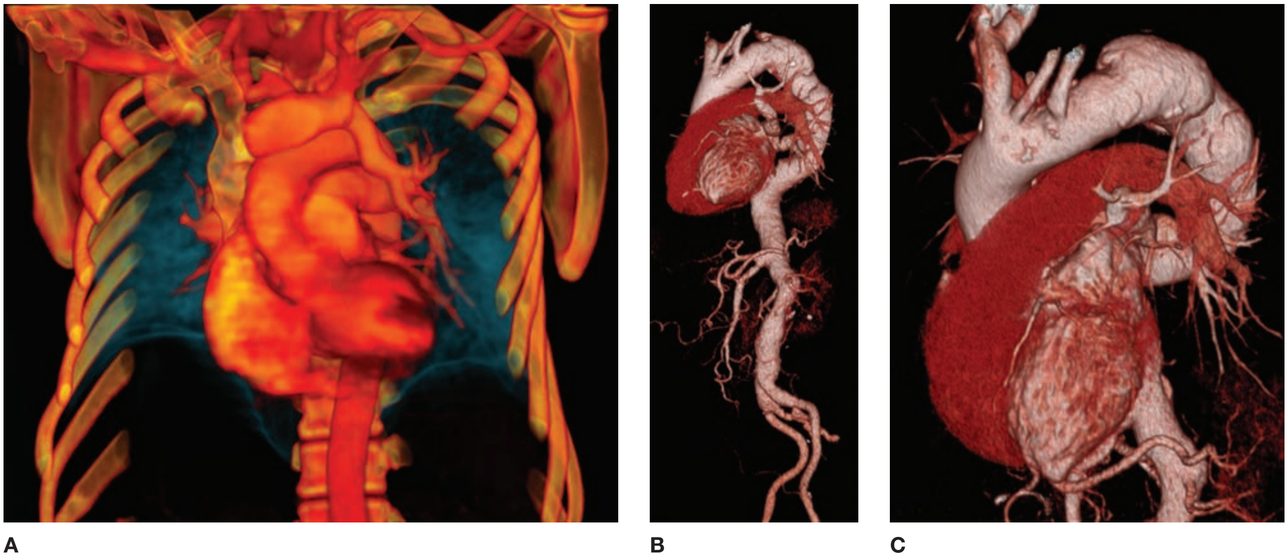

Figure 28-10 CT allows acquisition of isotropic volumetric images, in which advanced 3D postprocessing can be performed to demonstrate complex disease processes with a high level of detail. **A.** Volume rendering (VR) reconstruction demonstrating partial anomalous pulmonary venous connection of the left upper lobe to the left brachiocephalic vein; (**B**) and (**C**) VR reconstructions at different degrees of rotation, demonstrating the complex configuration of a thoracic aortic aneurysm. These images are invaluable for treatment planning.

the ability to quantitate iodine distribution in the lung parenchyma as a reflection of pulmonary blood volume; reconstruction of virtual unenhanced images obtained from contrast-enhanced studies; and detection of bone marrow edema (Fig. 28-11).[4]

An important concept is that of high-resolution CT ("HRCT") of the thorax. Historically, when early CT scanners were limited to the acquisition of relatively thick axial slices (7 to 10 mm) in the thorax, the only way to adequately assess lung parenchymal detail was to acquire serial, thin (1 mm) anatomic images utilizing an axial, rather than helical, mode; this required noncontiguous (i.e., slices with an interslice gap, typically 20 mm wide), rather than contiguous, slices. These images were also reconstructed using a high spatial frequency algorithm, sharpening edges and allowing improved visualization of fine detail. The result was a set of higher-spatial-resolution, thin-section images that sampled the lung parenchyma and provided excellent insight into certain pulmonary disorders. This was termed "high-resolution CT" or "HRCT" of the chest, differentiating it from the "standard" chest CT scan, in which thicker sections were acquired through the entire chest in a contiguous helical mode (i.e., without interslice gaps). Generally, a choice had to be made as to which of these two types of scans to perform, since both studies could not be performed simultaneously. Standard CTs were ordered for a general assessment of larger pulmonary lesions, as well as mediastinal, bone, and chest wall pathology. High-resolution chest CTs were ordered to assess pulmonary parenchymal disease, such as bronchiectasis, interstitial diseases, and micronodular diseases.

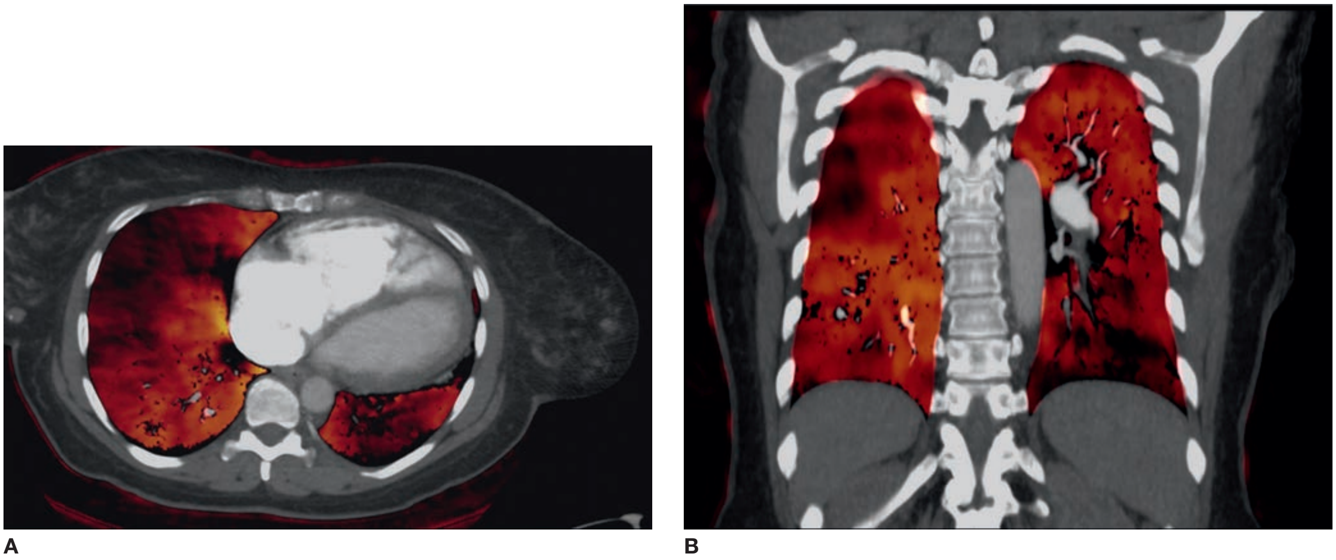

Figure 28-11 Dual-energy CT provides additional functional information with regards to iodine distribution in lung parenchyma thus allows characterization of pulmonary blood volume. This ability results in superior detection of pulmonary embolism in both acute and chronic setting. (**A**) Axial and (**B**) coronal reconstruction of pulmonary blood volume map in a patient with chronic thromboembolic disease demonstrates a chronic filling defect in a segmental artery to the left lower lobe with associated decrease in pulmonary blood volume consistent with decreased circulation in the affected region.

Video 28-1 **A.** Axial cine images using lung window and inspiratory acquisition. This CT airway examination demonstrates bronchiectasis, mosaic attenuation, and faint peribronchial opacities, compatible with a diagnosis of bronchiolitis obliterans. Inspiratory acquisitions should ideally reflect the lung appearance at TLC (total lung capacity). **B.** Same patient as in Video 28-1A. Axial cine images on lung window/level, expiratory acquisition, in this CT airway examination, demonstrating same findings earlier, plus dynamic partial collapse of the trachea and central bronchi, compatible with tracheobronchomalacia superimposed on bronchiolitis obliterans. Note the value of expiratory imaging to establish the diagnosis of tracheobronchomalacia and to increase the conspicuity of the mosaic attenuation pattern reflecting small airway disease. Expiratory acquisitions should ideally reflect residual volume (RV). *Video available on AccessMedicine.com.*

With advances in CT technology, however, it is currently feasible to acquire volumetric, isotropic, thin-section (1 mm) images throughout the entire thorax in a single breath-hold, and to reconstruct them in any arbitrary plane (typically, axial, sagittal, and coronal) using soft tissue and high-resolution algorithms. Consequently, every chest CT is now effectively both a standard, as well as a high-resolution, CT, combining the advantages of each in a single study. This simplifies the ordering process for clinicians. Currently, when ordering a chest CT, there are only two decisions that the clinician needs to make: (1) whether to include expiratory imaging; and (2) whether to perform the study with or without intravenous contrast (as discussed in detail below).

The first important decision is whether to perform expiratory images, noting that normally, a chest CT is acquired in full inspiration. The reason to avoid performing expiratory images for every patient is to decrease medically unnecessary radiation exposure. Typically, an expiratory CT is ordered if there is a clinical concern for an obstructive lung disease (e.g., asthma, COPD, or small airway disease) or if there is a risk of developing bronchiolitis obliterans (e.g., related to lung or bone marrow transplantation) **(Video 28-1A, B)**. Expiratory CT may also be ordered to assess for large airway diseases, such as tracheobronchomalacia. Expiratory CT is currently the best imaging test to demonstrate small airway air trapping and, therefore, is a very useful tool to evaluate potential causes of a "mosaic attenuation pattern" on CT (as discussed in detail in the following sections addressing specific diseases).

The second important decision is whether to perform the study with or without intravenous contrast administration. For the sake of decreasing medically unnecessary radiation exposure, there are very few indications for combined chest CT (i.e., with and without intravenous contrast); these are discussed below. The vast majority of chest CT is performed either with or without intravenous contrast. Generally, to assess the lung parenchyma and airways, no intravenous contrast is required. Assessment of bone lesions also usually does not benefit from intravenous contrast administration. On the other hand, vascular and cardiac assessment is greatly enhanced by intravenous contrast. Moreover, mediastinal and hilar pathology (including lymphadenopathy) and cervical and chest wall masses are more conspicuous and better evaluated using intravenous contrast. For certain thoracic neoplasms and pleural diseases, the enhancement pattern adds information to their diagnostic characterization. Finally, it is worth noting that if dual-energy CT is available, it is possible to produce virtual unenhanced images from an enhanced scan, thus minimizing radiation exposure.

It is important to emphasize that since iodinated CT intravenous contrast is excreted primarily by the kidneys, substantially impaired renal function may preclude intravenous contrast administration and may increase the risk of nephrotoxicity. Additional risks associated with intravenous contrast administration include local effects related to contrast extravasation at the injection site and anaphylactoid reactions, ranging from clinically insignificant symptoms to life-threatening airway or cardiovascular collapse; the latter is very rare with the low-osmolar contrast material currently utilized.

When performing chest CT with intravenous contrast, it is important to inform the radiologist of the clinical indication. Broadly, three different basic protocols can be utilized: (1) standard contrast-enhanced CT; (2) CT angiography (CTA) for visualization of the aorta or coronary arteries; and (3) CTA for visualization of the pulmonary arteries ("pulmonary embolism [PE] protocol").

For a standard contrast-enhanced CT, the injection rate and imaging acquisition relative to the contrast injection are tailored for maximum enhancement of parenchymal organs and soft tissues; consequently, the images are acquired during the venous or equilibrium phase of contrast distribution. This is the standard approach for routine, contrast-enhanced chest CT.

CTA of the aorta and CTA of the coronary arteries are dedicated examinations that are tailored for maximum enhancement of these systemic vessels and are not covered further in this chapter. In particular, cardiac CTA is a thriving application that is usually performed in conjunction with ECG gating to compensate for cardiac motion. CTA of the pulmonary arteries is a well-established application and the current reference standard for the diagnosis of PE **(Video 28-2A, B)**. With this CT technique, contrast injection and imaging acquisition are optimized for maximum enhancement of the pulmonary arteries. This requires a high rate of injection (4–6 mL/s, as opposed to 2 mL/s for regular contrast-enhanced CT) through a large-caliber peripheral IV access (ideally larger than 20G) and very fast volumetric imaging acquisition, usually using contrast bolus tracking to maximize the probability of scanning the patient at the peak of opacification of the pulmonary arteries. When optimally performed, this study allows confident diagnosis of PE in even small subsegmental vessels via direct visualization of vascular filling defects. It also allows accurate assessment of pulmonary vascular caliber and distribution to diagnose pulmonary hypertension, chronic thromboembolic disease, and vasculitides.

CTA of the pulmonary arteries has supplanted conventional pulmonary angiography (except for therapeutic applications) and largely supplanted ventilation–perfusion scanning, although the latter still has an important role in specific clinical settings, such as pregnancy, young patients with normal chest radiographs, or patients with renal insufficiency. This advanced CTA technique not only allows the diagnosis of PE and possible complications, such as pulmonary infarcts, but also accurately reflects the overall clot burden and signs of right ventricular strain, both important prognostic indicators.[5]

An additional, specific advanced application of CT in the chest is the evaluation of the airways. The imaging protocol for CT of the

Video 28-2 **A.** Axial cine images using soft tissue window, demonstrating a massive saddle embolus straddling the bifurcation of the main pulmonary artery. Note that the clot extends to the bilateral lower lobes; oligemia of the right lower lobe is demonstrated. Also note right ventricular enlargement and leftward deviation of the interventricular septum, findings compatible with right ventricular strain. **B.** Same patient as in Video 28-2A. Full-color, coronal, 3D VR (volume rendering) thick slab cine (anterior to posterior), emphasizing cardiovascular structures. This type of reconstruction provides exquisite detail of vascular anatomy and extent of massive pulmonary embolism. *Video available on AccessMedicine.com.*

Video 28-3 Full-color, coronal 3D VR (volume rendering) with 360 degrees of rotation about the long axis of the trachea, emphasizing central airways. **A.** Lower magnification with vertical and horizontal axis for spatial orientation. **B.** Higher magnification without axis. The images demonstrate an irregular, long region of segmental stenosis involving the upper trachea. The patient also presented with multiple pulmonary nodules, at least one of which was cavitary. A diagnosis of granulomatosis with polyangiitis or GPA (previously known as Wegener granulomatosis) was established on tracheal biopsy. *Video available on AccessMedicine.com.*

airways utilizes thin-section (1 mm), volumetric, isotropic images, both in full inspiration and end-expiration. The images are acquired from the base of the tongue to the basilar segmental bronchi to include the entire tracheobronchial tree and larynx. Postprocessing 3D techniques are routinely utilized—that is, volume rendering, minimal intensity projections, and virtual bronchoscopy (Video 28-3A, B). The result is accurate depiction of global, regional, and local large airway disorders, including tracheobronchomalacia, airway stenoses, infiltrative and obstructive neoplasms, and inflammatory conditions.

An important consideration recently receiving much attention is the issue of medical radiation exposure in CT. CT, as any imaging modality that utilizes x-rays, exposes the patient to ionizing radiation, which is a known carcinogen due to stochastic effects, and which, at very high doses, can have deterministic detrimental effects. To understand the true magnitude of the risks associated with radiation exposure related to diagnostic chest CT, it is critical to have a basic understanding of the ways in which radiation dose is measured, as well as how to quantitatively estimate risk based on best available evidence.

Ionizing radiation dose equivalent (which takes into account energy absorbed (J/kg) and the biologic effects of the specific type of radiation) is measured in Sieverts (Sv). Every human is exposed to approximately 3 mSv/year of background radiation from natural and man-made sources. In contrast, a chest radiograph delivers 0.1 to 0.2 mSv, whereas a chest CT performed using standard protocols delivers between 5 and 20 mSv. Deterministic effects are extremely rare below 2000 mSv of acute exposure. Although it is difficult to quantify the magnitude of stochastic effects, the International Commission of Radiological Protection (ICRP) estimates the risk coefficient (additional cancers due to radiation exposure) as 0.00005 per mSv of exposure (i.e., ∼5% per 1000 mSv). In summary, CT delivers a low, but nonnegligible, radiation dose that is unlikely to cause detrimental biologic effects if used in a prudent and medically justifiable manner.

Notwithstanding the relatively small risks, radiologists, engineers, and physicists have made substantial strides to develop reconstruction algorithms and protocol optimization techniques that decrease the radiation dose of thoracic CT to the lowest attainable level and that allows diagnostic-quality images. Among the recent dose-reduction methods that have become widely available are iterative reconstruction techniques, combined with tube current and voltage modulation. The combined effects can generate markedly reduced radiation dose, down to sub-mSv (<1 mSv) levels. This is particularly useful for low-dose screening CT, which is discussed in detail later (see "Lung Cancer Evaluation," below).[6,7]

Finally, CT has a major role for guidance of thoracic interventional procedures, which is described in detail below.

CHEST MRI

MRI is another advanced cross-sectional technique utilized in thoracic imaging. The physics behind MRI are complex and beyond the scope of this chapter. Fundamentally, MRI uses a very strong static magnetic field (main field) generated by superconducting coils in combination with a radiofrequency radiation pulse sequence and variable magnetic field (gradients) to cause oscillation of hydrogen proton nuclear spins. The result is generation of a radiofrequency signal, which is detected and measured. The signal can be also spatially localized to generate an image that can be obtained in any arbitrary plane. Image contrast with MRI depends on the physical properties of the tissue being imaged, as well as on the specific pulse sequence utilized (Fig. 28-12).

MRI has advantages and disadvantages with respect to CT. The main advantage of MRI is the lack of ionizing radiation. CT utilizes high-energy x-rays, whereas MRI utilizes low-energy radiofrequency radiation that has minimal biologic effects and no ionization potential. MRI also has better contrast resolution than CT and is exquisitely

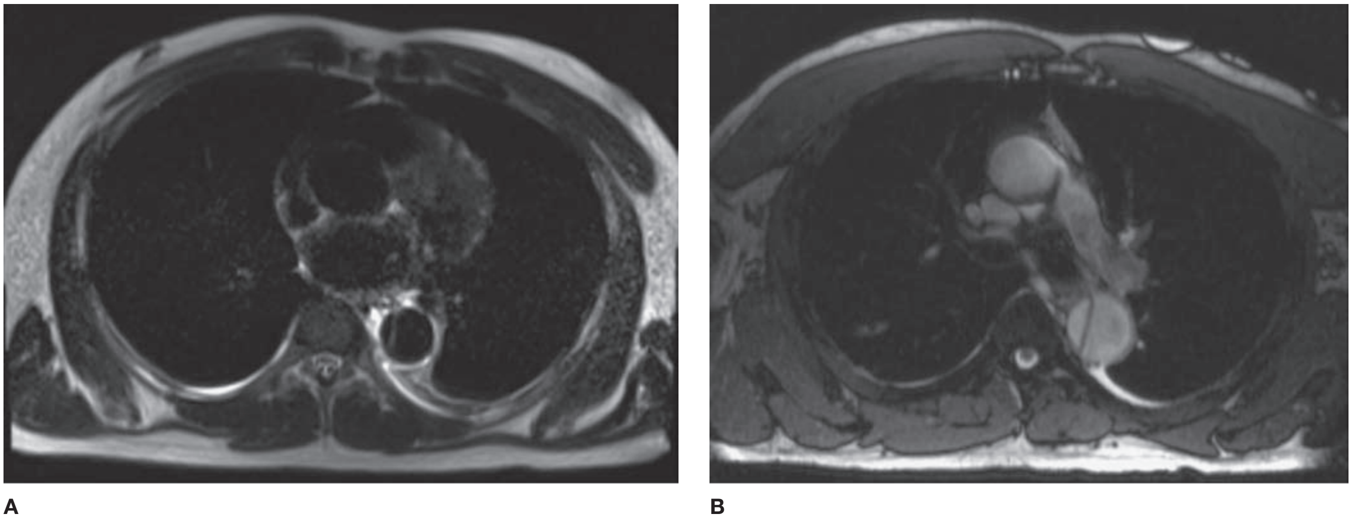

Figure 28-12 MR offers lower spatial resolution than CT; however, it allows better contrast resolution and tissue characterization through utilization of varied pulse sequences that emphasize specific aspects of tissue composition. For example, (**A**) and (**B**) demonstrate a dissection of the descending thoracic aorta. **A.** The blood pool appears black and this is, therefore, termed a "black blood" sequence (typically, spin echo sequence). In contrast (**B**) demonstrates the blood pool to be bright and is, therefore, termed a "bright blood" sequence (typically, steady-state free precession gradient echo sequence). (*continued*)

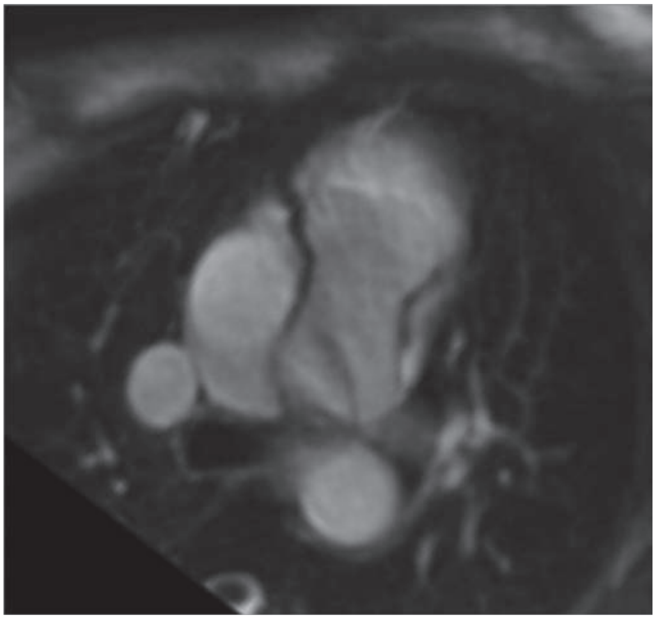

Figure 28-12 (*Continued*) **C.** Different patient with a patent ductus arteriosus (PDA), which causes a linear flow artifact (dark band from the aorta to the left PA).

sensitive in the detection of water and fat. MRI thus provides a greater degree of soft tissue characterization than is possible with CT. Examples of this greater resolution of soft tissue densities include identification of proteinaceous fluid in bronchogenic cysts (Fig. 28-13), which can appear solid on CT, and the presence of fat in confirming thymic hyperplasia as a cause for an anterior mediastinal mass, thereby enabling differentiation from lymphoma. Another advantage of MRI over CT is that iodinated contrast material is not used, obviating the potential problem of CT contrast allergy (Fig. 28-14). In the past, MRI also had the advantage of intrinsic multiplanar imaging, but modern multidetector-based CT now demonstrates similar capability.

The disadvantages of MRI include longer examination time, greater susceptibility to artifacts, lower spatial resolution, and generally very low signal-to-noise ratio in the lung parenchyma, traditionally making it less suitable than CT for optimal pulmonary parenchymal evaluation. However, it should be noted that use of better scanners and newer MRI sequences such as parallel imaging, respiratory gating, Half-Fourier acquisition, and ultra-short echo times are promising for the evaluation of patients who need to undergo multiple serial imaging studies and in whom cumulative radiation exposure is of particular concern, such as in young patients with cystic fibrosis, and for multiple imaging indications in the pediatric population.[8,9]

From a clinical perspective, MRI is still not the first-line modality for assessment of pulmonary diseases, but it is a well-established technique for evaluation of the heart and great vessels, for tissue characterization of mediastinal and chest wall masses, and for dynamic assessment of thoracic wall and diaphragmatic motion. Current applications of MRI, in addition to those mentioned earlier, include evaluation of the brachial plexus, local staging of superior sulcus tumors, evaluation of neurogenic tumors and lesions involving the thoracic spine, and cardiac or paracardiac masses, with early evidence showing promising results in evaluation of lung parenchyma.[10–12]

Recently, considerable interest has arisen in the use of hyperpolarized gases, including helium-3 and xenon-129, for MRI of the lungs. Hyperpolarized gas MRI can provide detailed images of pulmonary ventilation, as well as information on lung microstructure, beyond the resolution of CT. The latter includes measurements of alveolar

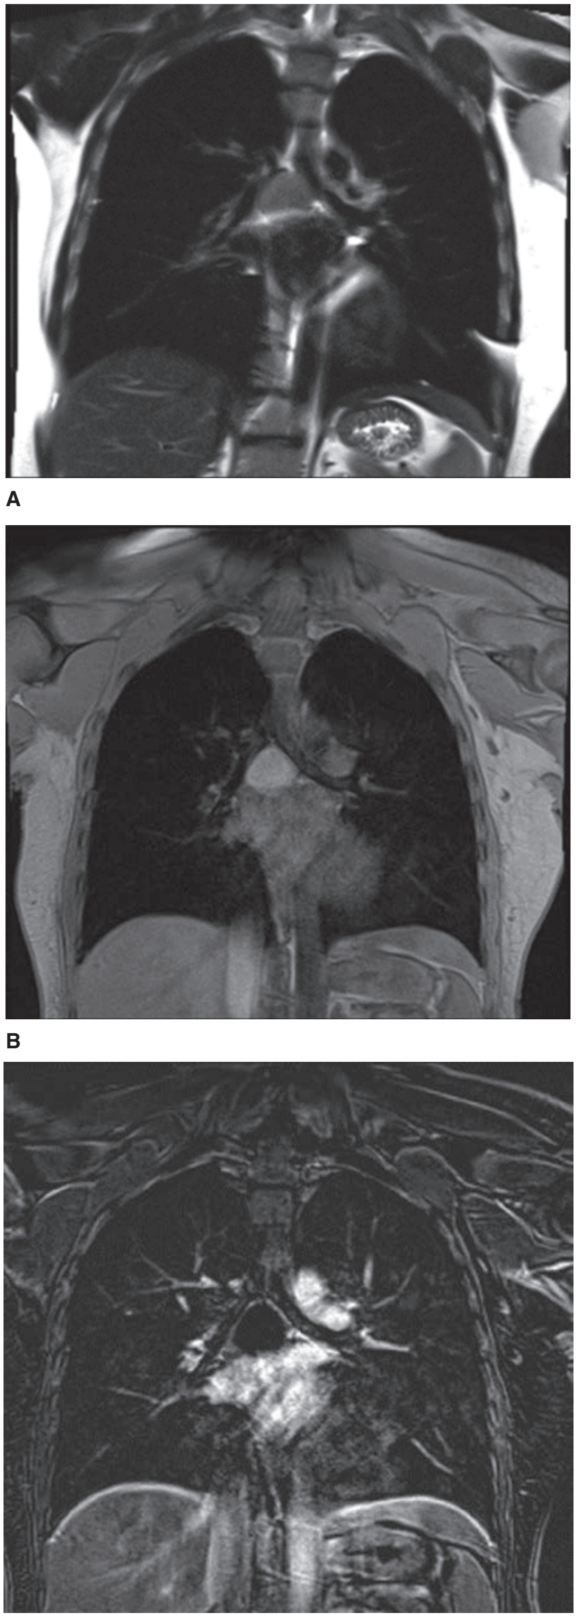

Figure 28-13 The superior contrast resolution of MRI allows for confident characterization of complex cystic lesions that are indeterminate on CT due to overlapping tissue density with solid lesions. An indeterminate mediastinal lesion detected on a chest CT in a 21-year-old female demonstrates intermediate T2 signal intensity on coronal T2 HASTE sequence (**A**), high T1 signal intensity on coronal T1 sequence before contrast injection (**B**), and no internal enhancement on T1 post contrast subtraction images (**C**), consistent with protein containing bronchogenic cyst.

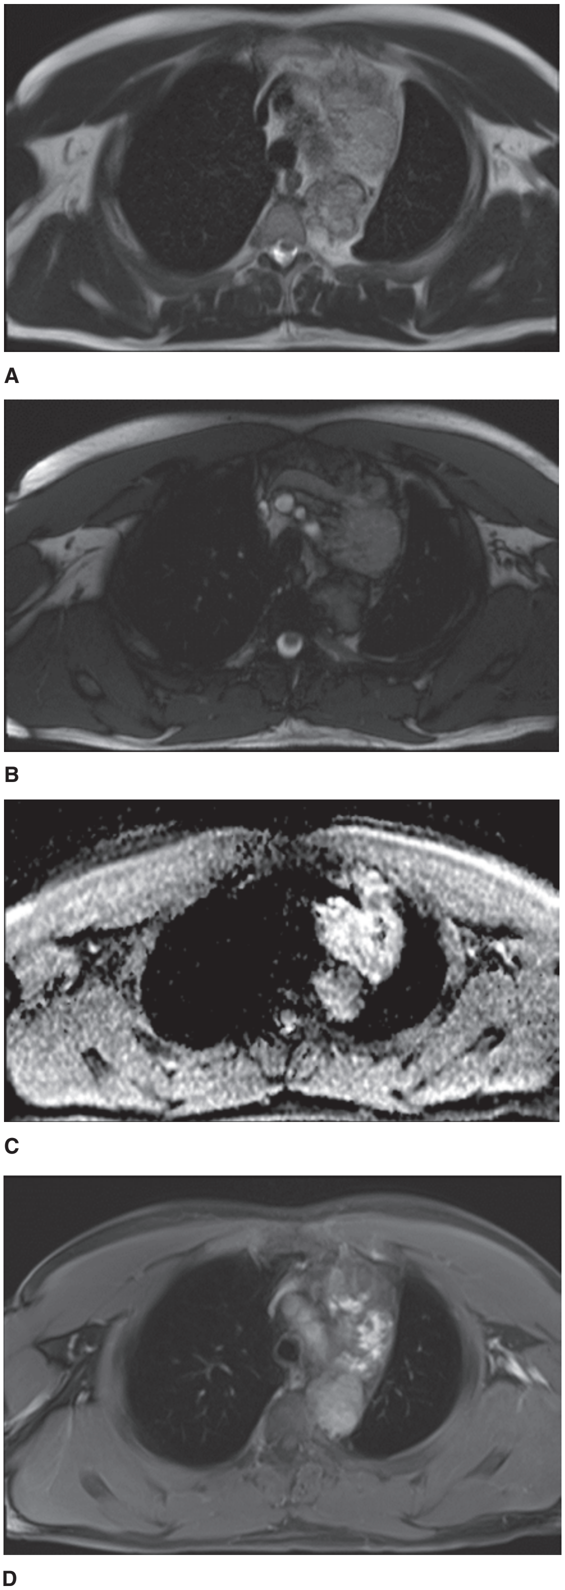

Figure 28-14 As opposed to CT, MRI allows acquisition of contrast enhanced images at multiple time points without the additional radiation exposure. Additionally, diffusion-weighted imaging allows characterization of cellular density thus facilitating better tissue characterization. A young patient with a large soft tissue mediastinal lesion demonstrating high signal on both T2 (**A**) and bright blood steady-state free precession (**B**) images without significant restricted diffusion on apparent diffusion coefficient (ADC) sequence (**C**) and showing gradual slow filling of the lesion on contrast-enhanced sequences (**D**) allowing a confident diagnosis of benign hemangioma.

size and alveolar–capillary membrane thickness. Nonetheless, to date, hyperpolarized gas MRI remains investigational.

PET, PET/CT, AND PET/MRI

PET is a nuclear medicine emission tomographic technique (see Chapter 30), in which an intravenously administered radionuclide that decays via positron emission (most often ^{18}F coupled to deoxyglucose [FDG]), generates an annihilation event (when a positron collides with an electron and two antiparallel 511-keV photons are simultaneously generated). The event is registered by coincidence detectors, allowing localization of the origin inside the body. Because FDG is very similar to glucose in biodistribution and pharmacokinetics, it effectively concentrates in tissues that have a high metabolic rate and, therefore, increased glucose uptake—namely, the brain, heart (in the non-fasting state), and many neoplasms; in addition, FDG is concentrated where it is metabolized and excreted: the liver, kidneys, and urinary collecting system. FDG-PET images essentially map the biodistribution of glucose in the body. CT and MRI may be performed almost simultaneously with PET in dedicated hybrid scanners (PET/CT and, more recently, PET/MRI). The higher spatial resolution of these modalities is helpful for localization of the abnormal PET signals in fused imaging analysis (Fig. 28-15).

It is a common misconception that PET/CT is specific for cancer diagnosis. In reality, it is not. Many normal tissues and inflammatory or infectious processes have a high metabolic rate and high glucose uptake and, therefore, are also avid on PET images. Moreover, many cancers are not highly metabolically active or are not FDG avid, and these may not be detectable by PET imaging. A typical example in the chest is an indolent adenocarcinoma in situ (AIS), formerly called bronchioloalveolar cell carcinoma (BAC), or certain subtypes of carcinoid tumors.

The strength of PET/CT relies on its ability to accurately stage malignancy if the primary neoplasm is FDG-avid. In this context, it is superior to CT or MRI because it may demonstrate small metastases in normal-sized structures, particularly lymph nodes, which would not be detectable by CT or MRI. PET/CT is, therefore, routinely employed for staging of malignancies such as lung cancer, lymphoma, head and neck carcinoma, and esophageal carcinoma.[13] Additionally, PET/CT increasingly plays a role in detection of inflammatory disorders such as detection of myocarditis, myocardial sarcoidosis, or large vessel vasculitis.[14]

ULTRASOUND

Ultrasound (US) has a more limited but evolving role in thoracic imaging. The primary limiting factor is that both the thoracic cage and the lungs act as reflecting interfaces that block penetration of the US mechanical wave. However, US has been shown to be useful for specific applications, such as detection of pneumothorax or pneumonia, as well as in evaluation of pleural effusions and chest wall pathology (Fig. 28-16) especially with increasing availability of hand-held devices, resulting in increased use in emergency departments, in intensive care units, in the setting of trauma, and in places with limited imaging resources. In addition, it is useful in guiding imaging interventions.[15] Thoracic US is discussed in detail in Chapter 29.

IMAGE-GUIDED INTERVENTIONS

Image-guided interventions have dramatically changed the diagnosis of thoracic diseases that require tissue sampling for pathologic confirmation. They have also impacted the treatment of many benign and malignant diseases. Increasingly, image-guided biopsy procedures are being performed for tumor genotyping to guide more targeted, personalized therapies. Half a century ago, surgical procedures were necessary to obtain tissue from the lungs, mediastinum, or chest wall. Surgical biopsies may require hospitalization, are costlier, and carry small but measurable rates of morbidity and

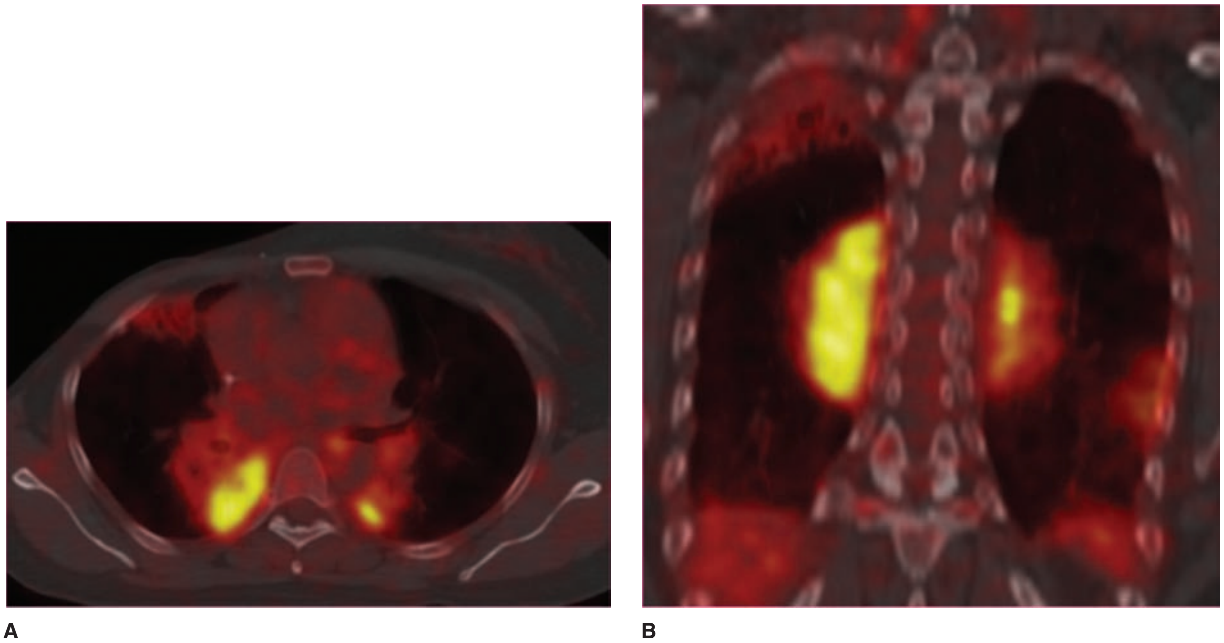

Figure 28-15 Fusion images combining CT and PET data in a patient with multifocal MALT pulmonary lymphoma. (**A**) Axial and (**B**) coronal images demonstrate that the areas of consolidation in the posterior medial lungs also demonstrate high FDG uptake, thus appearing bright yellow in this color scheme, a typical feature of metabolically active lymphomas.

Figure 28-16 US allows detection of even small amounts of pleural effusion and adjacent lung atelectasis. Transverse (**A**) and sagittal (**B**) views of the lower thoracic pleural space demonstrate moderate amount pleural effusion with adjacent passive atelectasis. A subsequently obtained steady free precession MRI (**C**) one day later demonstrates similar findings.

mortality. Currently, most diagnostic procedures can be performed percutaneously or via bronchoscopy in a minimally invasive fashion. Bronchoscopy and endobronchial interventions are described in Chapters 33 and 34 (Fig. 28-17).

Percutaneous transthoracic biopsy (PTB) may be performed via a variety of imaging guidance systems, most commonly CT, but also fluoroscopy or US (Videos 28-4 and 28-5A, B). Different

Video 28-4 4D cine using custom window. The images are acquired sequentially at the same level and used for guidance in performing a transthoracic fine-needle aspiration (TTNA). The needle was advanced to perfectly engage a small RUL nodule (9 × 7 mm). Final diagnosis was primary adenocarcinoma. *Video available on AccessMedicine.com.*

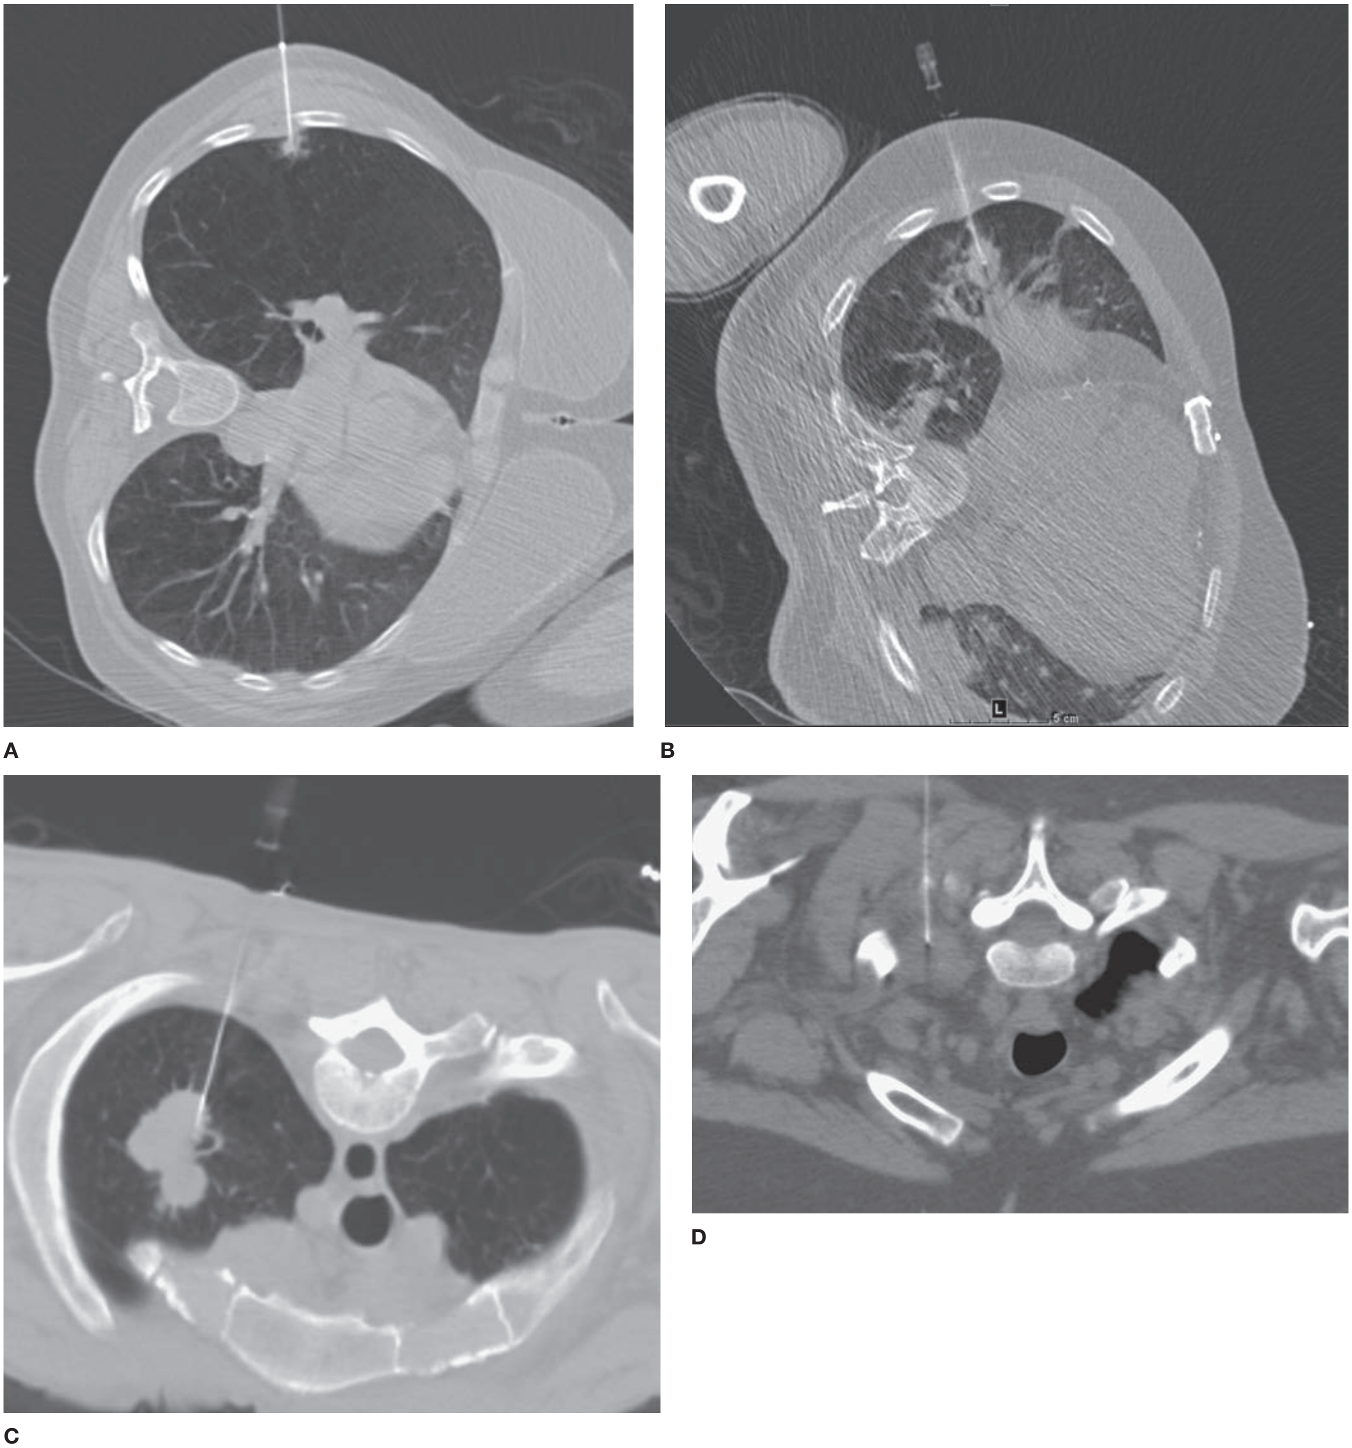

Figure 28-17 CT offers accurate, near–real-time localization of lesions for image-guided percutaneous small-needle biopsy. **A.** CT-guided biopsy of a small (0.8 cm) RUL spiculated nodule, a biopsy-proved adenocarcinoma; (**B**) CT-guided biopsy of a larger (1.8 × 2.2 cm) RML nodule, biopsy-proved small cell carcinoma; (**C**) CT-guided biopsy of a lobulated LUL mass (3.0 × 4.2 cm), biopsy-proved adenocarcinoma; (**D**) CT-guided biopsy of a soft tissue mass in the left superior sulcus, biopsy-proved malignant neurogenic neoplasm.

needle types, lengths, and calibers may be chosen according to the clinical question and lesion characteristics. As a general rule, superficial chest wall lesions can be accessed via US or CT; pleural, pulmonary, and anterior mediastinal lesions are accessed via CT; central hilar lesions and deep mediastinal masses are not accessible via PTB.

There are two basic types of PTB: fine-needle aspiration (FNA) and automated core needle biopsy (CNB). In FNA, a small-caliber needle (25–22G) is inserted through the chest wall into the lesion via CT guidance. The tip of the needle is positioned inside the lesion. Negative pressure (suction) is applied via a syringe, and fluid or clusters of cells are aspirated. The material obtained via FNA is processed using cytopathology techniques, and specific stains and molecular tests can be performed.

In contradistinction, CNB uses a larger coaxial system in which a 19G introducer (outer core) hollow needle is advanced to the pleura or close to the edge of the lesion, followed by introduction of a 20G automated inner core biopsy needle, which is advanced to the lesion. An automated mechanism is then activated, rapidly moving the needle forward and filling the needle trough, or shallow receptacle, with cylindrical "cores" of tissue. The outer sheath instantly moves forward to cut the tissue and keep it in the trough. This process is repeated several times as multiple tissue cores are obtained. The material obtained via CNB is processed using surgical pathology techniques. Both FNA and CNB provide material for microbiology studies, including stains and cultures.

From a diagnostic perspective, FNA is almost equally accurate to CNB for diagnosis of malignant diseases, although CNB is superior for diagnosis of benign diseases. FNA sensitivity for diagnosis of lung cancer is 80% to 95%, and the rate is higher if onsite cytopathology is available and the procedure is approved and performed by experienced radiologists. Limitations of FNA include diagnosis of indolent or low-grade malignancies (for which more tissue or histoarchitecture is required for confident pathologic diagnosis) and inflammatory or infectious diseases—scenarios in which CNB is superior. The advantage of FNA over CNB is a lower complication rate and the capacity to engage and sample very small lesions that would otherwise be inaccessible.

Lesion location, lesion size, and patient body habitus are major determinants utilized by the radiologist in deciding the optimal biopsy technique. All other factors being equal, large pulmonary masses (>3 cm), pleural masses, chest wall masses, and large anterior mediastinal masses are best sampled via CNB. On the other hand, small pulmonary nodules (as small as 0.8 cm), pulmonary nodules in highly mobile regions (posterior or anterior lung bases), and small lymph nodes are best approached using FNA.

Complications related to PTB are relatively infrequent, but occasionally can be life-threatening. For mediastinal, chest wall, and pleural biopsies, the major risk is hemorrhage, with infection and postprocedural pain following in incidence. Major vascular injury is rare, but it has been reported following biopsies of mediastinal masses. For lung biopsies, the major risk is pneumothorax, followed by hemorrhage, infection, and, rarely, air embolism. While air embolism is the rarest complication, with a reported frequency of 0.05% to 0.10%, it is potentially the most life-threatening, due to its unpredictable nature and difficult treatment. Pneumothorax rate varies widely according to institution, and estimates from 5% to 50% have been reported. Most postprocedural pneumothoraces are small and not clinically significant; however, in up to 5% to 10% of patients, a large or symptomatic pneumothorax requires chest tube placement.

The following precautions are advised to minimize the risks associated with PTB: (1) critical appraisal of the clinical need for biopsy and whether PTB is the best approach; (2) thorough preprocedural laboratory assessment to ensure normal platelet count and function and normal coagulation profile. Anticoagulants and antiplatelet medications should be discontinued after conferring with the referring physician; (3) performance or supervision of the procedure by an experienced radiologist; (4) careful preprocedural planning, choosing a patient position and needle trajectory that minimizes the risk of vascular injury and decreases the distance to the lesion; (5) proper biopsy technique with purposeful, fast, accurate needle motion, confirming with imaging the needle location, depth, and relationship to the lesion prior to, and after, each needle movement; (6) minimization of the effects of patient motion by tracking chest wall movement and advancing the needle in a consistent phase of the respiratory cycle; and (7) intraprocedural maneuvers such as introduction of saline solution into the outer core of the biopsy needle during exchanges, to provide a water seal, and positioning the patient in a lateral decubitus position with the biopsied lung in dependent position.[16–20]

Therapeutic, percutaneous, image-guided techniques also have been increasingly accepted and utilized. These range from percutaneous chest tube or drain placement to preoperative localization of lung lesions and ablation of neoplasms utilizing microwave or cryoablation techniques. The same principles of imaging guidance described for PTB apply for percutaneous therapeutic interventions. Given their complexity and the availability of alternative treatment options (such as surgery or radiation therapy), their use is best reserved for selected patients following discussion with multidisciplinary healthcare teams.

OBSTRUCTIVE LUNG DISEASES, WITH EMPHASIS ON COPD

Pulmonary ventilation, as is the case for pulmonary perfusion, is not homogeneous; it is affected by gravity, airway caliber, and chest wall mechanics. Ventilation is greater at the bases in the erect position due to greater regional changes in lung volume with inspiration, but the apical–basal ventilation gradient is smaller than the perfusion gradient (noting that perfusion is also greater at the bases). Therefore, the ventilation–perfusion ratio ($\dot{V}/\dot{Q}$) is greater at the apices in the erect patient. A similar pattern occurs in the supine patient between the dependent posterior and the nondependent anterior lungs, albeit to a lesser extent. Changes in relative ventilation affect the relative volume and average density of the lung parenchyma and, therefore, can be depicted by imaging.

Chronic obstructive pulmonary disease (COPD) is a complex group of disorders characterized by chronic, progressive airflow limitation that is not fully reversible and is associated with a range of pathologic changes in the lungs (Chapters 37 and 38). In addition, significant extrapulmonary effects caused by chronic inflammation and structural changes are observed. The chronic airflow limitation is caused by a mixture of small airway disease (obstructive bronchiolitis) and parenchymal destruction (emphysema). In addition, large airway inflammation, with increased sputum production and cough, is the hallmark of chronic bronchitis, part of the spectrum of COPD. The relative contributions of these components vary substantially from patient to patient. The presence and extent of each component has the potential to affect clinical presentation, disease severity, prognosis, and therapeutic response. COPD is strongly related to smoking. It has emerged as the third leading cause of death in the United States.

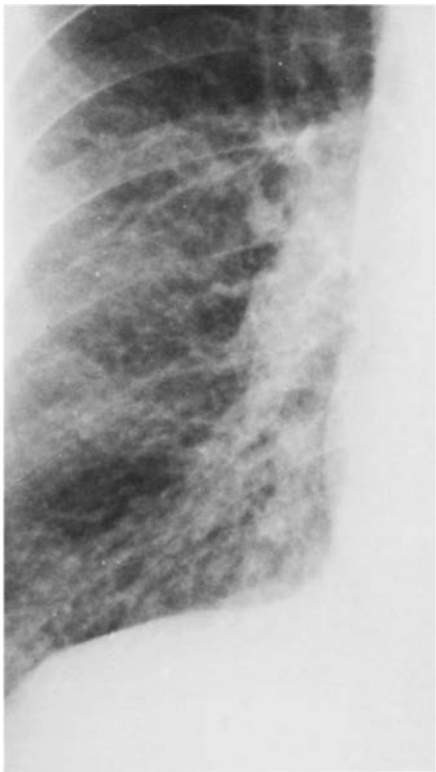

Figure 28-18 Detail view of the lung parenchyma in a PA radiograph, demonstrating increased bronchovascular markings, which are particularly prominent throughout the central lung fields. The patient has COPD with predominant chronic bronchitis. Hyperaeration is minimal.

Another clinically prevalent obstructive lung disease is asthma, which is an inflammatory condition affecting mainly small airways, with increased mucus production, airway wall inflammation, and reduced luminal caliber (Chapters 43–45). Asthma differs from COPD from an imaging standpoint in that the clinical manifestations are usually intermittent and reversible, and the degree of hyperinflation tends to be mild, except in severe, long-standing disease.[21,22]

Chest radiographs are not particularly useful in diagnosing obstructive lung disease. In early disease, these are generally normal, as is the case with most asthmatic patients. In more severe or advanced disease, hyperinflation ensues and can be detected radiographically. The classic radiographic appearance of hyperinflation is manifested by increased radiolucency of the lungs; low, flat diaphragms; exaggerated verticality of the heart; increased AP diameter of the chest; and widening of the retrosternal lucent space. Of all these criteria, diaphragmatic flattening is probably the most reliable in supporting a diagnosis of COPD, as it is likely associated with severe emphysema. Care must be taken in making a diagnosis, however, as hyperinflation can be simulated radiographically when a healthy person exerts a maximal inspiratory effort. The lungs also appear hyperinflated in very slender persons. Therefore, it is unwise to make the diagnosis of emphysema solely on the basis of the radiographic finding of hyperinflation (Figs. 28-18 and 28-19).

Radiographic evaluation of the pulmonary vessels may also support a diagnosis of emphysema. Two distinctly different vascular patterns have been identified in patients with chronic bronchitis and emphysema: arterial deficiency and increased lung markings. Patients who show the arterial deficiency pattern often have panlobular emphysema and manifest the clinical syndrome of the "pink puffer." Those who have the pattern of increased lung markings often have centrilobular emphysema and manifest the "blue bloater" syndrome. Notably, these radiographic findings occur relatively late in the clinical course of emphysema. Moreover, these findings are not specific and must be considered in the clinical context provided.

Similarly, the diagnosis of chronic bronchitis is a clinical one, based upon a history of chronic cough and sputum production and supplemented by characteristic abnormalities in pulmonary function tests. The radiograph rarely provides substantive help. Vascular markings throughout the lung fields are sometimes prominent, but this finding is nonspecific.

CT, on the other hand, is capable of demonstrating the pathologic changes associated with COPD, including large and small airway inflammation and parenchymal destruction (emphysema). Three

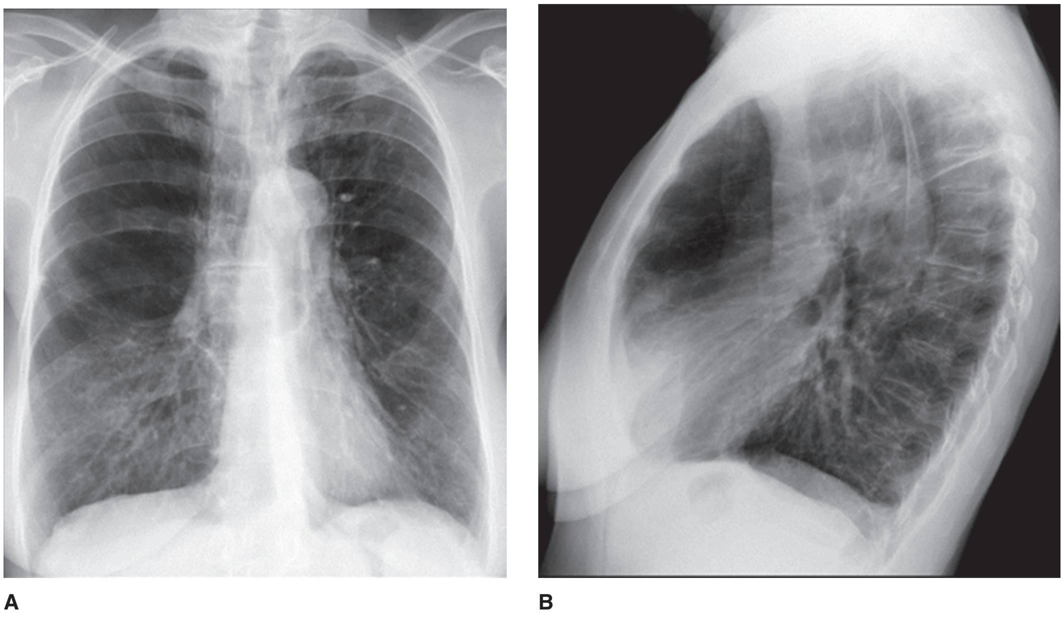

Figure 28-19 (**A**) PA and (**B**) lateral of a patient with severe emphysema-predominant COPD. Salient features are upper lobe predominant hyperinflation (denoted by flattening of the diaphragms and increased craniocaudal and anteroposterior diameters of the chest), hyperlucency of the parenchyma, and increased interstitial markings.

basic types of emphysema can be detected by CT—centrilobular, paraseptal, and panlobular.

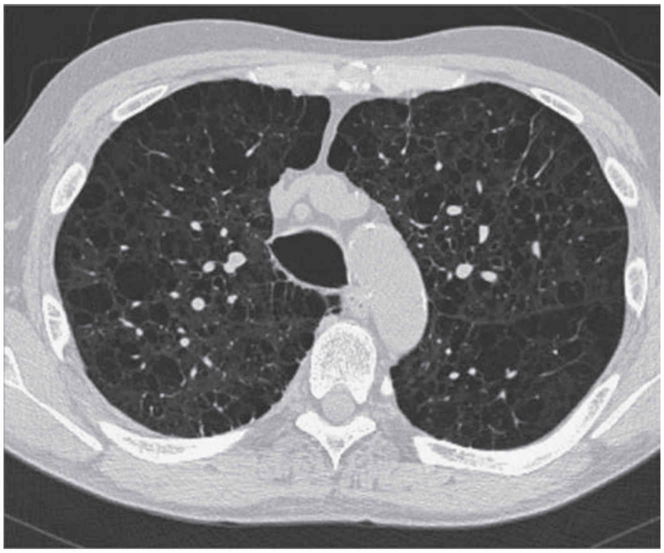
Centrilobular emphysema is characterized by focal areas of lucency within the centers of secondary pulmonary lobules and without perceptible walls. The lobular arteries and bronchi are maintained, appearing as small dots within the involved secondary lobules. These features help to differentiate the holes of centrilobular emphysema from the cysts of cystic lung disease, as the latter have thin walls and are devoid of internal structure.

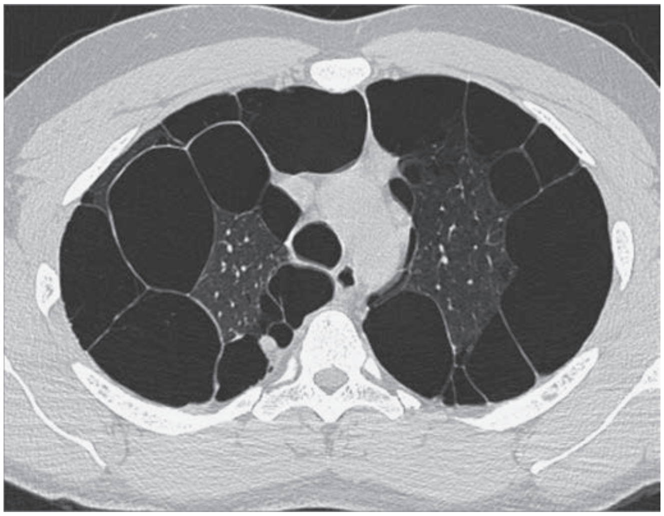
Paraseptal emphysema occurs peripherally, adjacent to the visceral pleura, and adjacent to the bronchovascular interstitium. Centrilobular and paraseptal emphysema are both associated with smoking and, therefore, tend to coexist, although the contribution of each form for the total amount of emphysema varies substantially. There is generally upper lung predominance, except in very severe disease. The extreme form of paraseptal emphysema is evident as bullous disease, in which the cystic spaces may become large enough to compromise lung mechanics due to their mass effect.

Finally, panlobular emphysema is a distinct entity in which there is diffuse hyperlucency, hypovascularity, and a paucity of interstitial markings, often with a basilar predominance. These important findings can be overlooked, even in patients with marked panlobular emphysema, since there are no discrete holes, as is the case in centrilobular emphysema. This form of emphysema is less likely associated with smoking, and more likely associated with α1-antitrypsin deficiency, a genetic condition that can be exacerbated by smoking (Figs. 28-20 and 28-21).[23–25]

Large airway inflammation as a manifestation of chronic bronchitis may be suggested by the presence of airway wall thickening, the diagnosis of which is somewhat subjective, although several studies have described computer-assisted quantitative measurement methods. Mucoid impaction is a reliable indicator of airway inflammation, but it is not specific for COPD, as it can be seen in the setting of asthma, acute bronchitis, or bronchopneumonia.

Small airway inflammation was previously the most difficult component of COPD to diagnose by imaging. While it is still not possible to directly image inflammation of the very distal airways, expiratory CT now provides the best technique to indirectly diagnose small airway disease. The presence of small airway disease may be inferred by the presence of expiratory air trapping. Normally, the average CT attenuation of aerated lung parenchyma increases in expiration due to volume averaging of voxels that contain less air. In contrast, with air trapping, the increased lung attenuation with expiration is not observed. Thus, in the presence of small airway disease,





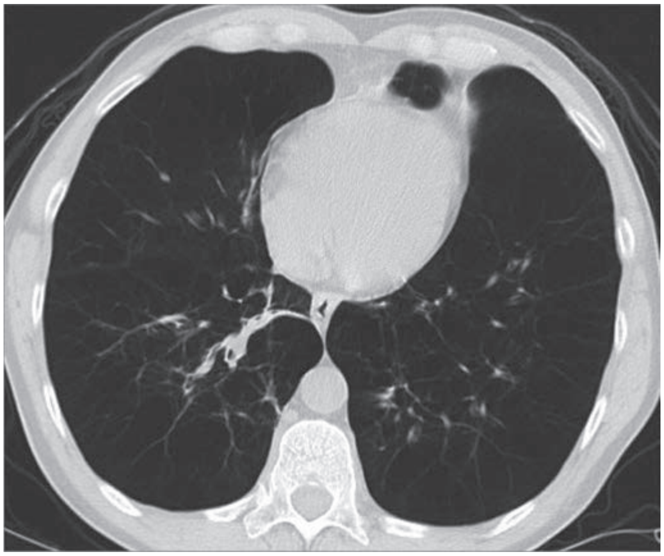


Figure 28-20 Three different phenotypes of emphysema. **A.** Centrilobular. **B.** Paraseptal. **C.** Panlobular. The images demonstrate different configurations and anatomic distribution of parenchymal destruction. (**A**) and (**B**) are typically smoking-related, whereas the patient in (**C**) had α1-antitrypsin deficiency.

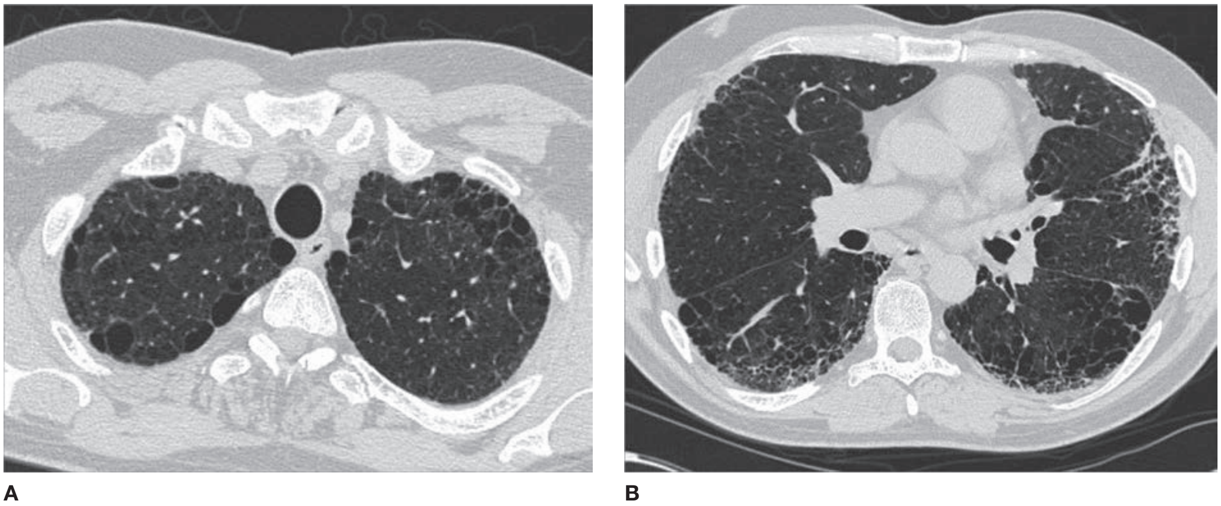

Figure 28-21 Severe emphysema and pulmonary fibrosis in a long-term smoker. **A.** Paraseptal and centrilobular emphysema involving the upper lung fields; (**B**) Additional presence of traction bronchiectasis, peripheral reticulation and honeycombing—features of fibrosis. Smoking-related pulmonary fibrosis is associated with COPD and resembles UIP from an imaging standpoint.

a "mosaic attenuation pattern" is demonstrated on CT images obtained in end expiration, with the darker (lower attenuation) areas corresponding to areas of regional air trapping. Up to 25% of the lung may show air trapping in healthy subjects (typically at the lung bases); higher degrees of air trapping correlate with decreases in functional parameters assessed with pulmonary function testing, such as residual volume (RV) or functional residual capacity (FRC) (Figs. 28-22 and 28-23).

A major trend in the imaging of COPD is the development of semi-quantitative approaches and quantification techniques for COPD phenotyping. In 2015, a semi-quantitative analysis was proposed in a statement by the Fleischner Society, aiming to better define the phenotypic abnormalities that can be identified on CT in subjects with COPD. The goal of the statement is to categorize COPD into distinct structurally and functionally defined subtypes, thereby allowing a personalized approach to treatment. The statement defines emphysema on imaging as the presence of >6% of pixels measuring <–950 HU by quantitative CT and/or visual identification. Airway-predominant subtypes of COPD are defined by evidence of obstructive physiology on pulmonary function testing, with <6% of pixels measuring <–950 HU by quantitative CT. Quantitative CT analysis can be used to determine the severity of emphysema and the magnitude of expiratory gas trapping. Associated features that may affect prognosis or risk of exacerbations also are emphasized, including interstitial abnormalities and pulmonary arterial enlargement.[26] These categories are summarized in Table 28-1.

For quantitative imaging, strict standardization of the scanning technique is required. Sophisticated computer algorithms are also required to accurately separate the lung parenchyma, central airways, central vasculature, mediastinum, and chest wall structures, based upon attenuation characteristics and geometric constraints; the algorithms employ thin-section, isotropic volumetric data sets primarily obtained using CT. A variety of computational methods can then be applied to detect several disease patterns and characterize their extent and distribution. These methods can be used for both diagnosis and disease quantification, as well as for assessment of prognosis and response to therapy.[27–29]

It has been established that "attenuation masks" that separate all low-attenuation voxels in the segmented lung parenchyma (e.g., areas of <–950 HU), not including central airways, can accurately quantify the volume of emphysema compared with the reference

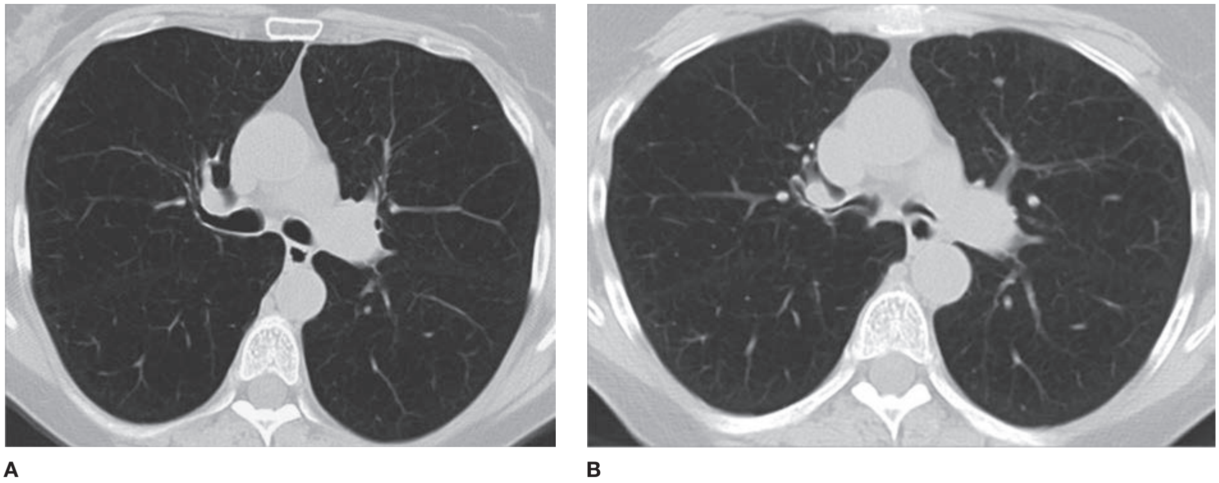

Figure 28-22 (**A**) Inspiratory and (**B**) expiratory CT images at the level of the mainstem bronchi, demonstrating dynamic expiratory collapse of the central airways, indicative of bronchomalacia, a common association with COPD.

AL GRAWANY

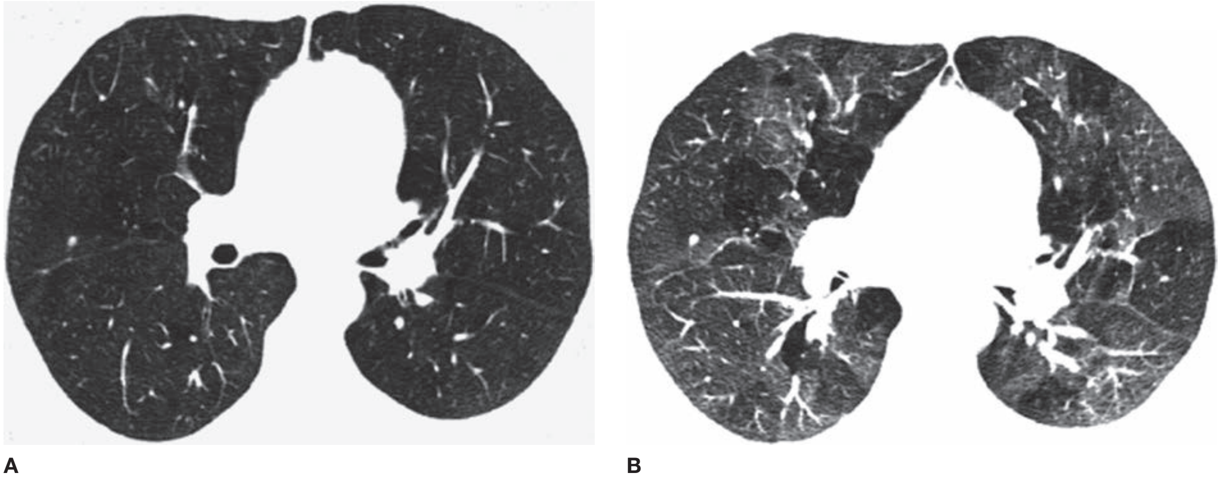

Figure 28-23 (**A**) Inspiratory and (**B**) expiratory CT images demonstrate the presence of mosaic attenuation (i.e., geographic areas of low parenchymal attenuation interspersed within normal, higher-attenuation areas in expiration), characteristic of air trapping. This patient had a diagnosis of bronchiolitis obliterans.

TABLE 28-1 Phenotypes of Emphysematous Destruction and Airway Changes Seen in COPD Patients on CT Imaging Defined by the Fleischner Society

Emphysema

1. Centrilobular
    a. Trace-minimal amount of lucencies involving <0.5% of the lung
    b. Mild-scattered lucencies involving 0.5%–5% of the lung
    c. Moderate: lucencies involving >5% of the lung
    d. Confluent: coalescent lucencies that may span several secondary lobules without hyper-expansion of secondary pulmonary lobules or distortion of lung architecture
    e. Advanced destructive emphysema: panlobular lucencies with hyperexpansion of secondary pulmonary lobules and distortion of lung architecture
2. Panlobular emphysema—lower lobe predominant with generalized acinar destruction, most commonly associated with α1-antitrypsin deficiency
3. Paraseptal
    a. Mild: juxta-pleural or peri-fissural small lucencies measuring <1 cm
    b. Substantial: juxta-pleural or peri-fissural large lucencies measuring >1 cm

Airway disease—may be associated with emphysema or present as the predominant expression of COPD

1. Bronchial disease—segmental or subsegmental wall thickening
2. Small airway disease (SAD)—inflammatory SAD, identified by the presence of peripheral centrilobular micronodular opacities; obstructive SAD, identified by gas trapping on expiratory CT in the absence of significant emphysema

Associated features

1. Large airway disease—presents with tracheobronchomalacia, saber sheath trachea, or tracheobronchial diverticula
2. Interstitial abnormality—patchy ground glass or presence of subpleural reticulation
3. Pulmonary arterial enlargement—a sign suggestive of pulmonary hypertension
4. Bronchiectasis

standard of pathologic assessment. Such CT measures of emphysema demonstrate strong correlation with functional metrics that denote obstruction (e.g., FEV1/FVC, %). Moreover, it is possible to measure the thickness of the central airways (to the fifth or sixth generation) as a quantitative metric in chronic bronchitis. In addition, small airway disease can be indirectly measured using quantification of expiratory air trapping, which can be accomplished via several different techniques. The simplest method uses attenuation masks in expiration. Voxels measuring less than −856 HU on expiratory CT are considered areas of air trapping. This attenuation threshold has been validated in multiple publications. More sophisticated techniques take into account how much each voxel varies in attenuation between full inspiration and end expiration (at FRC). The latter approach requires mathematical, nonrigid registration techniques that track individual voxel motion and regional volume changes between data acquired at two different time points, allowing for a one-on-one correspondence between lung voxels in inspiration and expiration.[30–32]

While these sophisticated, quantitative applications are still largely investigational, they will likely reach the clinical realm in this decade. Studies continue to validate the superiority of quantitative imaging over standard qualitative assessment of thoracic imaging studies, demonstrating improved correlations with disease severity and functional impairment. Such quantitative imaging will ultimately provide better tools to estimate prognosis and monitor the efficacy of therapy.

INTERSTITIAL LUNG DISEASE

Interstitial lung disease (ILD) is a broad and complex topic, with many distinct and unrelated clinical entities potentially contributing to a single imaging pattern. Their detailed pathophysiology is described elsewhere. The focus of this discussion is the contribution of imaging to the differential diagnosis of ILD, emphasizing the most common and clinically relevant diseases.

The chest radiographic pattern of interstitial disease differs from the pattern of alveolar disease in that with interstitial disease, the imaging pattern tends to be discrete and sharp, rather than fluffy and irregular; the lesions tend to be diffuse, rather than localized. In addition, coalescence is not a typical feature in ILD, and the small opacities are characteristically nodular, reticular, or linear. Large masses or consolidations are not characteristic of the interstitial pattern (Fig. 28-24).

In and of itself, the recognition of an interstitial pattern on chest radiographs is not specific for a particular diagnosis. Most often a CT is necessary for further characterization. However, two

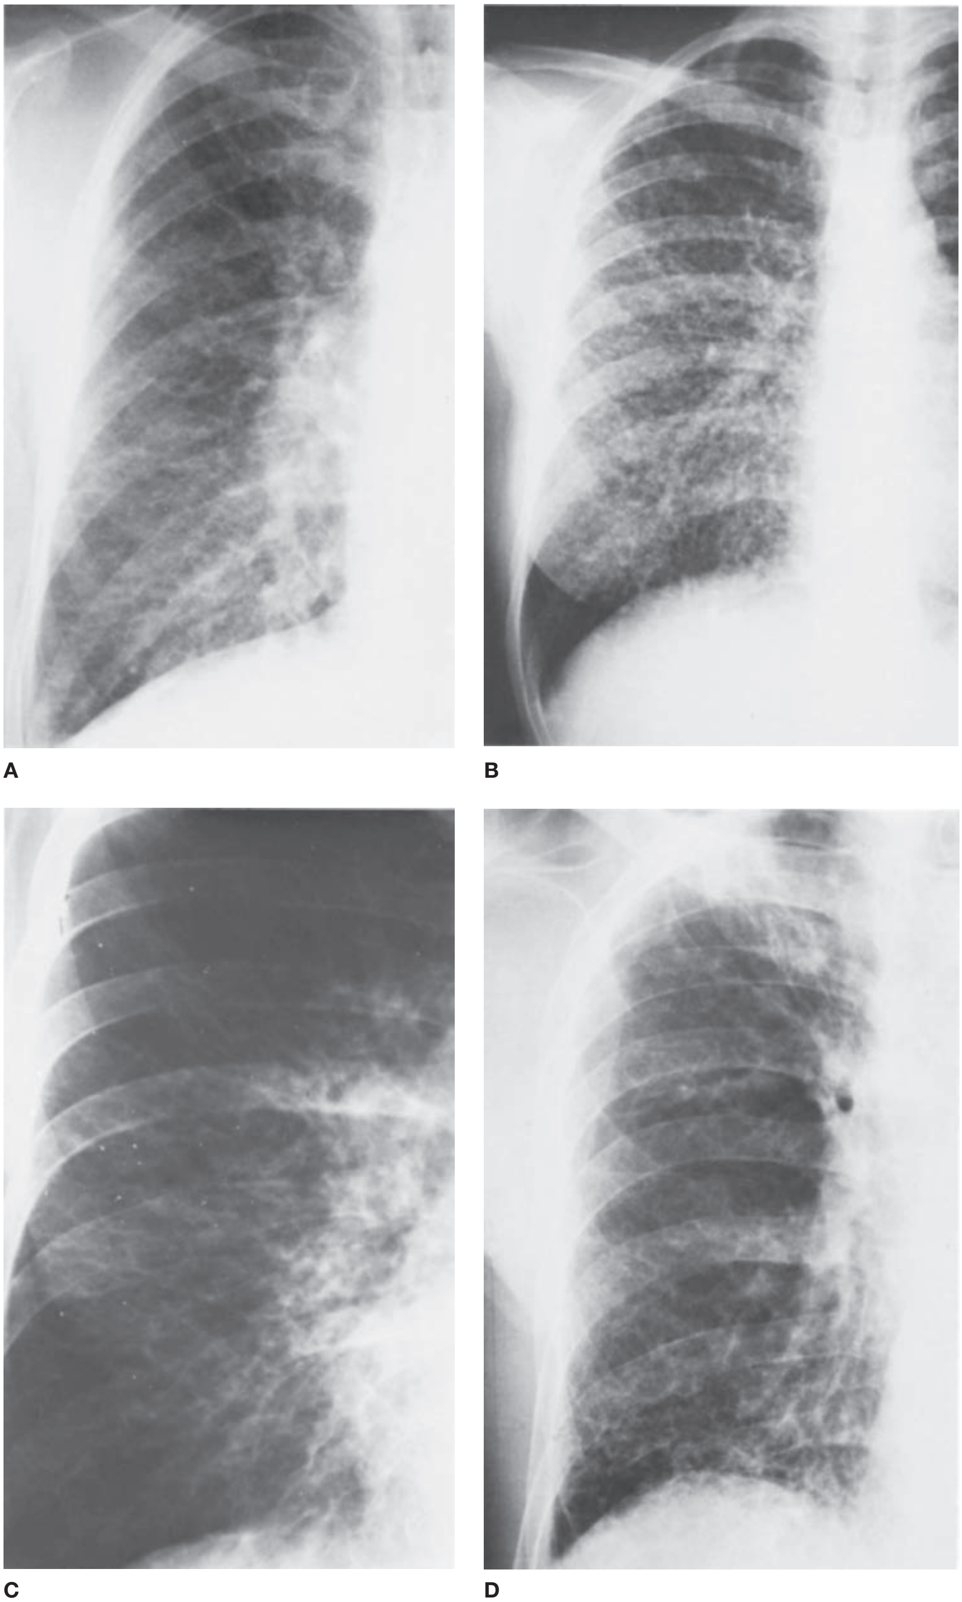

Figure 28-24 Radiographic patterns of interstitial disease. **A.** Linear interstitial pattern produced by interstitial pulmonary edema. The pattern is caused by fluid in the axial and septal interstitial spaces of the lungs, particularly in interlobar septae. **B.** Nodular interstitial pattern due to sarcoidosis. Multiple small, discrete nodules involve both lung fields diffusely. Adenopathy is absent. **C.** Lymphangitic spread of neoplasm. The linear interstitial pattern was caused by metastatic carcinoma of the pancreas. **D.** Reticular interstitial lung pattern. The pattern is most marked at the bases and is characteristic of idiopathic pulmonary fibrosis or collagen vascular disease, particularly scleroderma (as in this patient).

observations that may provide useful insight into the likely diagnosis are the temporal course and distribution of disease.

Most interstitial diseases have a chronic, progressive course. Therefore, recognition of an acute interstitial pattern, that is, development and rapid evolution over hours or a few days, is strongly suggestive of interstitial pulmonary edema. This is even more likely if ancillary findings indicative of congestive heart failure or volume overload are present, such as cardiomegaly, pleural effusions, and widening of the vascular pedicle in the mediastinum. Occasionally, a rapidly changing interstitial pattern represents atypical pneumonia due to *Pneumocystis jiroveci*, cytomegalovirus, or *Mycoplasma*. The acute interstitial disorders typically cause a radiographic linear or reticular pattern, which is characterized by prominent Kerley lines throughout the lungs.

In his original description in 1951, Kerley associated thin, radiographic parenchymal opacities with left ventricular failure.

Initially, Kerley lines were thought to represent swollen pulmonary lymphatics. It is now recognized that Kerley lines usually represent edematous septae within the pulmonary interstitium. Three patterns exist. Kerley type B lines are the most familiar and are particularly prominent at the lung bases, where they appear as straight, thin, peripheral lines approximately 1 cm long and oriented parallel to the diaphragm. Kerley type A lines represent septae deep within the substance of the lungs; they radiate from the hili, but they are thinner than central vessels. Kerley type C lines probably represent coalescence of A and B lines and are difficult to recognize.

Chronic ILDs may be caused by a wide variety of diseases, including idiopathic interstitial pneumonias, connective tissue diseases, pneumoconiosis, sarcoidosis, lymphangitic spread of malignancy, infections, Langerhans cell histiocytosis (LCH), and lymphangioleiomyomatosis (LAM). Of note, LCH and LAM are not interstitial diseases per se, but rather cystic lung diseases that can present as an interstitial pattern on chest radiography; they are better characterized as cystic diseases on CT.

Characterization of the pattern of interstitial disease as nodular, reticular, or linear on chest radiograph may help in differential diagnosis, since many of the ILDs have a predilection for one of these three patterns. However, beyond that, the radiographic findings are not sufficient for a specific diagnosis. Nonetheless, separation of the distribution of disease into two broad categories can be helpful—upper lung predominant versus basilar predominant.

Upper lung–predominant distribution favors airway-related pathology, with inhalational diseases such as infections, LCH, and pneumoconiosis predominating in this group. Moreover, sarcoidosis is also typically upper lung predominant, a finding compatible with the hypothesis that the disease is triggered by an inhaled agent, although its exact cause remains elusive. On the other hand, basilar-predominant distribution favors idiopathic interstitial pneumonias and connective tissue diseases, in which increased blood flow and greater regional volume changes may play a role in explaining the lower lung predominance. Following such radiographic assessment, CT is generally the next diagnostic step.[33,34]

CT has been validated as the optimal imaging technique for evaluating chronic ILDs. CT can often identify interstitial disease that is not seen on chest radiography, and it provides better disease pattern characterization to enable identification of the underlying etiology, as well as better qualitative or quantitative assessment of severity. CT patterns of ILD follow, to some degree, the patterns seen on the chest radiograph; however, CT allows distinction of reticular, linear, and nodular patterns much more confidently. In addition, it permits evaluation of ancillary findings, such as honeycombing, traction bronchiectasis, ground-glass opacities, and cystic changes, all of which may be very challenging or impossible to recognize on chest radiographs. Important to emphasize is that, as previously discussed, every chest CT performed using current protocols on modern scanners may serve as a high-resolution examination. Therefore, the distinction between standard and high-resolution chest CT is obsolete, and detailed interstitial disease characterization can be performed on all current chest CT studies.[35,36]

Careful analysis of the CT in evaluating ILD can be described as comprising three steps.

The first step in the diagnostic approach of ILD on CT is to exclude interstitial pulmonary edema as the cause. An acute course and ancillary findings of cardiomegaly, bilateral pleural effusions, and central vascular engorgement strongly suggest interstitial pulmonary edema. CT findings include symmetric bilateral axial (peribronchovascular) and interlobular septal thickening, with central and basilar predominance. Ground-glass opacities may be present, denoting concomitant alveolar edema. It is important to remember that lymphangitic spread of neoplasm may present with a similar CT pattern; however, the temporal course is not acute, and the findings are often asymmetric and more nodular, with additional features of malignancy present, such as pulmonary masses and hilar or mediastinal lymphadenopathy.[37,38]

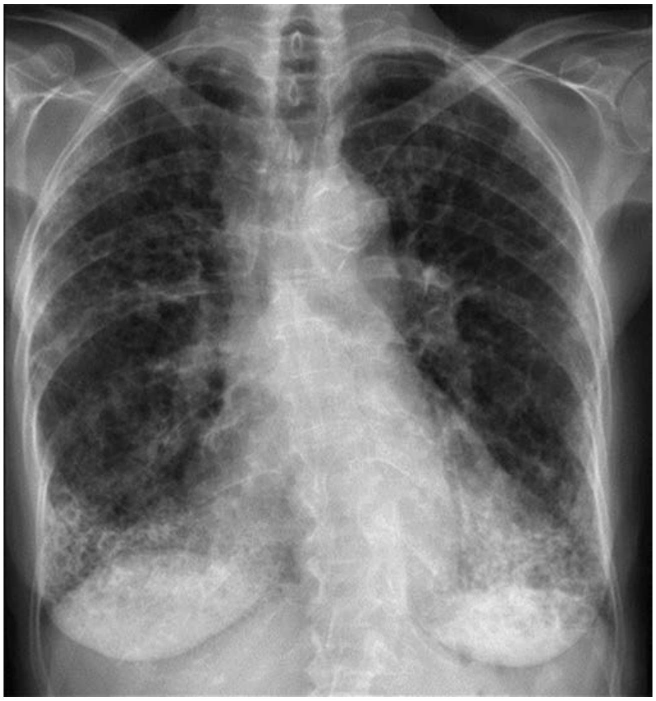

Figure 28-25 PA chest radiograph demonstrating typical changes of UIP pattern with increased basilar predominant reticulations and microcystic changes in a female patient with IPF.

The second step is to decide whether usual interstitial pneumonia (UIP) is the most likely cause of the pattern (Fig. 28-25).

UIP is the pathologic correlate of idiopathic pulmonary fibrosis (IPF), although it may also be associated with connective tissue disorders and asbestosis, with both needed to be excluded to establish diagnosis of IPF. The latter should be considered if other findings that correlate with asbestos exposure, such as pleural plaques, are present. It is important to recognize UIP because it generally has a much worse prognosis than other causes of ILD. Multiple recent consensus statements and clinical guidelines have been published in an effort to standardize the description of imaging description and a clinical approach to diagnosis. A Fleischner Society white paper, published in 2018, suggests four categories of diagnostic confidence, as summarized in Table 28-2.

In the setting of a typical UIP pattern on CT, most authorities do not recommend surgical biopsy. Even in patients with a probable UIP pattern on CT, a surgical lung biopsy may not be necessary, since 82% to 94% of these patients have a UIP histopathologic pattern on surgical biopsy. Thus, a biopsy should be reserved for cases falling in the “indeterminate” or “inconsistent with UIP” categories.

Additionally, strong emphasis is currently placed on the importance of a multidisciplinary approach to diagnosis, based on a team comprising a pulmonary clinician, radiologist, and pathologist with interest and experience in ILD. The team should discuss clinical and radiologic findings to define when a biopsy can be of value, especially in cases where imaging and or clinical features do not provide a confident diagnosis. A multidisciplinary approach can be also of value in cases where the longitudinal course is discordant with the clinical diagnosis, or in establishing an appropriate clinical approach after a biopsy is performed—based on the cumulative experience of all team members (Video 28-6).[39–41]

Many patients with an idiopathic interstitial pneumonia (IIP) have clinical features that suggest an underlying autoimmune disease

TABLE 28-2 Diagnostic Categories of UIP on CT Imaging Recommended by the Fleischner Society

	Typical UIP CT Pattern	Probable UIP CT Pattern	CT Pattern Indeterminate for UIP	CT Features Most Consistent with Non-IPF Diagnosis
CT distribution	Basal (occasionally diffuse) and subpleural predominant. Distribution is often heterogeneous.	Basal and subpleural predominant. Distribution is often heterogeneous.	Variable or diffuse.	Upper- or mid-lung predominant fibrosis. Peribronchovascular predominance with subpleural sparing.
CT features	Honeycombing. Reticular pattern with peripheral traction bronchiectasis/bronchiolectasis.[a] Absence of features to suggest an alternative diagnosis.	Reticular pattern with peripheral traction bronchiectasis/bronchiolectasis.[a] Honeycombing is absent.	Evidence of fibrosis, with some inconspicuous features suggestive of non-UIP pattern.[a]	Any of the following: predominant consolidation, extensive pure ground-glass opacity (without acute exacerbation), extensive mosaic attenuation with extensive sharply defined lobular air trapping on expiration, diffuse nodules or cysts.

[a] Reticular pattern is superimposed on ground glass opacity and, in these cases, is usually fibrotic. Pure ground glass opacity, however, would not support the diagnosis of UIP/IPF and would suggest acute exacerbation, hypersensitivity pneumonitis, or other conditions.

process, but that do not meet established criteria for any connective tissue disease (CTD). The current term for this subgroup is *interstitial pneumonia with autoimmune features (IPAF)*. In 2015, criteria for imaging and clinical features describing these patients were proposed by an Official European Respiratory Society/American Thoracic Society research statement. The radiologic patterns included in the IPAF criteria are nonspecific interstitial pneumonia (NSIP), imaging features of which are described below; organizing pneumonia (OP); and NSIP with OP, which includes basal predominant consolidation, often peri-diaphragmatic, with associated features of fibrosis and lymphoid interstitial pneumonia (LIP). These patterns are commonly found in CTD-ILD, and their presence should raise the suspicion for an underlying autoimmune process.

Additional thoracic manifestations are often encountered among patients with CTD and include unexplained airways disease (e.g., airflow obstruction, bronchiolitis, bronchiectasis), vascular abnormalities (e.g., several categories of pulmonary hypertension), and pleural or pericardial abnormalities (e.g., presence of serositis and effusion).[42]

Other common causes of fibrotic lung disease include fibrotic nonspecific interstitial pneumonia (NSIP), end-stage sarcoidosis, and chronic hypersensitivity pneumonitis (CHP). Fibrotic NSIP is favored over UIP if there is central, rather than peripheral, predominance, sometimes accompanied by subpleural sparing. The fibrosis is more uniform, and honeycombing is usually absent. Inflammatory opacities (ground-glass) may or may not be present, and, if present, reflect active inflammation. Moreover, the early phase of NSIP may manifest as multifocal bilaterally symmetric ground-glass opacities without fibrotic features or consolidation, denoting early inflammatory changes (cellular NSIP) (Video 28-7). Untreated cellular NSIP generally progresses to fibrotic NSIP, although cellular NSIP tends to respond to anti-inflammatory drugs, such as steroids. Nonetheless, significant overlap occurs between fibrotic NSIP and atypical manifestations of UIP. Both may be idiopathic or associated with connective tissue disorders. Clinical correlation and laboratory tests usually are required to exclude a connective tissue disorder. Of note, the presence of a patulous esophagus may be a clue to the diagnosis of CREST syndrome or systemic sclerosis (Figs. 28-26 and 28-27).[43,44]

Video 28-6 Axial cine images using lung window, demonstrating a typical usual interstitial pneumonia (UIP) pattern of fibrosing interstitial lung disease—in this case, idiopathic (and, therefore, classified as IPF, or idiopathic pulmonary fibrosis). *Video available on AccessMedicine.com.*

Video 28-7 Axial cine images using lung window, demonstrating mild interstitial lung disease characterized by basilar-predominant ground-glass opacities without overt fibrotic features, likely reflecting cellular nonspecific interstitial pneumonia (NSIP). In this case, the findings were attributed to connective tissue disease (likely due to scleroderma). *Video available on AccessMedicine.com.*

Sarcoidosis is suspected when there is a combination of upper lung–predominant disease that is bilaterally symmetric, axial, and accompanied by interlobular septal interstitial thickening, multiple diminutive nodules with perilymphatic distribution (see "Pulmonary Nodules and Lung Cancer," below), and associated mediastinal and hilar lymphadenopathy. Mosaic air trapping also may be present. The presence of fibrotic features denotes end-stage disease (radiographic stage IV). The differential diagnosis includes interstitial pulmonary edema and lymphangitic spread of neoplasm, with interlobular septal thickening as the unifying theme for these three entities. Nuclear imaging, and specifically PET-CT, can play a supplementary role in diagnosis and management of lung involvement by sarcoidosis by directing biopsy to areas of increased FDG uptake. Additionally, the technique serves as a tool to assess inflammatory activity in patients with pulmonary fibrosis, as well as prognostic marker of future pulmonary function. In the heart, both MRI (which may demonstrate myocardial function, scarring, and edema) and PET-CT (demonstrating abnormal FDG uptake) have been shown to be valuable in the detection of disease, in assessment of response to therapy, and as a prognostic tool.[45–47]

IIPs are frequently confused with hypersensitivity pneumonitis, except when the environmental exposure is readily apparent. The imaging features of chronic HP have been more accurately defined in recent publications, helping to separate these cases from the IIPs, particularly IPF and NSIP. HRCT findings suggesting HP include centrilobular/peribronchial nodules, mosaic attenuation due to air-trapping that is accentuated on expiratory imaging (denoting heterogeneous small airway disease), and upper lobe–predominant distribution. The presence of air trapping is somewhat specific for CHP in the setting of pulmonary fibrosis that does not conform to typical UIP or show features of sarcoidosis, unless the patient has superimposed asthma or COPD (Figs. 28-28 and 28-29).[48–50]

Pneumoconioses, particularly silicosis and berylliosis, may present with interstitial interlobular septal and axial thickening, as well as with perilympathic nodules—a pattern that can be indistinguishable from sarcoidosis. The presence of calcified nodules and mediastinal or hilar lymph nodes support the diagnosis of pneumoconiosis,

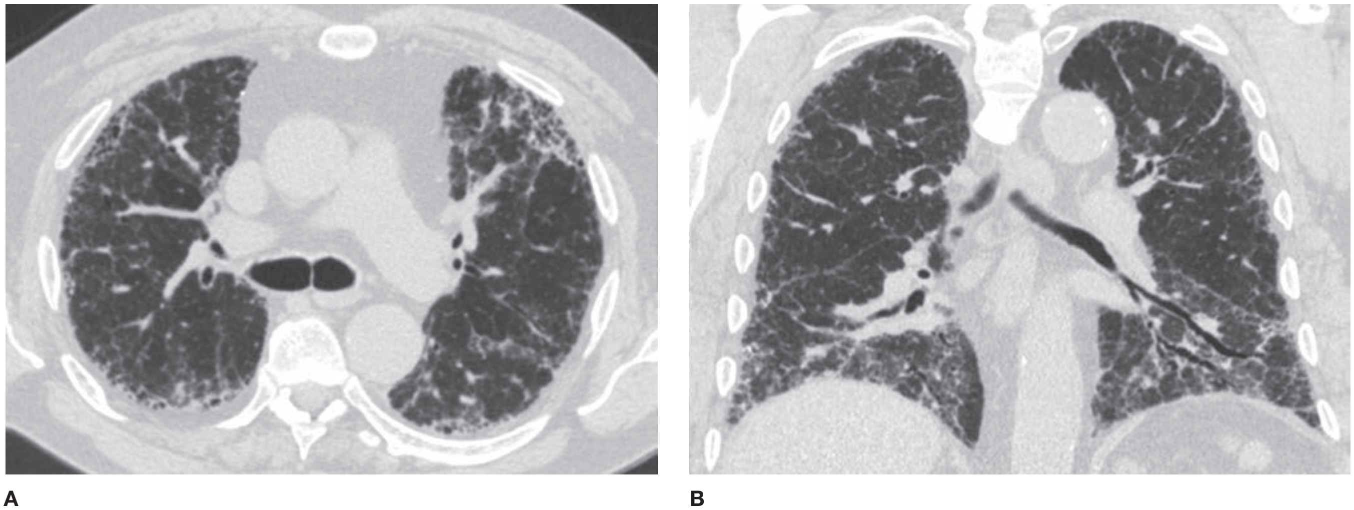

Figure 28-26 (**A**) Axial and (**B**) coronal CT images demonstrate a classic usual interstitial pneumonia (UIP) pattern, depicting symmetric, basilar- and peripheral-predominant reticulation, traction bronchiectasis, and honeycombing. A UIP pattern confers the worst prognosis among interstitial diseases and is associated with the clinical diagnosis of idiopathic pulmonary fibrosis (IPF).

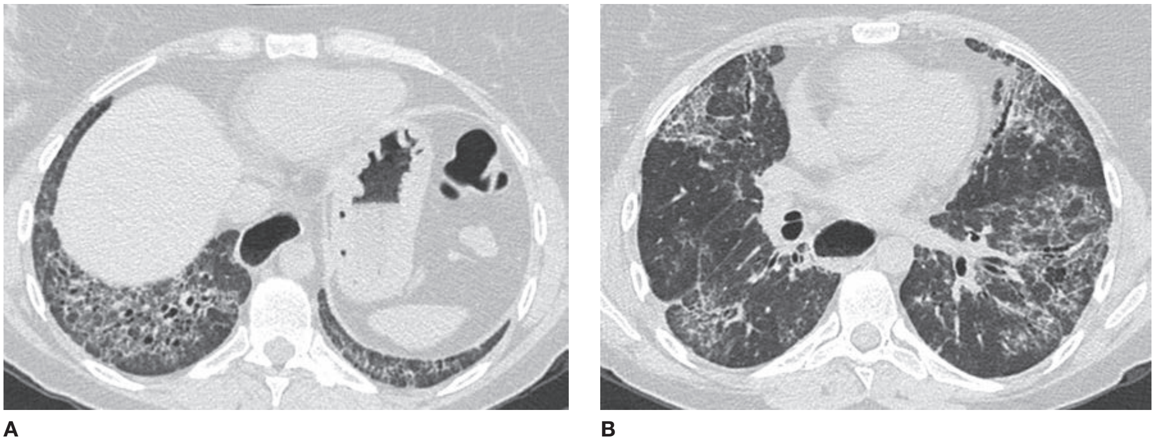

Figure 28-27 (**A**) Axial basilar and (**B**) axial midlung CT images in a patient with nonspecific interstitial pneumonia (NSIP) pattern. This pattern is distinguished from UIP by the absence of honeycombing and the more central (or peribronchovascular) distribution of reticulation denoting fibrosis. Traction bronchiectasis is also noted. The patient had a clinical diagnosis of scleroderma.

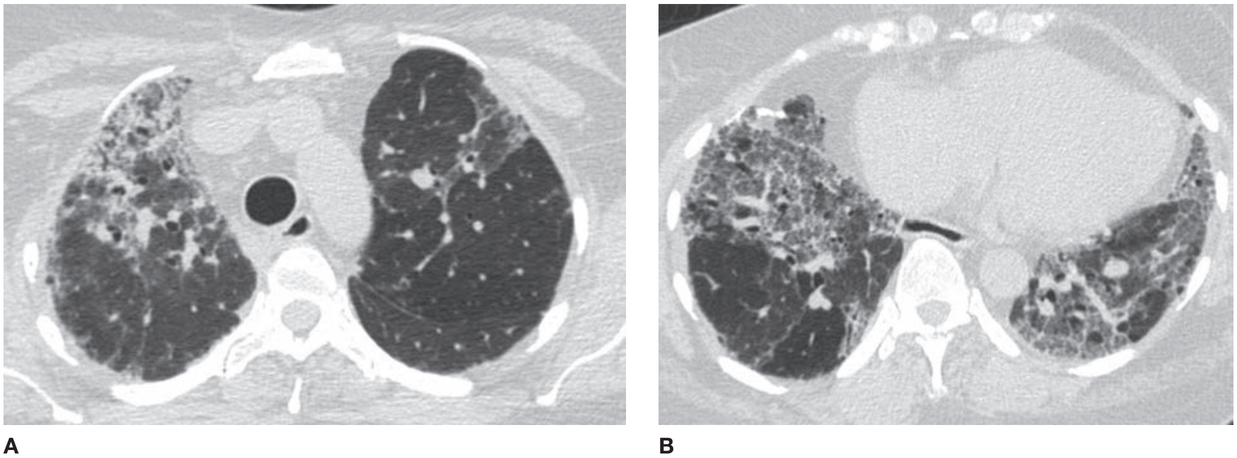

Figure 28-28 (**A**) and (**B**) are axial apical and axial basilar CT images in a patient with biopsy-proved CHP (chronic hypersensitivity pneumonitis);

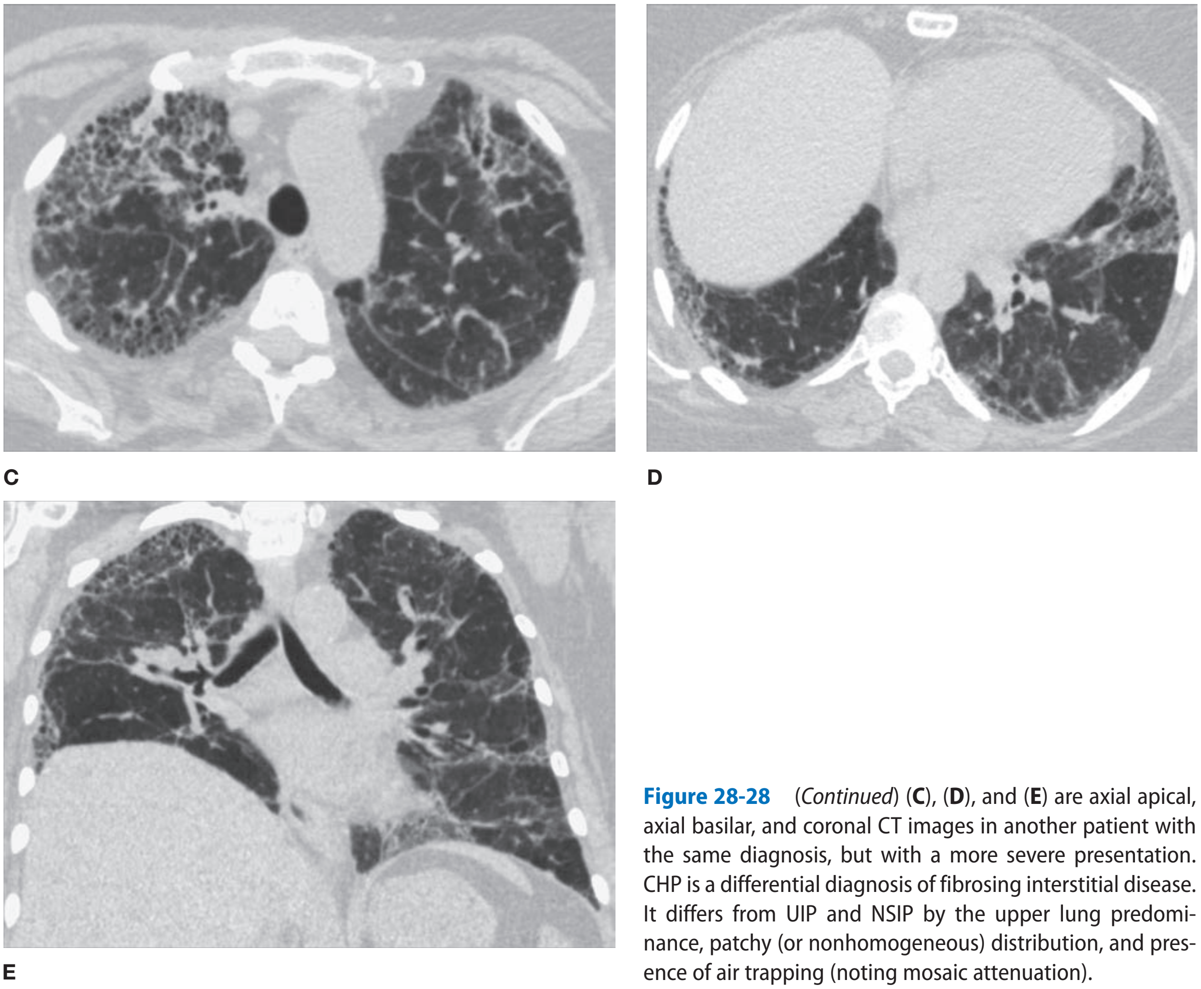

Figure 28-28 (*Continued*) (**C**), (**D**), and (**E**) are axial apical, axial basilar, and coronal CT images in another patient with the same diagnosis, but with a more severe presentation. CHP is a differential diagnosis of fibrosing interstitial disease. It differs from UIP and NSIP by the upper lung predominance, patchy (or nonhomogeneous) distribution, and presence of air trapping (noting mosaic attenuation).

but these findings may also be seen with sarcoidosis. Specific environmental exposure history is, of course, central in suggesting the diagnosis of pneumoconioses.

Currently, severity of ILD is assessed routinely via subjective analysis of disease extent on CT, along with evaluation of the degree of restriction on pulmonary function testing. Ongoing research has shown the promise of computational quantitative imaging techniques, which allow not only accurate diagnosis based upon pattern, but also quantification of the individual contributions of each pattern feature (e.g., ground-glass opacities and septal thickening) to the overall disease extent. This approach offers the potential for better tools for monitoring disease progression, refining prognosis, and developing quantitative, surrogate imaging biomarkers for future medication trials.[51,52]

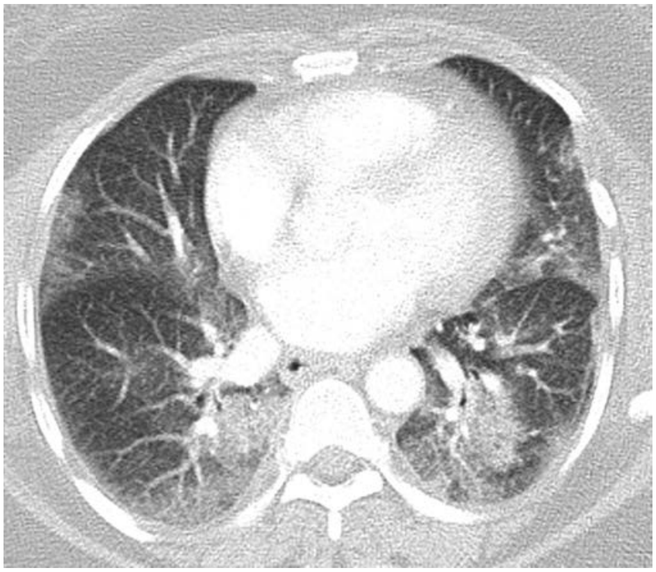

Figure 28-29 Multifocal airspace consolidation and ground-glass opacities in a patient with cryptogenic organizing pneumonia (COP). Infection is the most common differential diagnosis.

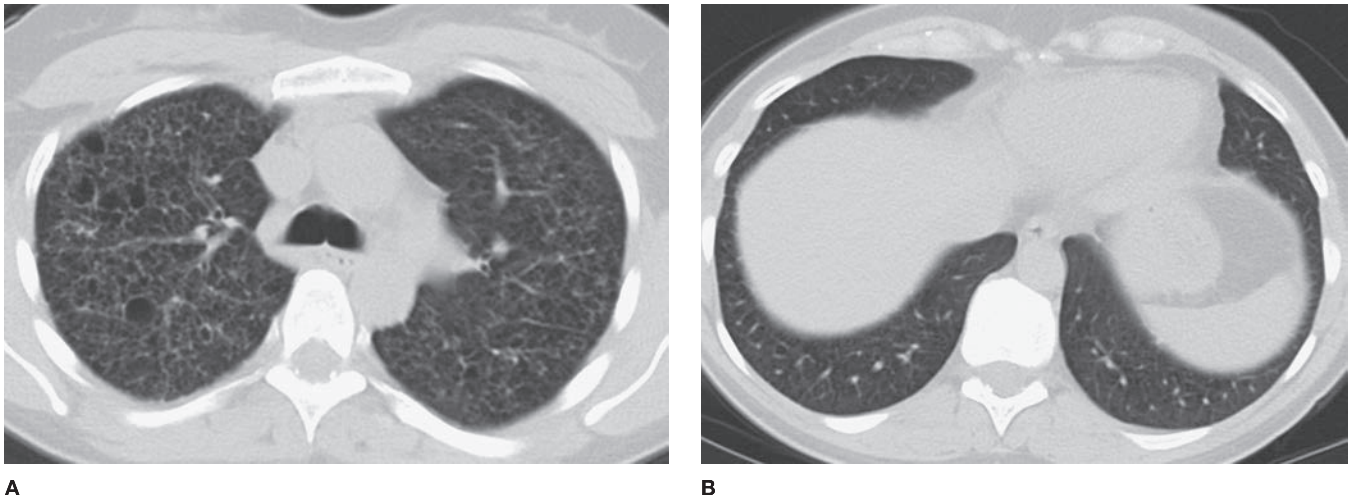
PULMONARY NODULES AND LUNG CANCER

Pulmonary nodules are exceedingly common and may be noted in up to 50% of CT examinations performed in hospital settings. Furthermore, the differential diagnosis is extremely broad and the imaging findings often nonspecific. Therefore, management of pulmonary nodules can be very challenging. We aim here to present a practical, evidence-based approach that is centered on answering four key questions: (1) Is the nodule likely malignant? If so, what is the best approach to tissue sampling? (2) If not, does the nodule need to be followed? If so, how often and for how long? (3) If it is not likely malignant, is the nodule likely to be a manifestation of an infectious or inflammatory process that requires pathologic confirmation for proper management? (4) Does the nodule have any features that allow either a specific diagnosis or a confident diagnosis of benignity? The reader is also referred to Chapter 110 for further discussion.

The discussion of pulmonary nodules starts with their definition, which is not always straightforward. While there is no question that well-circumscribed round or ovoid opacities should be characterized as nodules, the distinction of nodules from focal consolidations



A

B

Figure 28-30 (**A**) and (**B**) are axial apical and axial basilar CT images in a patient with Langerhans cell histiocytosis (LCH). Although LCH is not considered an interstitial lung disease proper (instead, it is classified as a cystic lung disease), this disease does cause an interstitial pattern on chest radiographs. Key features are cysts with upper lung predominance, occasional nodules, and associated hyperinflation. A strong smoking history is often elicited.

and interstitial opacities can sometimes be cloudy, particularly when ill-defined or ground-glass nodules are taken into account. As a general rule, any opacity that has mostly convex borders and a shape that can be described as round or ovoid should be classified as a nodule. This has implications for differential diagnosis (Figs. 28-30 and 28-31).

From an imaging perspective, the following descriptors are important in assigning a nodule to a particular differential diagnostic category: number (solitary versus multiple), size, border, CT attenuation, and distribution (if multiple). Below, each category is described and a strategic approach to diagnosis and management discussed, emphasizing a combination of clinical and CT findings.[53,54]

To answer the first question, that is, is the nodule likely to be malignant, one must be cognizant of the pretest clinical probability. Age is important; the older the patient, the more likely that a lung nodule is malignant. Smoking history and COPD are major risk factors for lung cancer and should be taken into account. A history of prior lung cancer or a known diagnosis of malignancy also places the patient at a higher risk of an additional lung cancer and pulmonary metastases, respectively.

Nodule features on CT are of considerable importance in suggesting malignancy. For a solitary nodule, the larger its size, the more likely it is malignant and represents a primary bronchogenic carcinoma. Ill-defined borders are also more highly associated with primary bronchogenic carcinoma than benign etiologies, although infectious processes, such as fungal pneumonia, also have to be considered in the proper clinical setting. Mixed-attenuation nodules, that is, subsolid nodules with coexistence of solid and ground-glass components, are highly associated with a diagnosis of primary bronchogenic carcinoma. Multiple nodules that are well circumscribed, vary in size, and are basilar predominant are strongly suggestive of metastatic disease (Figs. 28-32–28-41).

Figure 28-33 CT allows accurate volumetric measurement, which is not possible with chest radiographs, with the use of postprocessing software for nodule segmentation and volume calculation. This nodule grew from 441 mm^3 (**A**) to 539 mm^3 (**B**) in 7 months, an increase of 19%; it was later confirmed as metastasis from colon cancer.

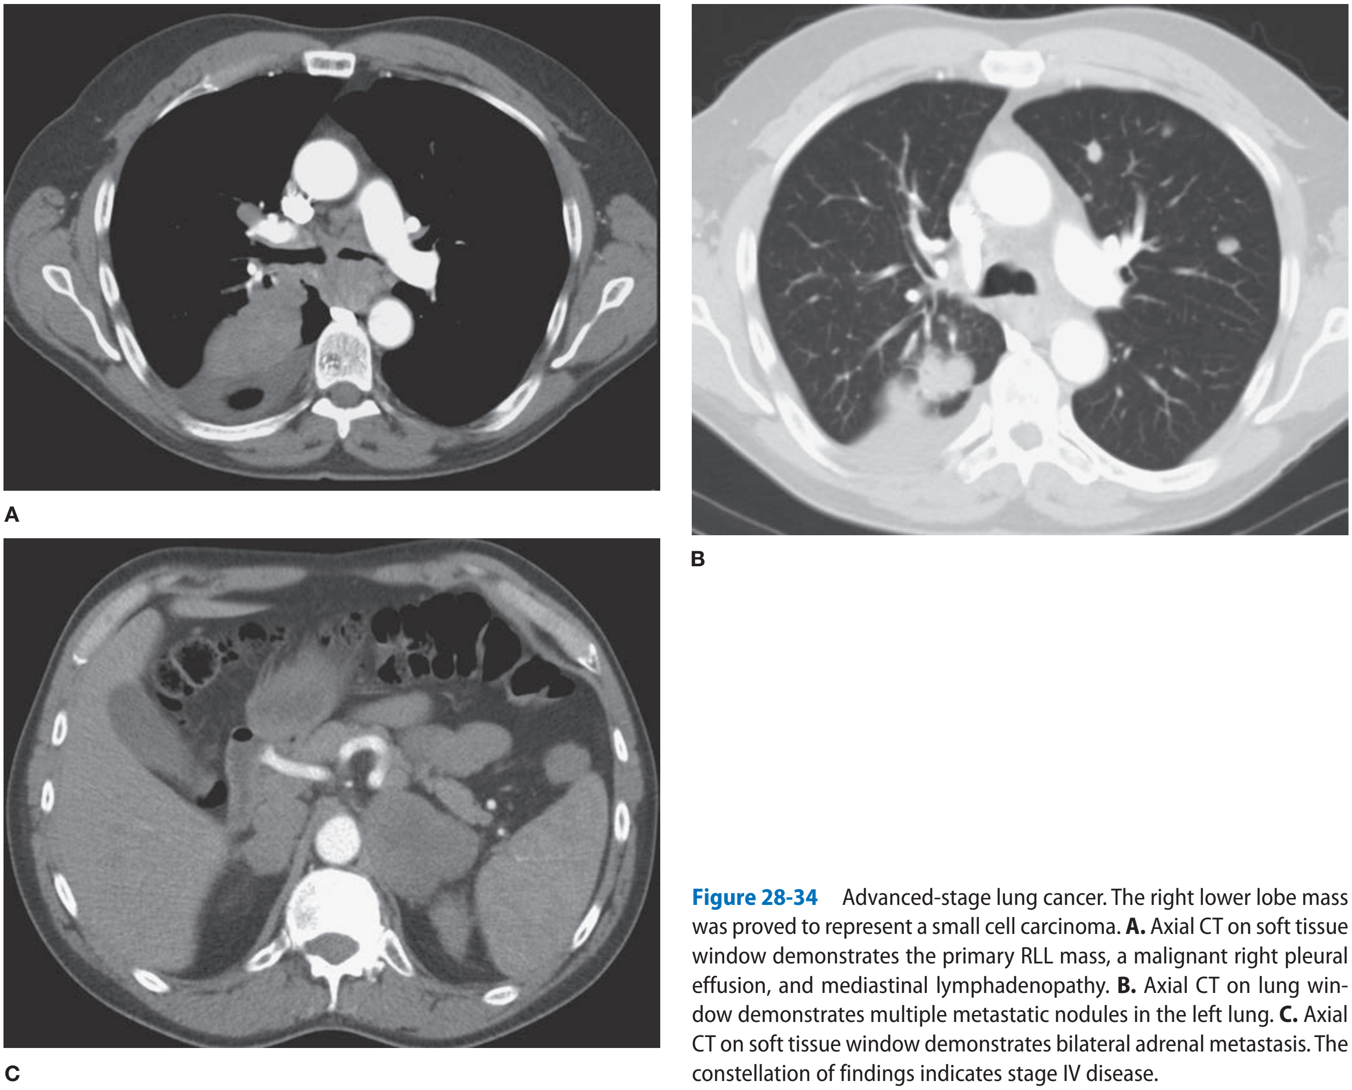

Figure 28-34 Advanced-stage lung cancer. The right lower lobe mass was proved to represent a small cell carcinoma. **A.** Axial CT on soft tissue window demonstrates the primary RLL mass, a malignant right pleural effusion, and mediastinal lymphadenopathy. **B.** Axial CT on lung window demonstrates multiple metastatic nodules in the left lung. **C.** Axial CT on soft tissue window demonstrates bilateral adrenal metastasis. The constellation of findings indicates stage IV disease.

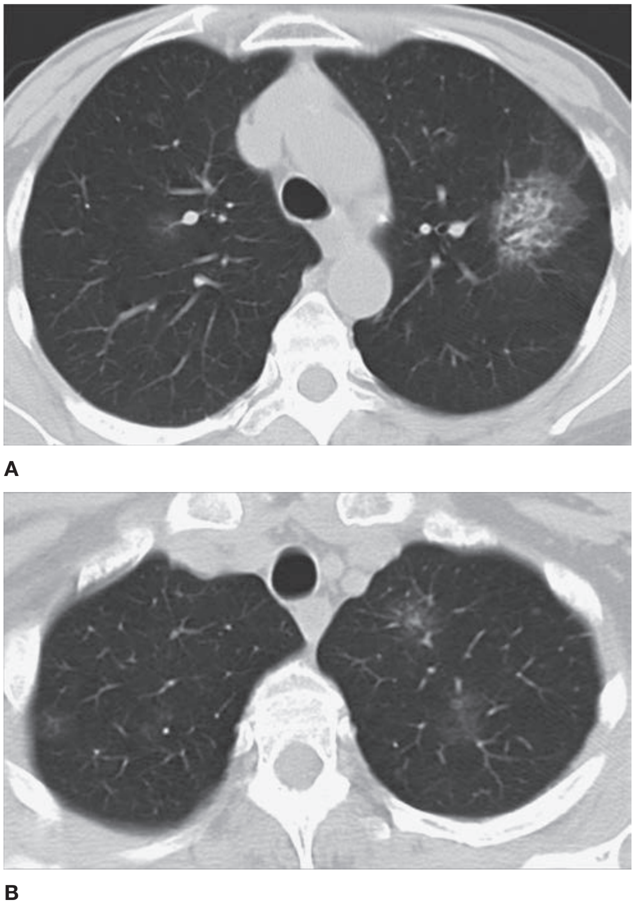

Figure 28-35 Spectrum of pulmonary adenocarcinoma. **A.** Axial CT image demonstrates a dominant, mixed-attenuation left upper lobe nodule, with solid and ground-glass components, which was resected and characterized as an adenocarcinoma. **B.** Axial CT image at a higher level demonstrates multiple smaller nodules, some of them mixed, most of purely ground-glass attenuation, which are compatible with multiple lesions in the spectrum of atypical adenomatous hyperplasia (AAH), adenocarcinoma in situ (AIS), and minimally invasive adenocarcinoma (MIA). In the past, all of these lesions would have been classified as BACs (bronchoalveolar carcinomas), a terminology that should no longer be utilized, as discussed in the text.

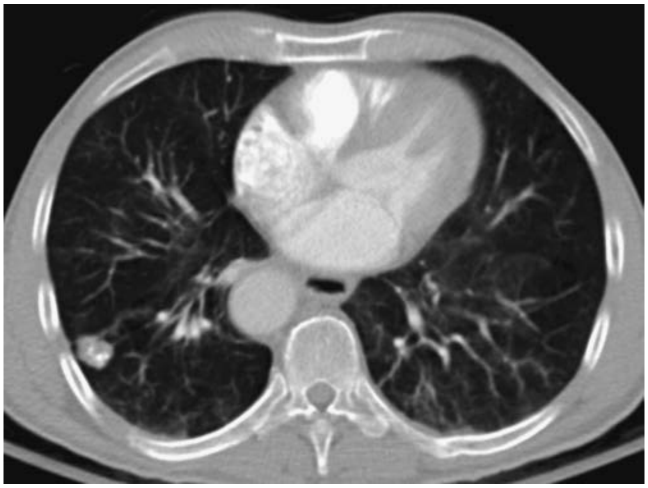

Figure 28-37 Right lower lobe nodule with coarse calcification, typical of a benign pulmonary hamartoma. Incidentally noted is a right-sided descending thoracic aorta.

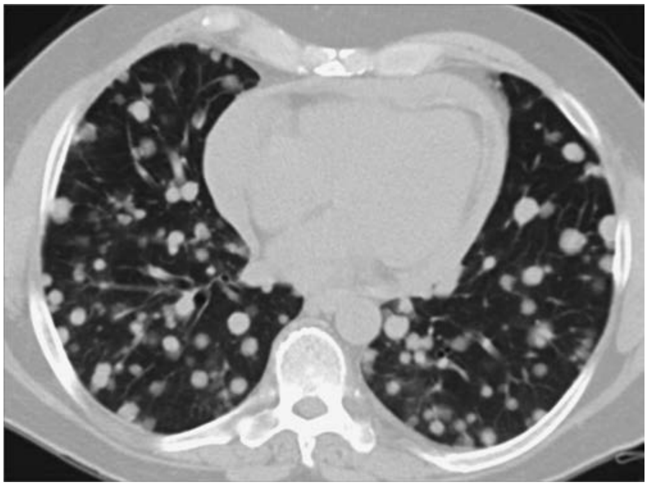

Figure 28-38 Differential diagnosis of multiple pulmonary nodules: axial CT image showing multiple well-circumscribed nodules, of varying size, characteristic of pulmonary metastases, in this case from renal cell carcinoma.

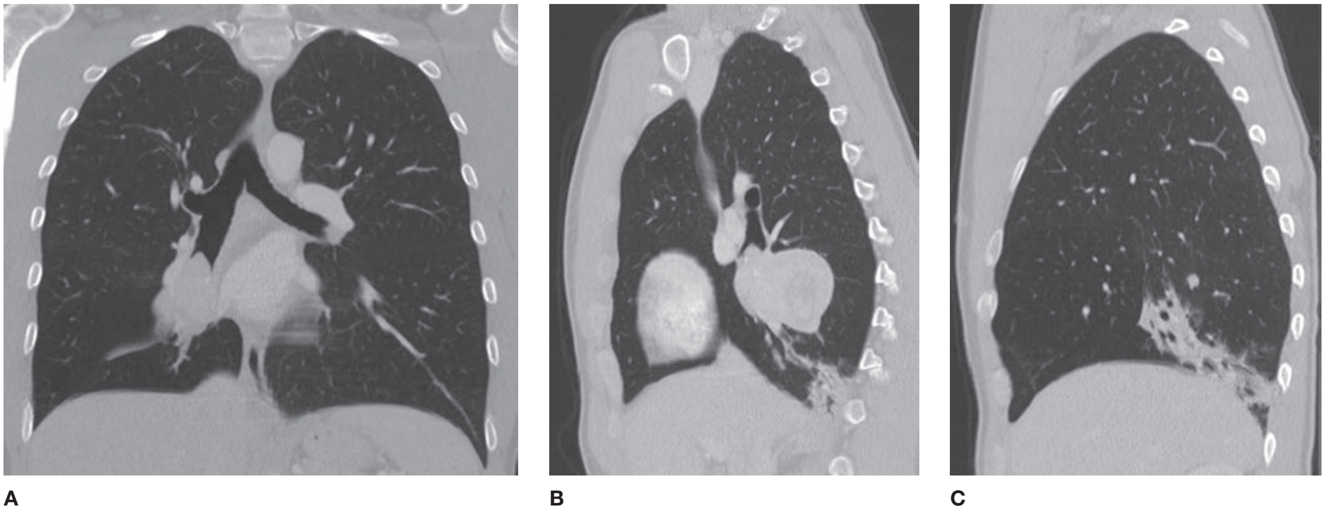

Figure 28-36 Coronal (**A**) and two sagittal CT images (**B**) and (**C**) showing a large endobronchial mass obstructing the RLL and growing concentrically into the lung parenchyma, with well-circumscribed borders. Note the associated atelectasis of the RLL basilar posterior segment. This mass was a carcinoid neoplasm.

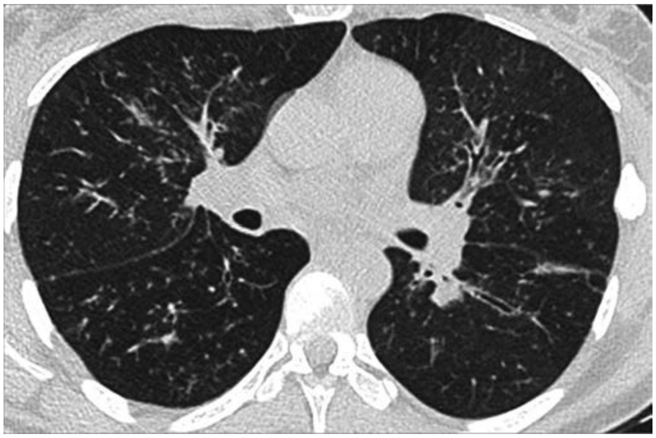

Figure 28-39 Differential diagnosis of multiple pulmonary nodules: axial CT image demonstrating very numerous, very small (1–2 mm) pulmonary nodules with a perilymphatic distribution (along the septal and axial interstitial compartments), typical of sarcoidosis—the diagnosis in this patient. This pattern can also be seen in lymphangitic carcinomatosis.

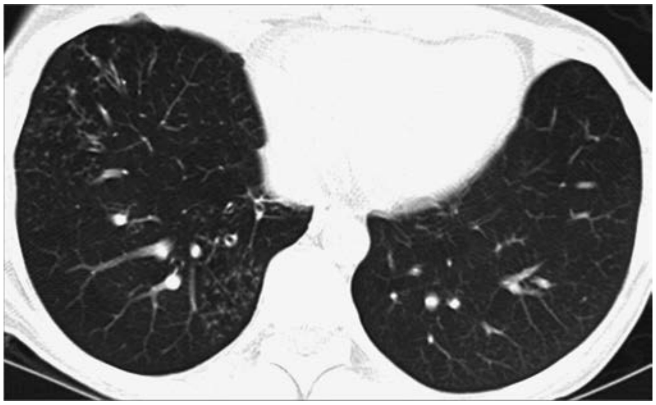

Figure 28-40 Differential diagnosis of multiple pulmonary nodules: axial CT images demonstrating multiple clusters of small nodules (measuring <2–3 mm each) in the RLL and RML, with centrilobular distribution and tree-in-bud configuration. This pattern is typical of infection and usually represents bronchiolitis. In this case, it was due to nontuberculous mycobacterial infection.

Several prediction models were developed for malignant risk estimation in individuals with lung nodules and utilize the above described clinical and imaging components. Several notable ones include the Brock University, Mayo Clinic, and Peking University People's models. The Brock University model was developed in the screening setting, while the latter two arose in a standard clinical setting (incidental nodules). The models vary in the components incorporated, and they have been shown to have an area under the curve of 0.80 and higher for assessing lung nodules in both the screening setting and for incidentally noted nodules. The Brock university model has been shown to be slightly superior to other models.[55–59]

The best evidence-based guidelines for management of solid pulmonary nodules are those published in 2017 by the Fleischner Society.[60] Although originally described only for solitary solid nodules, the guidelines are now also applied to sub-solid, as well as multiple, nodules.

The Fleischner Society guidelines stratify the risk of malignancy and recommend imaging follow-up intervals according to nodule size and clinical risk factors (Table 28-1). Nodules measuring <6 mm in a low-risk patient do not require follow-up, whereas larger nodules in higher-risk patients require follow-up at progressively shorter intervals (between a maximum of 18 months and a minimum of 3 months for solid nodules, and up to 24 months for sub-solid nodules). Most nodules measuring more than 8 mm and lacking definitive benign imaging characteristics or confirmation of temporal stability are potentially malignant and, therefore, require more aggressive evaluation. Evaluation may include short-term interval CT follow-up, PET imaging, and often, tissue sampling, which can

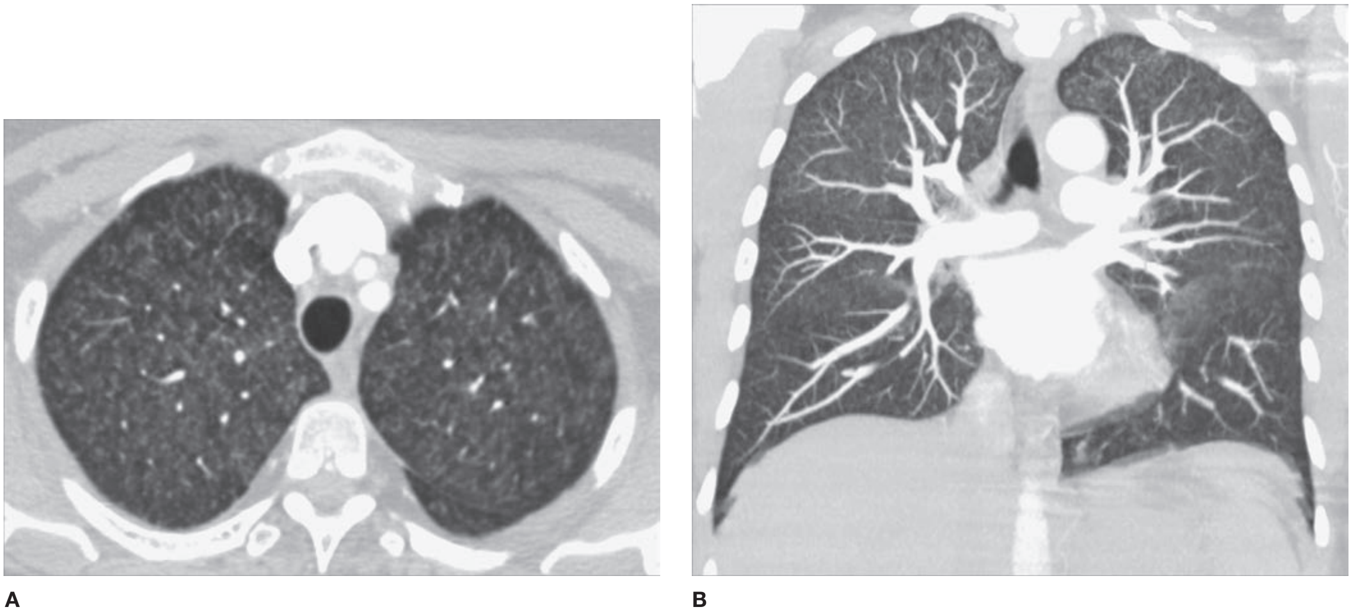

Figure 28-41 Differential diagnosis of multiple pulmonary nodules: (**A**) axial and (**B**) coronal MIP (maximum intensity projection) images demonstrate very numerous, very small (1–2 mm) pulmonary nodules with centrilobular distribution, low attenuation, and indistinct contours. Also noted is symmetric upper lung field predominance. The diagnosis is acute hypersensitivity pneumonitis. In a smoker, the differential diagnosis includes respiratory bronchiolitis.

TABLE 28-3 Solid Nodule Recommendations

Size	Follow up		
<6 mm (<100 mm^3)	Single	Low risk	No routine follow-up
		High risk	Optional CT at 12 months
	Multiple	Low risk	No routine follow-up
		High risk	Optional CT at 12 months
6–8 mm (100–250 mm^3)	Single	Low risk	CT at 6–12 months, then consider 18–24 months
		High risk	CT at 6–12 months, then 18–24 months
	Multiple	Low risk	CT at 3–6 months, then consider 18–24 months
		High risk	CT at 3–6 months, then 18–24 months
>8 mm (>250 mm^3)	Single	All	Consider CT at 3 months, PET/CT or biopsy
	Multiple	Low risk	CT at 3–6 months, then consider 18–24 months
		High risk	CT at 3–6 months, then 18–24 months

be accomplished via minimally invasive transthoracic CT-guided or bronchoscopic techniques, or rarely, via surgical biopsy. As a general rule, peripheral and smaller nodules are more accurately sampled using transthoracic CT-guided techniques, whereas central or larger masses are more safely approached via bronchoscopic techniques (Table 28-3). It is important to note that these guidelines are not intended for use in patients with known primary cancers who are at risk for metastases, nor are they intended for use in immunocompromised patients who are at risk for infection; in these patients, treatment should be based on the specific clinical situation. Also, because lung cancer is rare in children and adults younger than 35 years, these guidelines are not appropriate for such patients, in whom management decisions should be made on a case-by-case basis.

It has been shown that only two CT features generally allow confident diagnosis of benignity for solid nodules: (1) a benign pattern of calcification, and (2) absence of growth for at least 2 years.

A benign pattern of calcification includes any of the following: central, concentric, diffuse, or coarse ("popcorn" calcification). On the other hand, punctuate or eccentric calcifications are considered indeterminate, as both benign and malignant nodules may demonstrate these findings. Recognition of a benign pattern of calcification is, therefore, very important, as it may obviate the need for imaging follow-up or intervention, alleviating patient and clinician anxiety.

As noted, the second benign feature is interval stability for 2 years as measured by CT, following the Fleischner Society guidelines. The feature is based on the concept of doubling time, which is the time required for a nodule to double in volume. A very fast doubling time (<1 month) is most characteristic of inflammatory or infectious nodules. An extremely slow doubling time (>24 months) is more typical of benign processes, such as granulomas, hamartomas, intraparenchymal lymph nodes, or pulmonary arteriovenous malformations. Intermediate doubling times (>1 month but <24 months) are observed with most malignancies, as well as some indolent infections. In this indeterminate range of growth rate, tissue sampling should be strongly considered to exclude primary or metastatic malignancy.

A CT finding of low-attenuation areas compatible with macroscopic fat in an otherwise well-circumscribed pulmonary nodule is strongly suggestive of a benign pulmonary hamartoma and can obviate the need for more aggressive workup. Care must be taken, however, in differentiating true fat from noise on thin-section CT performed with high-resolution ("HRCT") reconstruction kernels. The use of soft tissue kernels may help in making a more confident diagnosis of fat.[61]

Finally, a note should be made concerning perifissural and juxtapleural nodules that exhibit a triangular or oval form on transverse images, and a flat or lentiform configuration in sagittal or coronal reconstructions and a fine, linear septal extension to the pleura. Multiple publications have addressed the invariably benign nature of these findings; they should not be routinely followed, even if the average dimension exceeds 6 mm.

Cavitation is a useful finding in narrowing the differential diagnosis, although it is not specific for malignancy. A cavitary nodule suggests a necrotizing malignancy, particularly primary or metastatic squamous cell carcinoma. However, a number of benign entities may present with cavitary nodules, most typically septic emboli (if multiple), granulomatous infections (including mycobacterial and fungal), bacterial abscesses, and granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis).

Ancillary findings on chest CT that support a diagnosis of malignancy include hilar and mediastinal lymphadenopathy, unilateral pleural effusion, pleural nodules, and hepatic, osseous, or adrenal metastases.

MULTIPLE PULMONARY NODULES

Most of the prior discussion applies to solitary or few pulmonary nodules, which should be approached similarly. In the setting of numerous, usually small (subcentimeter) pulmonary nodules, a different diagnostic approach must be utilized, emphasizing the distribution of the nodules. Two characteristics of the spatial distribution of nodules are relevant: (1) upper lung–predominant versus basilar predominant versus widespread; and (2) centrilobular versus perilymphatic versus random. The otherwise very long differential diagnosis can be substantially narrowed by correctly recognizing the distribution.

As discussed previously, an upper lung–predominant distribution suggests inflammatory or infectious etiologies, in which the inciting factor is inhaled; the exception is primary bronchogenic carcinomas that are more likely in the upper lungs, but uncommonly multiple. A lower lung–predominant distribution suggests hematogenously disseminated disease processes, such as hematogenous metastasis or hematogenous infectious processes. Diffuse distribution comprises a combination of both differential diagnoses and is the least specific.

The centrilobular distribution implies that the majority of nodules are in or near the center of the secondary pulmonary lobule. Such a distribution suggests small airway and acinar disease, indicative of endobronchial spread. This distribution can be further subclassified into two groups: (1) centrilobular nodules in which the nodules are fuzzy, ill-defined, and often of ground-glass attenuation—findings indicative of small airway inflammatory diseases, as can be seen with respiratory bronchiolitis–interstitial lung disease (RB-ILD) and subacute hypersensitivity pneumonitis; and (2) centrilobular nodules in which the nodules are sharp, well defined, and measure less than 2 mm—findings associated with distal bronchiolar filling, a pattern referred to as "tree-in-bud." A tree-in-bud pattern strongly suggests infectious bronchiolitis of bacterial, viral, or mycobacterial etiology. Least commonly, the centrilobular distribution may indicate small vessel disease, such as pulmonary vasculitides or capillary hemangiomatosis. Among the vasculitides, eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome) and microscopic polyangiitis are primary considerations.

A perilymphatic distribution implies that the majority of nodules are within the septal and bronchovascular interstitial compartments. A perilymphatic distribution is associated with diseases with lymphatic system involvement. Such a distribution suggests a narrow differential diagnosis, including pulmonary interstitial edema, sarcoidosis, or lymphangitic spread of neoplasm ("lymphangitic

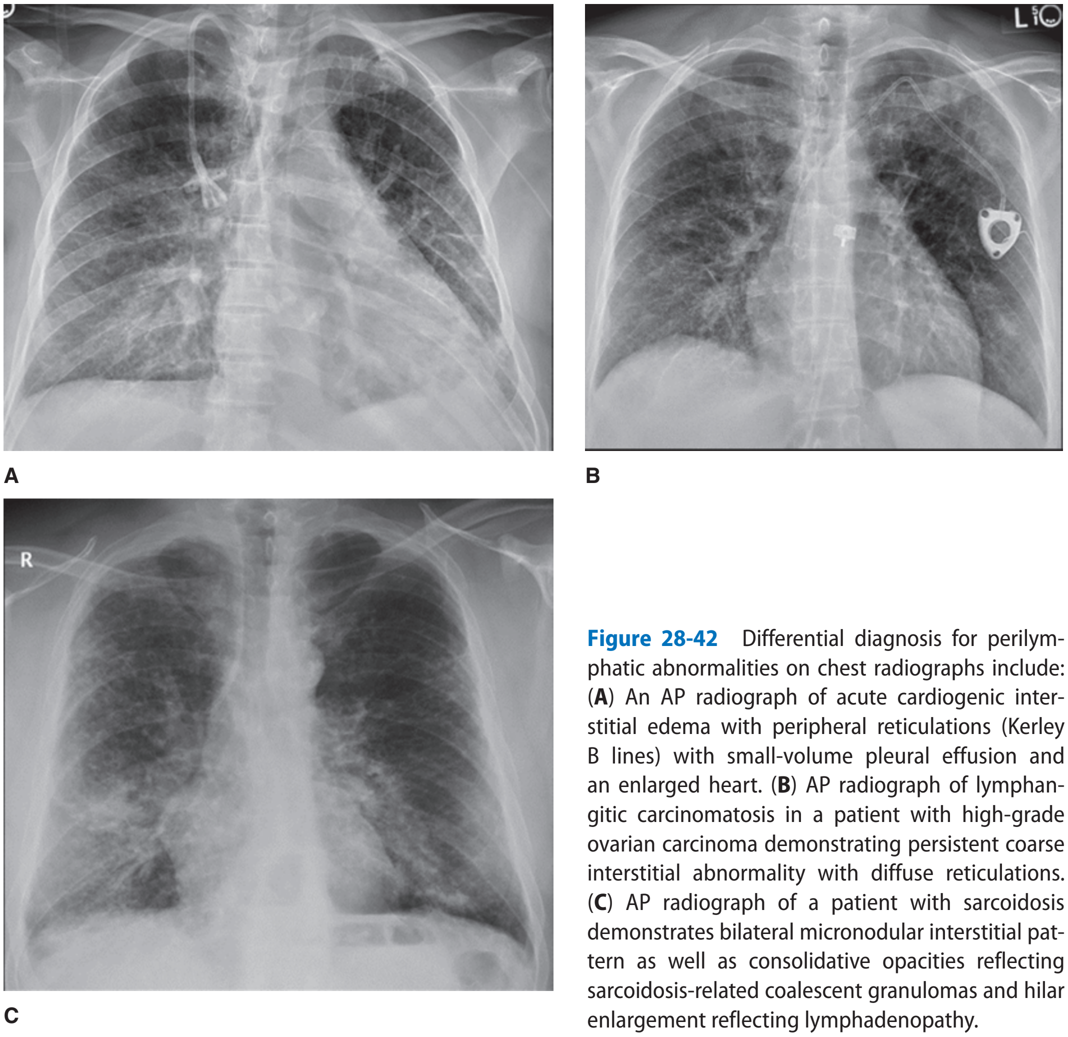

Figure 28-42 Differential diagnosis for perilymphatic abnormalities on chest radiographs include: (**A**) An AP radiograph of acute cardiogenic interstitial edema with peripheral reticulations (Kerley B lines) with small-volume pleural effusion and an enlarged heart. (**B**) AP radiograph of lymphangitic carcinomatosis in a patient with high-grade ovarian carcinoma demonstrating persistent coarse interstitial abnormality with diffuse reticulations. (**C**) AP radiograph of a patient with sarcoidosis demonstrates bilateral micronodular interstitial pattern as well as consolidative opacities reflecting sarcoidosis-related coalescent granulomas and hilar enlargement reflecting lymphadenopathy.

carcinomatosis”) (Fig. 28-42). The latter two diagnoses are more likely if there is nodular interstitial thickening.

A random distribution usually implies hematogenous dissemination of metastases or infection. The archetypal infectious process with numerous random nodules is miliary tuberculosis, although miliary fungal infections can be indistinguishable. Patients with miliary infectious are often immunocompromised and may present with bacteremia or fungemia.

GROUND-GLASS PULMONARY NODULES

Ground-glass nodules deserve separate consideration, as their pathophysiology, differential diagnosis, biologic behavior, and management strategies differ considerably from solid pulmonary nodules.

Ground-glass attenuation is defined as increased attenuation of the lung parenchyma, although the attenuation is not as high as soft tissue attenuation and, therefore, is insufficient to obscure adjacent pulmonary vessels. From a pathology perspective, ground-glass attenuation implies partial filling of the distal airspaces (acini) at a scale below the spatial resolution of CT, causing volume averaging of gas, acinar structures, and material partially filling the alveoli. It is often associated with the lepidic growth pattern, that is, cellular proliferation along the walls of the alveoli, rather than the more common hilic (radial) growth pattern characteristic of most neoplasms.

Multiple ground-glass nodules were described previously, and the rationale for their imaging assessment is included in the description of multiple pulmonary nodules.

Solitary or few ground-glass-attenuation nodules carry a different implication from solid nodules. The differential diagnosis is essentially limited to nonspecific infectious or inflammatory processes versus indolent primary bronchogenic adenocarcinoma or premalignant lesions. Therefore, these lesions must be followed to assess their persistence and chronicity. Most nonspecific infectious or inflammatory processes resolve spontaneously within 3 months. Therefore, lesions that persist on a 3-month follow-up chest CT are suspicious for malignancy.

Ground-glass nodules include a spectrum of premalignant to low-grade malignant diseases, which correlate pathologically with the diagnoses of atypical adenomatous hyperplasia (AAH) (a premalignant precursor to adenocarcinomas), AIS, and minimally invasive adenocarcinoma (MIA). These specific diagnoses cannot be differentiated accurately by CT imaging findings or by small biopsies; surgical biopsy is generally necessary. Nonetheless, CT features suggest a specific diagnosis. Namely, smaller lesions (particularly those $\leq$5 mm) with pure ground-glass attenuation are more likely AAH, whereas the larger the lesion and the more complex its structure (particularly if solid or cystic areas are noted), the more likely it represents AIS (formerly called bronchioloalveolar carcinoma, BAC) or MIA. Large ($\geq$5 mm) or progressive solid components are strongly associated with invasive adenocarcinomas.

The Fleischner Society originally published in 2013 a statement with evidence-based recommendations for management of ground-glass (subsolid) nodules and incorporated a revised version of the recommendations into a unified statement in 2017.[62,63] The statement is mostly based on the revised classification of pulmonary adenocarcinoma proposed in 2011 by the International Association

TABLE 28-4 Part-Solid Nodule Recommendations

Ground glass	<6 mm	No routine follow-up indicated
	≥6 mm	CT at 6–12 months to confirm persistence, then CT at 3 and 5 years
Part solid	<6 mm	No routine follow-up indicated
	≥6 mm	CT at 3–6 months to confirm persistence, then CT annually for 5 years
Multiple	<6 mm	CT at 3–6 months, if stable follow at 2 and 4 years
	≥6 mm	CT at 3–6 months; subsequent management based on the most suspicious nodule

for the Study of Lung Cancer (IASLC), the American Thoracic Society (ATS), and the European Respiratory Society (ERS).[64] In the same spirit as the original recommendations for solid nodules, subsolid nodules are stratified according to size, and different follow-up intervals are proposed. However, unlike the guidelines for solid nodules, those for ground-glass nodules do not differentiate between low- and high-risk groups because of the incidence of subsolid lesions in younger and nonsmoking patients.

The algorithm for subsolid lesions is more involved, also accounting for multiplicity of nodules and the fact that many subsolid nodules are inflammatory (Table 28-4). For example, a subsolid nodule measuring <6 mm does not need any follow-up. If it is >6 mm, then an initial follow-up chest CT should be obtained at 6 to 12 months to determine persistence. If persistent, then CT at 3 and 5 years is recommended. (Many institutions, including our own, pursue longer surveillance.) If a subsolid nodule >6 mm demonstrates a solid component measuring more than 6 mm that is persistent after 3 to 6 months, then tissue sampling, PET-CT, and/or resection is recommended, as these nodules have a very high probability of representing AIS or MIA. The size of the solid component correlates with the likelihood of an invasive component being present.

For multiple ground-glass opacities measuring >6 mm, the algorithm is similar, and management is dictated by the CT characteristics of the most suspicious nodule; in multiple nodules measuring <6 mm, an initial 3- to 6-month follow-up is recommended to exclude infectious etiologies, after which 2- and 4-year follow-up intervals are suggested, as infectious or inflammatory etiologies become far more likely in that setting. Important caveats are the limited usefulness of PET/CT for evaluation of subsolid nodules, since most are not substantially metabolically active (therefore, a negative PET/CT can be misleading), the need to obtain clinical correlation, and the requirement for a meticulous evaluation protocol that includes thin-section (1 mm) volumetric images and consistent use of low-radiation-dose CT technique.[62]

A comprehensive management algorithm for both solid and subsolid pulmonary nodules was published by the American College of Chest Physicians in 2013.[65] The algorithm commences with identification of a new nodule on chest CT and proceeds with follow-up recommendations according to size, risk factors for malignancy, and surgical risk. The recommendations emphasize the need for tissue sampling for most nodules larger than 8 mm and compare the advantages and disadvantages of surgical biopsy, CT-guided percutaneous biopsy, and bronchoscopy with biopsy. The specific recommendations for nodules measuring <8 mm are in line with the 2005 Fleischner Society guidelines.

LUNG CANCER

The classification, pathophysiology, epidemiology, and management of lung cancer are described elsewhere (Chapters 112–118). This chapter focuses on the contributions of imaging to lung cancer screening, initial diagnosis, and staging.

Lung cancers are typically initially identified on chest radiography or are noted incidentally on chest CT performed for another clinical indication (except in the context of lung cancer screening). Most lung cancers present as pulmonary nodules or masses. Hilar or mediastinal lymphadenopathy and overt signs of metastatic disease are indicative of more advanced stages of disease. Central masses may cause obstructive atelectasis or consolidation.

At initial presentation, the clinical aim is to confirm the diagnosis pathologically, for which tissue sampling is required. In the past, surgical biopsies were the only available options, but in the last three decades, minimally invasive biopsies performed either percutaneously using CT guidance, or transbronchially with bronchoscopic techniques, have been strongly favored for their better risk/benefit ratio, lower complication rate, faster patient recovery, and high diagnostic accuracy. As a general rule, most peripheral lesions (i.e., those within 3 cm of a costal pleural surface) are better accessed percutaneously using CT guidance, whereas central lesions, particularly if an airway visible on CT leads to the lesion, are better accessed via bronchoscopy.[64,66]

Once the diagnosis of lung cancer is pathologically confirmed and fully characterized, staging is of paramount importance to determine the extent of disease and, therefore, the management approach. The most current staging system for lung cancer is the eighth edition of the TNM classification, which was published in 2016. Several references depict visual maps of the T, N, and M criteria and tables with the detailed revised classification.[67–70]

In summary, the most important aspects of staging are the size and location of the primary tumor (T), the presence of abnormally enlarged lymph nodes and their location and distribution (N), and the presence of distant metastasis (M). By combining the T, N, and M scores, a specific stage from I to IV is obtained, and management strategies are tailored for the type of cancer (histology and genotypic profile) and the staging classification. It cannot be overemphasized that imaging, particularly CT, plays an overarching role not only in tumor detection, but also in tumor staging. It is the primary method for obtaining TNM staging information. PET/CT is also valuable, particularly for nodal staging and identification of distant metastasis. Finally, nodal metastasis may be evaluated using endobronchial US combined with transbronchial biopsies of suspicious lymph nodes.

LUNG CANCER SCREENING

A discussion of the role of modern imaging in the diagnosis of lung cancer would not be complete without mention of the current status of lung cancer CT screening (Fig. 28-43).

The 20.0% decrease in mortality from lung cancer observed with implementation of low-dose computed tomography (LDCT) screening in the National Lung Screening Trial (NLST) has led to approval of annual screening in the United States as a benefit covered by both private insurers and by Medicare (Centers for Medicare and Medicaid Services).[71] Lung cancer screening guidelines in the United States are based mainly on the same criteria for which participants in the NLST study were chosen and include patients with history of heavy smoking, defined as 30 pack-years or more; who smoke currently or have quit within the past 15 years; and who are between 55 and 80 years of age. The Lung CT Screening Reporting and Data System (Lung-RADS 1.1) is the most used system for classification and management of screened patients.

Eligibility requirements exist for the interpreting radiologist(s), as well as the imaging facilities that perform LDCT screening. The

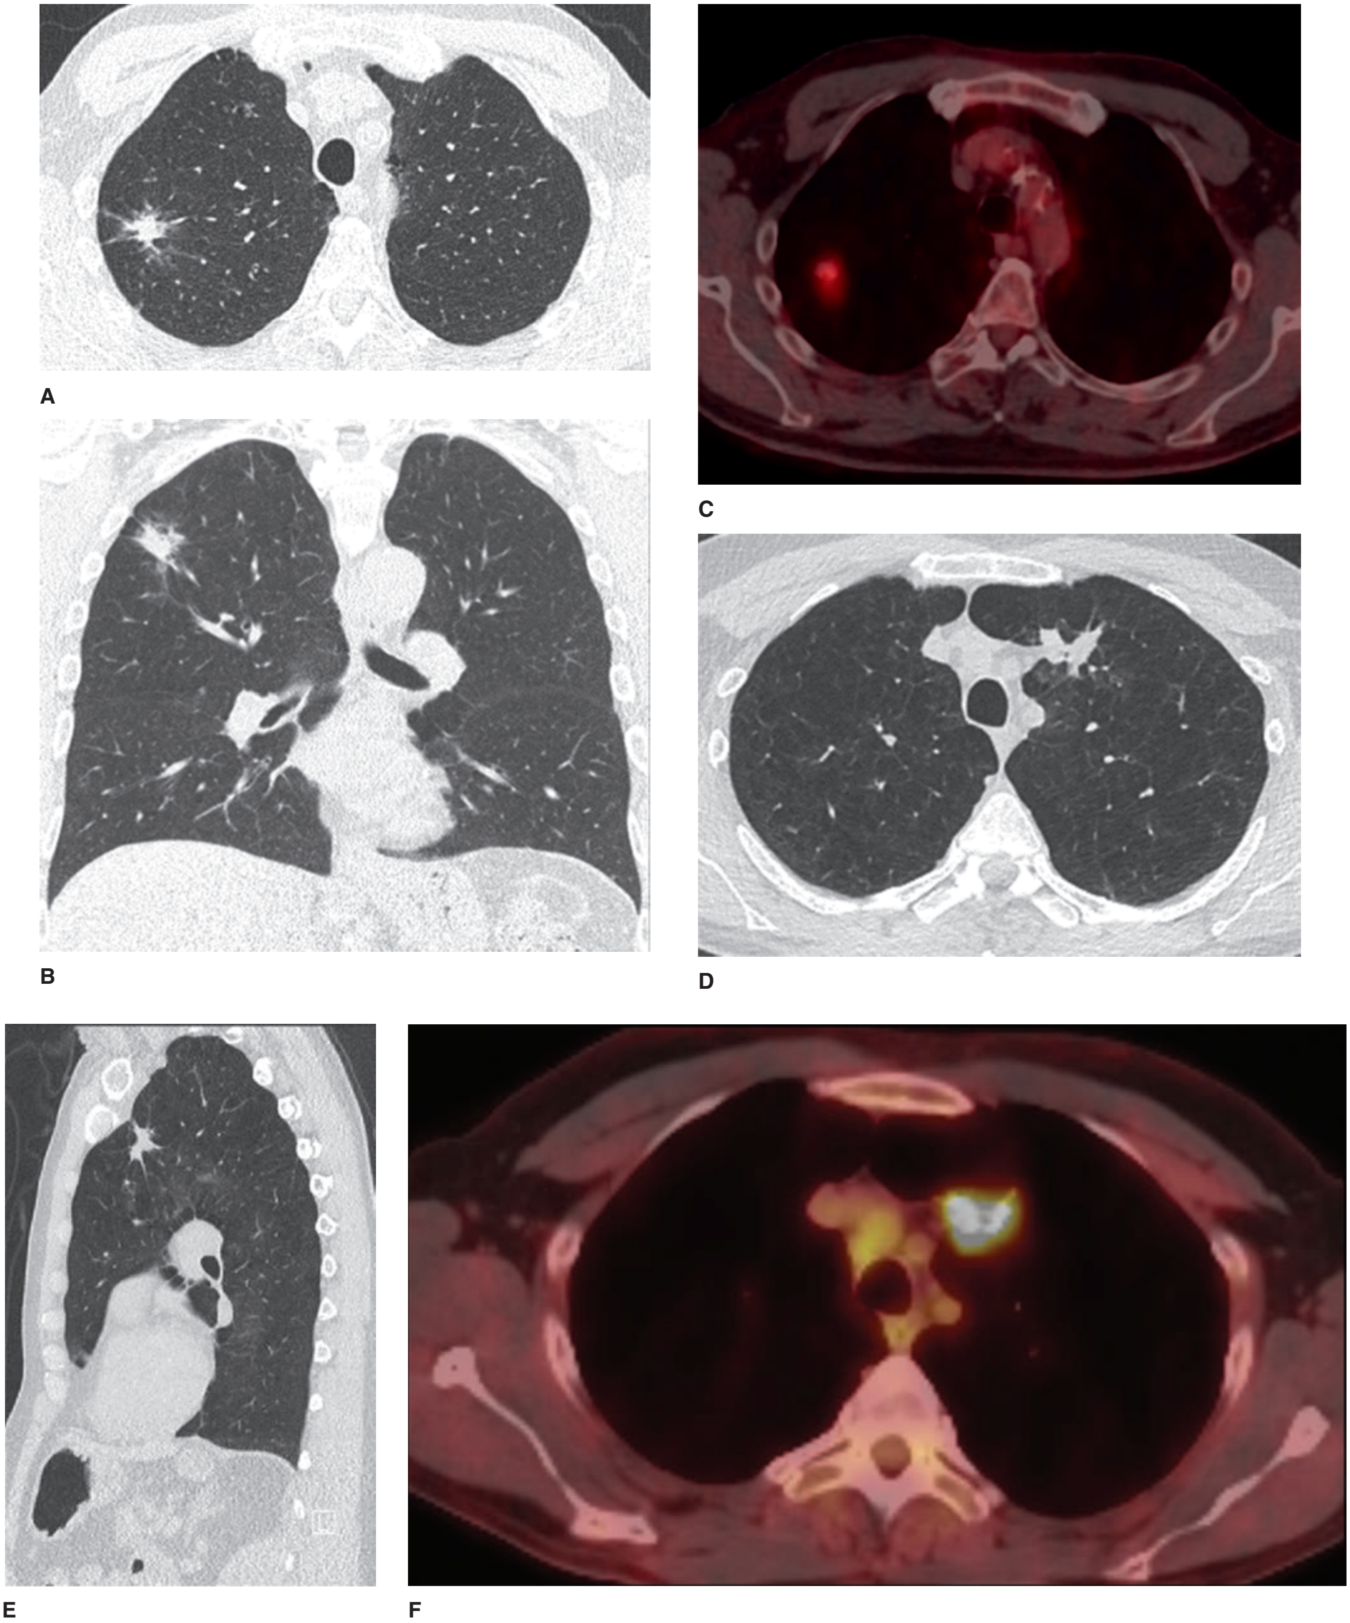

Figure 28-43 Category 4X finding on first lung screening CT examination. Axial (**A**) and coronal (**B**) reconstructions CT images demonstrate a spiculated irregular right upper lobe lung nodule with pleural tagging highly suspicious for primary lung malignancy. Fused images (**C**) from a subsequently obtained PET-CT demonstrate FDG uptake in the lesion, which was later confirmed to represent a primary lung adenocarcinoma. A similar-appearing lesion identified on a screening exam of another patient in a left upper lobe demonstrating spiculations and mediastinal tagging on axial (**D**) and sagittal (**E**) CT images as well as marked FDG uptake on fused PET-CT images (**F**). This lesion was subsequently resected, with pathology revealing necrotizing granuloma without evidence of malignancy.

latter include: (a) performing LDCT with a volumetric CT dose index (CTDIvol) of <3 mGy; (b) using a standardized lung nodule identification, classification, and reporting system, such as the American College of Radiology (ACR) Lung-RADS; (c) making smoking cessation interventions available for current smokers; and (d) collecting and submitting screening data to a CMS-approved registry for all LDCT screening examinations, including those covered by private insurers.[72]

The American College of Radiology has developed a quality-assurance tool, Lung-RADS 1.1 (Table 28-5), with the aim of standardizing the reporting of LDCT screening results. Lung-RADS defines positive examinations on lung-cancer screening CT and is designed to decrease the false-positive rate, with a minimum effect on test sensitivity; it includes management recommendations. Applying Lung-RADS retrospectively has been shown to substantially reduce the false-positive rate when compared to NLST criteria; however, a decrease in detection sensitivity has been noted.[73]

Additional methods of nodule evaluation and nodule detection that are gaining recognition and have the potential to assist radiologists to decrease the rate of missed lung nodules are nodule volumetry and computer-assisted detection (CAD). These tools were recommended as the preferred evaluation tools for nodule assessment by the 2015 European Society of Radiology white paper on lung cancer screening. Although volumetric analysis is less widely practiced in the United States than in the Europe, it has the potential to improve measurement accuracy in positive screening examinations, leading to lower false-positive rates, as well as to reduce variability in size assessment. The advantages of nodule volumetry are that size measurements make use of all voxels representing the nodule, not a single cross-sectional subset, and that three-dimensional volumes can be viewed at any angle, which is advantageous in asymmetrically growing nodules, increasing the likelihood of detecting subtle growth over time.

Moreover, CAD has the potential to enhance radiologist productivity in clinical settings; it can automatically detect lung nodules and calculate both two-dimensional and volumetric measurements of lung nodules using standard CT images. Using those measures, nodule progression can more accurately be tracked over time by assessing its growth rate, a very important metric in predicting biologic behavior and malignant potential. The advantage for the clinical workflow is potentially to increase radiologist efficiency and produce more repeatable results for nodule follow-up.

Recent studies have demonstrated the ability of CAD to detect lung cancer at an earlier stage and to improve detection of small or subtle nodules.

Another hallmark study, the Nederlands-Leuvens Longkanker Screenings Onderzoek (NELSON), conducted in the Netherlands and Belgium and launched in 2003, compared low-dose CT against no screening. NELSON differed from the NLST in many important aspects, including the serial imaging protocol utilized and patient selection criteria.[74]

Similar to the NLST trial, NELSON demonstrated that lung-cancer mortality was significantly lower among those who underwent volume CT screening compared with those who underwent no screening.

The interval between LDCT studies is a main subject of debate regarding the optimization of lung cancer screening. This topic was assessed in NELSON, which showed similar performance of annual and biennial screening intervals. However, an interval longer than 2 years was discouraged by recent results of the fourth round of NELSON; there was a reported excess of interval cancers associated with a screening interval of 2.5 years.

A white paper published in 2015 by the European Society of Radiology (ESR) and the European Respiratory Society (ERS) encouraged lung cancer screening using LDCT, either in clinical trials or in routine clinical practice at certified multidisciplinary medical centers. The ESR/ERS recommendations include specific selection of high-risk patients, based on several pretest parameters (e.g., age 55–80 years, smoking history ≥30 pack-years and having stopped smoking within <15 years, a dedicated comprehensive risk model, biologic profiling) and adaptation of screening intervals based on refined risk predictive models. The ESR/ERS recommendations encourage inclusion of additional CT findings, such as chronic obstructive pulmonary disease (COPD) and vascular calcification, which can be used along with nodule records for posttest refinement of cardiovascular and general mortality risk, in addition to lung cancer risk.[75]

PULMONARY INFECTIONS

Pulmonary infections constitute a very broad group of diseases caused by a wide variety of viruses, bacteria, and fungi. The imaging findings are helpful to establish a diagnosis of pneumonia, but they are virtually never specific as to etiology. Therefore, most patients with suspected pulmonary infections are treated empirically, based upon epidemiologic considerations. Subgroups of vulnerable patients (particularly very ill or immunocompromised patients) may require etiologic confirmation, which can be obtained by sampling the abnormalities via percutaneous or bronchoscopic techniques and requesting microbiologic testing of the material.

The imaging approach to a suspected pulmonary infection involves identifying the imaging patterns that are more likely associated with an infectious etiology, as well as recognizing the more likely associations with a specific pattern. The most typical pattern of pneumonia is focal or multifocal consolidation, denoted by dense, conspicuous alveolar opacities that obscure vascular contours on CT and which may or may not be associated with air bronchograms. Other patterns include focal or multifocal ground-glass opacities (which can be difficult to recognize on chest radiographs and require CT for adequate evaluation); peribronchovascular patchy opacities (bronchopneumonia pattern); centrilobular nodules with tree-in-bud configuration (bronchiolitis pattern); multiple nodules or masses (cavitary or not); solitary cavitary nodule or mass; and nodules or masses associated with calcifications or ground-glass halo. None of these patterns is specific for infection; they are even less specific for a particular infectious etiology. Nonetheless, some imaging patterns allow a narrower differential diagnosis in the proper clinical setting and are worth recognizing.[76–83]

Notable radiographic patterns include: (1) Focal or multifocal consolidation, which favors typical bacterial infection (e.g., *Streptococcus pneumoniae*). A bronchopneumonia pattern can be seen in a variety of bacterial and viral infections. (2) Focal or multifocal ground-glass opacities favor atypical infections, including *Pneumocystis jiroveci* and hematogenously disseminated bacterial and viral infections (e.g., CMV pneumonitis).[84–86] (3) A bronchiolitis pattern may be seen in community-acquired viral infections, including influenza, parainfluenza, and adenovirus. If associated with air trapping, respiratory syncytial virus (RSV) should be considered. (4) Multiple cavitary nodules or masses suggest septic emboli or virulent infections, such as those due to *Staphylococcus aureus*. (5) A solitary cavitary mass suggests a pulmonary abscess; anaerobic infections related to aspiration are primary considerations, although if in the upper lobes, reactivation tuberculosis must be excluded.[87] (6) Calcified nodules or masses suggest granulomatous infectious, typically chronic, and favor mycobacterial (tuberculous and nontuberculous) or fungal etiologies.[88–90] (7) Nodules or masses with ground-glass halo are suggestive of opportunistic fungal infection, particularly invasive aspergillosis, in the setting of immunocompromised hosts who are neutropenic.

TABLE 28-5 Lung-RADS 1.1: Standardizing the Reporting of LDCT Screening Results

Category Descriptor	Lung RADS Score	Findings	Management	Risk of Malignancy	Est. Population Prevalence
Incomplete	0	Prior chest CT examination(s) being located for comparison Part or all of lungs cannot be evaluated	Additional lung cancer screening CT images and/or comparison to prior chest CT examinations is needed	N/A	1%
Negative No nodules and definitely benign nodules	1	No lung nodules Nodule(s) with specific calcifications: complete, central, popcorn, concentric rings, and fat-containing nodules	Continue annual screening with LDCT in 12 months	<1%	90%
Benign appearance or behavior Nodules with a very low likelihood of becoming a clinically active cancer due to size or lack of growth	2	Perifissural nodule(s) <10 mm (524 mm^3) Solid nodule(s): <6 mm (<113 mm^3) new <4 mm (<34 mm^3) Part-solid nodule(s): <6 mm total diameter (<113 mm^3) on baseline screening Non-solid nodule(s) (GGN): <30 mm (<14,137 mm^3) *or* ≥30 mm (≥14,137 mm^3) and unchanged or slowly growing Category 3 or 4 nodules unchanged for ≥3 months			
Probably benign Probably benign finding(s)—short-term follow-up suggested; includes nodules with a low likelihood of becoming a clinically active cancer	3	Solid nodule(s): ≥6 to <8 mm (≥113 to <268 mm^3) at baseline *or* new 4 mm to <6 mm (34 to <113 mm^3) Part-solid nodule(s): ≥6 mm total diameter (≥113 mm^3) with solid component <6 mm (<113 mm^3) *or* new <6 mm total diameter (<113 mm^3) Non-solid nodule(s) (GGN): ≥30 mm (≥14,137 mm^3) on baseline CT or new	6-month LDCT	1%–2%	5%
Suspicious Findings for which additional diagnostic testing is recommended	4A	Solid nodule(s): ≥8 to <15 mm (≥268 to <1767 mm^3) at baseline *or* growing <8 mm (<268 mm^3) *or* new 6 to <8 mm (113 to <268 mm^3) Part-solid nodule(s): ≥6 mm (≥113 mm^3) with solid component ≥6 mm to <8 mm (≥113 to <268 mm^3) *or* with a new or growing <4-mm (<34-mm^3) solid component Endobronchial nodule	3-month LDCT; PET/CT may be used when there is a ≥8-mm (≥268-mm^3) solid component	5%–15%	2%
Very suspicious Findings for which additional diagnostic testing and/or tissue sampling is recommended	4B	Solid nodule(s): ≥15 mm (≥1767 mm^3) *or* new or growing, and ≥8 mm (≥268 mm^3)	Chest CT with or without contrast, PET/CT, and/or tissue sampling depending on the probability of malignancy and comorbidities; PET/CT may be used when there is a ≥8-mm (≥268-mm^3) solid component; for new large nodules that develop on an annual repeat screening CT, a 1-month LDCT may be recommended to address potentially infectious or inflammatory conditions	>15%	2%
	4B	Part-solid nodule(s) with a solid component ≥8 mm (≥268 mm^3) *or* a new or growing ≥4 mm (≥34 mm^3) solid component			
	4X	Category 3 or 4 nodules with additional features or imaging findings that increases the suspicion of malignancy			
Other clinically significant or potentially clinically significant findings (non–lung cancer)	S	Modifier—may add to category 0–4 coding	As appropriate to the specific finding	N/A	10%

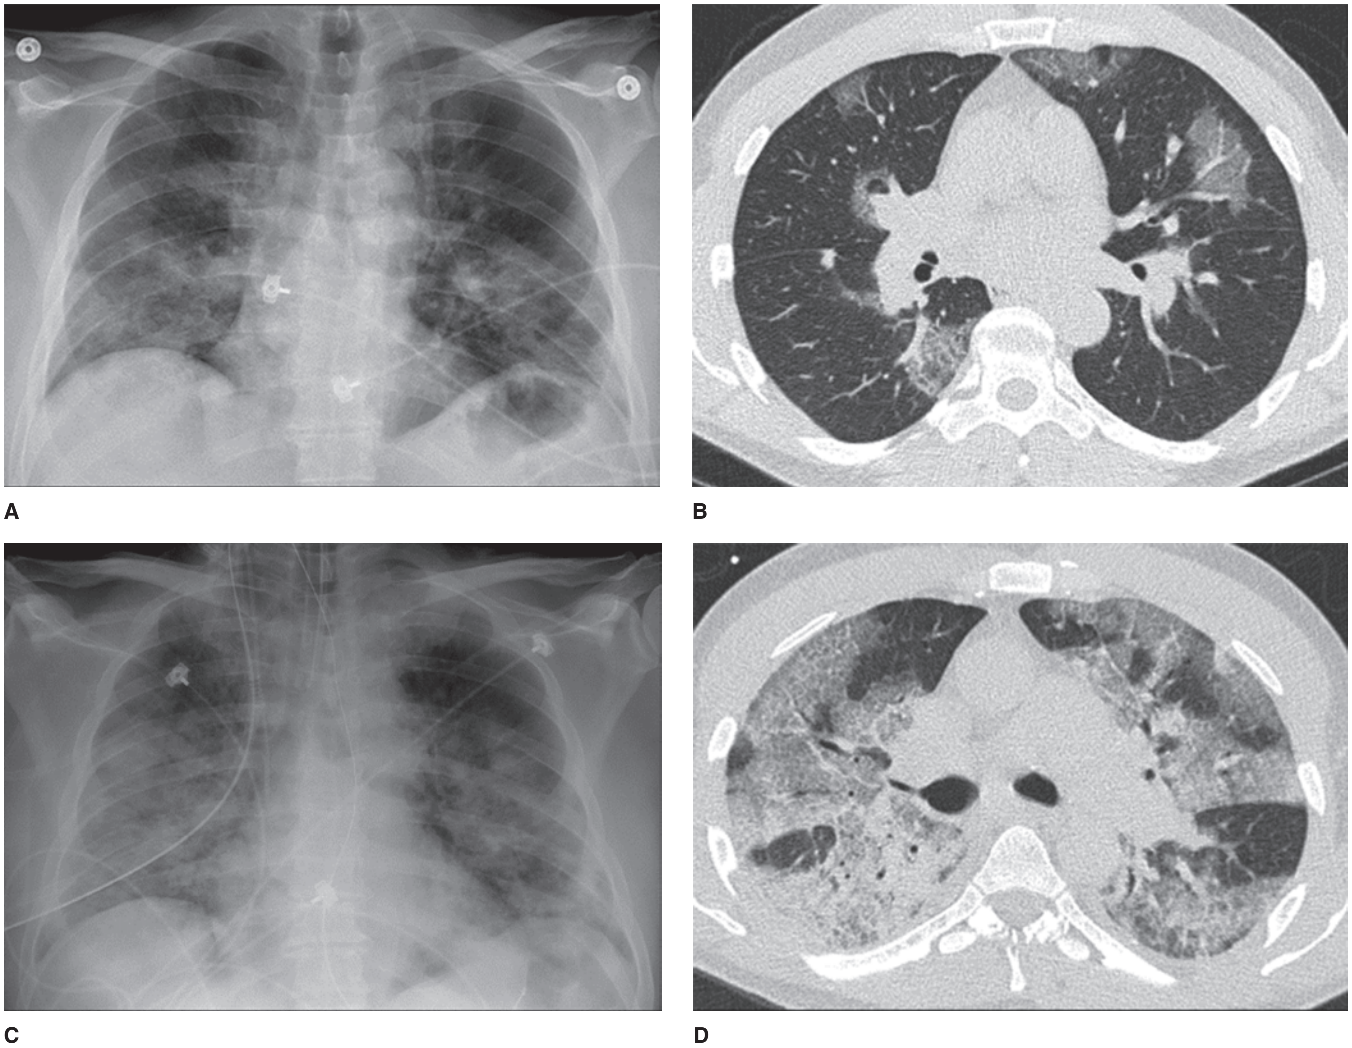

Figure 28-44 Characteristic imaging features of evolving COVID-19 pneumonia. **A.** AP view chest x-ray demonstrates lower lung zone predominant patchy opacities without sizable pleural effusions in a patient presenting with 5 days of respiratory symptoms. **B.** Axial CT image obtained 7 days after initial presentation reveals typical peripheral predominant ground glass opacities. With worsening symptoms, an AP view chest x-ray (**C**) and axial CT–obtained image (**D**) demonstrate progressive disease with more extensive radiographic opacities and correlating bilateral, confluent mixed-density consolidations and ground glass opacities some with associated interlobular septal thickening forming what is called a "crazy paving" pattern.

Special note should be made of pneumonia due to COVID-19, an illness caused by a novel SARS-CoV2 coronavirus that rapidly progressed to a global pandemic starting in early 2020. This virus has typical, but not specific, imaging characteristics, manifest most commonly as bilateral, lower lobe–predominant ground-glass opacities mimicking the imaging appearance and distribution of organizing pneumonia (Fig. 28-44). The specificity of these findings is directly linked with local prevalence of the virus. Although the primary diagnosis is based upon PCR testing for detection of viral RNA in nasal, nasopharyngeal, or oral secretions, CT imaging has gained an established role in patient care. A 2020 Fleischner Society guideline on imaging in COVID-19 disease recommended that it be used only in the setting of moderate or severe symptoms, in the setting of worsening respiratory status in patients with confirmed disease, or if alternative diagnoses are sought.[91,92]

With regard to localized alveolar disease, the very important distinction between atelectasis and consolidation needs to be clarified. Patchy opacification of airspaces without a decrease in the volume of the affected area suggests consolidation, while opacification of airspaces associated with a decrease in the volume of the affected area suggests atelectasis. The differential diagnosis depends largely on the extent to which lung volume is decreased. However, assessment of the magnitude of volume loss is not always useful. For example, while pneumonia usually is associated with minimal or no volume loss, occasionally, volume loss is considerable. On the other hand, atelectasis usually has moderate or severe loss of volume, but in some instances, there may be little volume loss (Figs. 28-45–28-49).

Consolidations are statistically likely to represent pneumonias, especially in the acute setting, whereas atelectasis indicates airway obstruction (obstructive atelectasis), adjacent mass effect (compressive atelectasis), or, more rarely, surfactant deficiency or scarring (adhesive atelectasis). For practical purposes, focal airspace opacities, particularly if lobar, are considered consolidations if the degree of volume loss is negligible or mild, and atelectasis if the degree of volume loss is substantial. The various patterns of lobar atelectasis are important to recognize, since this radiographic finding is a very common manifestation of carcinoma of the lung or, occasionally, some other endobronchial neoplasm.

Atelectasis is also common in the postoperative patient ("dependent atelectasis"), presumably because of hypoventilation of

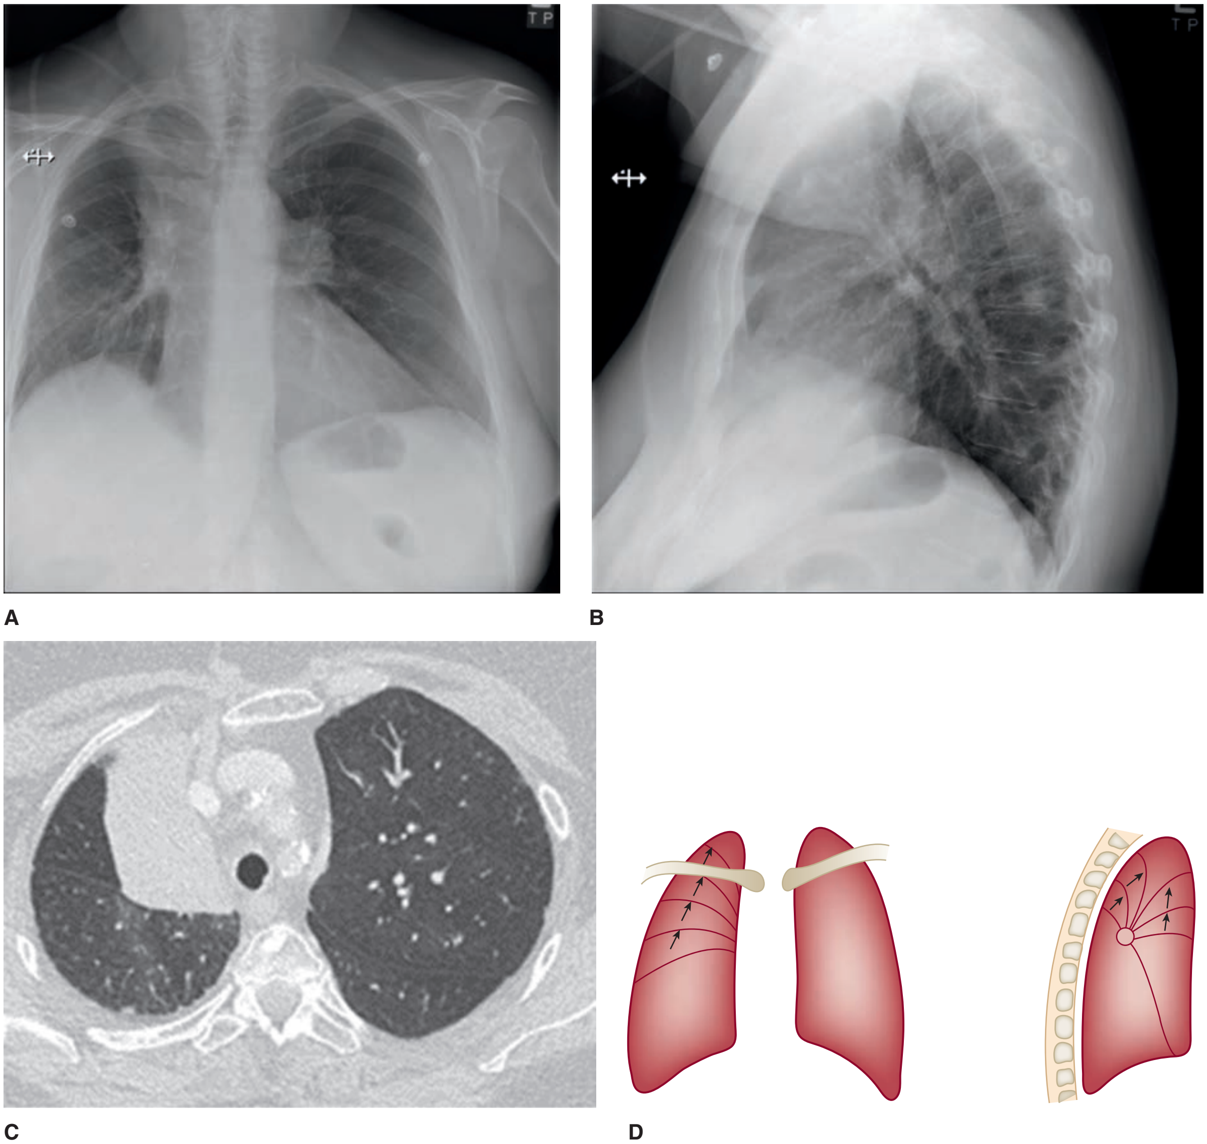

Figure 28-45 Right upper lobe atelectasis secondary to bronchogenic carcinoma. **A.** PA view. The minor fissure is elevated. **B.** Lateral view. Increased anterior opacity with the major fissure is displaced anteriorly. **C.** Axial CT image demonstrating partial RUL collapse with a central density with convex borders reflecting the obstructing mass. **D.** Schematic representation of atelectasis of the right upper lobe.

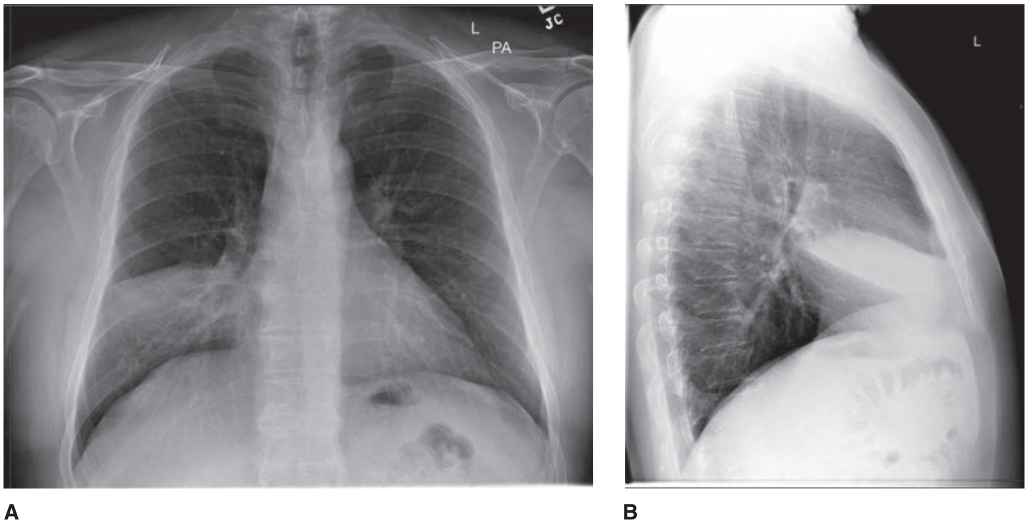

Figure 28-46 Right middle lobe atelectasis secondary to calcified lymph node eroding into and obstructing the RML bronchus. **A.** PA view. The middle lobe is collapsed against the right side of the heart. **B.** Lateral view. The major and minor fissures are drawn together, creating an opacity that overlies the cardiac shadow.

A B C D

Figure 28-47 Atelectasis (severe) of the right lower lobe due to chronic radiation changes for primary lung malignancy. **A.** PA view. Secondary signs of atelectasis are present in the right lung: small hemithorax, hyperlucent lung, and small hilus. In this instance, these secondary signs are important in suspecting atelectasis. In addition, the collapsed lower lobe can be seen (poorly) through the right heart border. **B.** Lateral view. The entire right lower lobe appears only as a diffuse opacity overlying the spine. The posterior portion of the right hemidiaphragm cannot be identified (silhouette sign). **C.** Axial CT image demonstrates a complete RLL collapse. **D.** Schematic representation of collapse of right lower lobe.

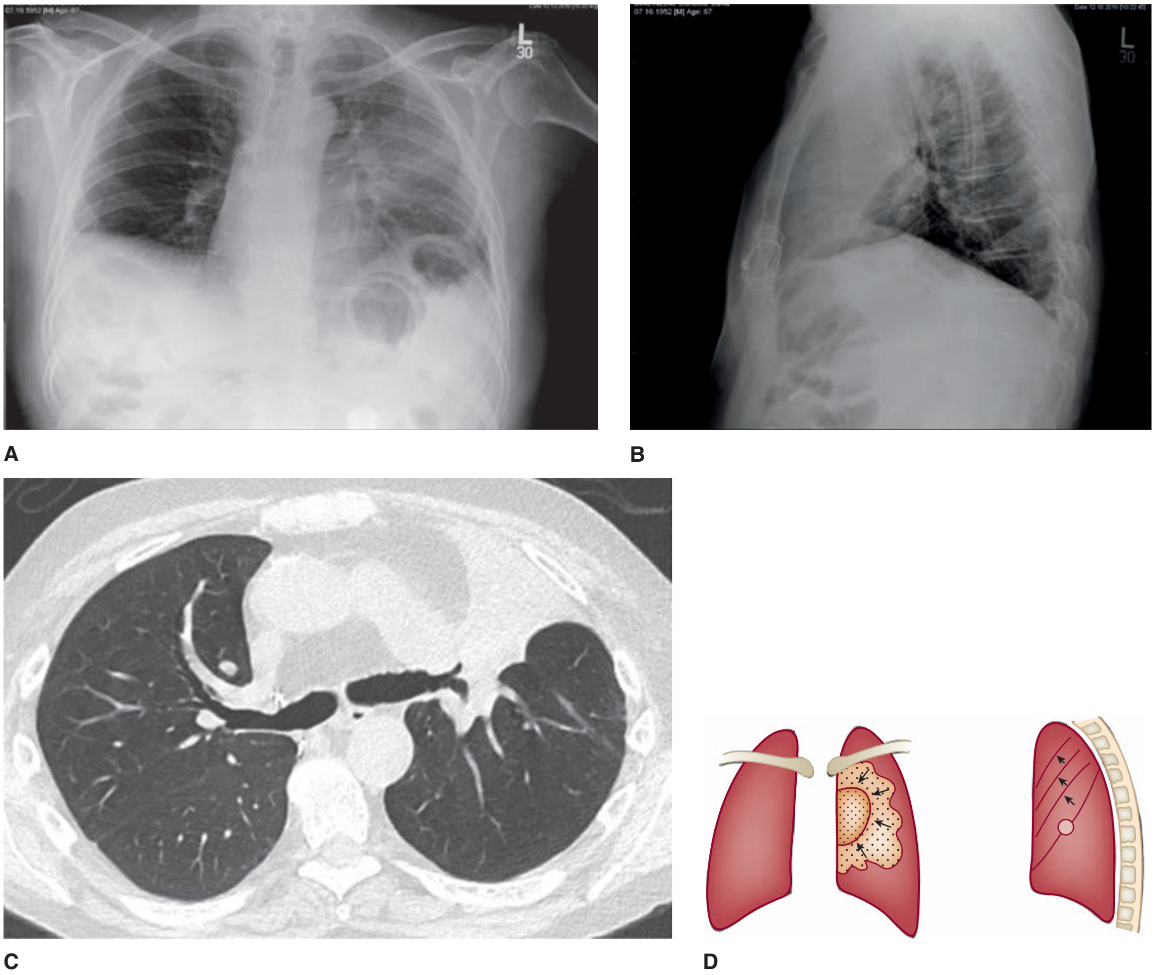

Figure 28-48 Left upper lobe atelectasis secondary to chronic bronchial occlusion in a transplanted lung. **A.** PA view. Increased hazy opacity at the left hemithorax; the left side of the heart is indistinct due to collapse of the left upper lobe. Hyperinflation of superior segment of the left lower lobe between the left upper lobe and the aorta, resulting in a sickle-shaped lucency medially (luftsichel sign) **B.** Lateral view. The collapsed lung is seen as an opacity anterior to the major fissure, which is displaced anteriorly. **C.** Axial CT image demonstrates a complete LUL collapse. **D.** Schematic representation of collapse of left upper lobe.

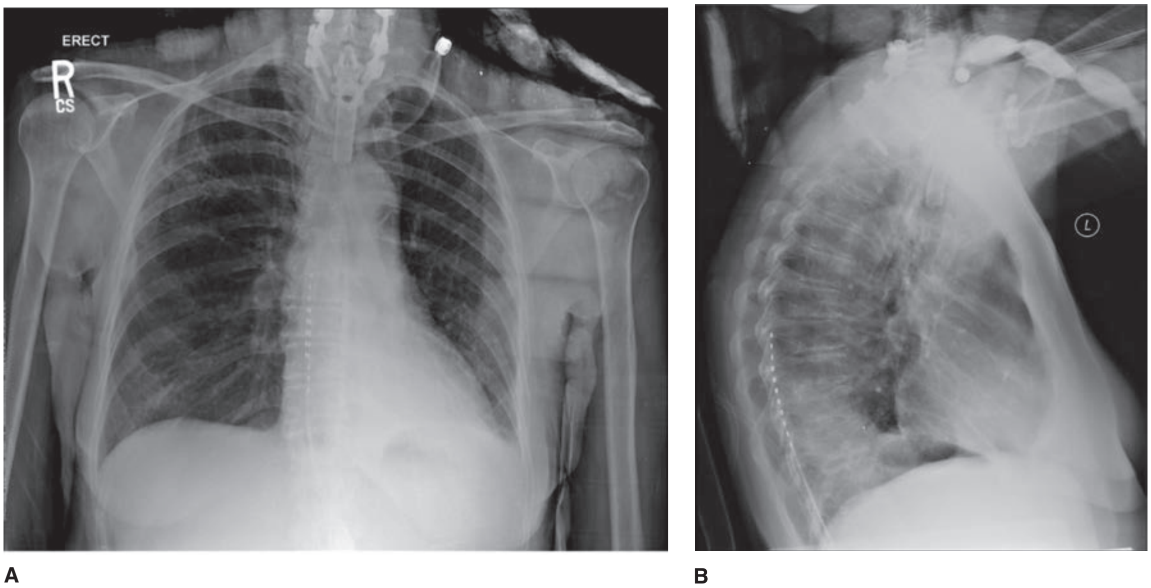

FIGURE 28-49 Left lower lobe atelectasis due to aspiration. **A.** PA view. The collapsed left lower lobe is seen as a straight line behind the left heart border. No vasculature can be seen through the heart shadow, and the medial border of the left hemidiaphragm is obscured by the collapsed left lower lobe. **B.** Lateral view. Opacity over the spine and absence of left posterior diaphragm. This is difficult to differentiate from a pleural effusion.

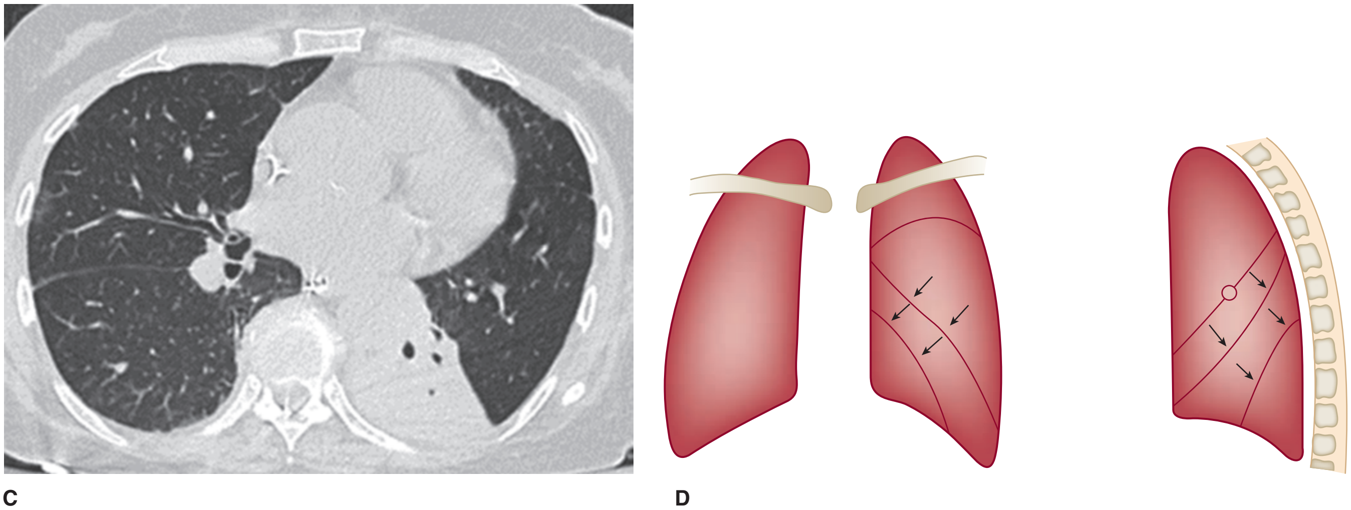

Figure 28-49 (*Continued*) **C.** Axial CT image demonstrates a complete LLL collapse. **D.** Schematic representation of collapsed left lower lobe.

dependent parts of the lungs and inadequate clearing of respiratory secretions. In this instance, loss of volume may be mild or absent. Atelectasis may also occur as a consequence of inflammatory disease of the airways or aspiration of a foreign body. Atelectasis also invariably accompanies pleural effusions and pneumothorax. With pleural effusions, atelectasis is greatest in the vicinity of the pleural effusion. Rounded atelectasis is a subtype characterized by ovoid peripheral opacity, associated with underlying chronic pleural disease (manifested by loculated effusion or pleural thickening). Architectural distortion and convergence of the bronchovascular structures supplying the area of rounded atelectasis ("comet tail sign") are seen. It is important to recognize the typical features of rounded atelectasis, as it can be confused with pulmonary neoplasms.

In non-immunocompromised hosts, most acute consolidations reflect bacterial pneumonias and should improve to complete resolution with treatment, generally within 4 to 6 weeks; radiographic clearance lags a few weeks behind clinical improvement. Therefore, in adult patients it is important to obtain chest radiographs at the end of this time frame to demonstrate complete resolution of the consolidation. Any consolidation that persists (>1 month) in spite of optimal empirical treatment should be considered potentially neoplastic; the differential diagnosis includes pulmonary mucinous adenocarcinoma (formerly classified as BAC), pulmonary lymphoma (of the MALT type, denoting low-grade extranodal lymphomas), or hemorrhagic metastasis (such as from breast, renal cell carcinoma, or melanoma primaries). In addition, atypical infectious processes (such as fungal or mycobacterial infection) may present as persistent consolidations, as well as several noninfectious or inflammatory processes, such as cryptogenic organizing pneumonia (COP), eosinophilic pneumonia, and granulomatous vasculitides (e.g., granulomatosis with polyangiitis). Most chronic consolidations ultimately require chest CT and tissue sampling (via transthoracic or bronchoscopic approaches) for final diagnosis (Figs. 28-50–28-55).

PULMONARY EDEMA: CARDIOGENIC AND NONCARDIOGENIC

Imaging offers a comprehensive display of the anatomy of the cardiopulmonary system and its function. Chest radiographs can demonstrate the heart size and configuration, the width of the vascular pedicle, and the caliber and distribution of the pulmonary arteries and veins. Pulmonary arteries and veins can generally be distinguished on chest radiographs by their anatomic location, with the pulmonary veins more horizontal, more inferior, and more lateral to the pulmonary arteries in relationship to the hila. The distinction is, nonetheless, seldom useful radiographically and, therefore, the generic terms *pulmonary vessels* and *pulmonary vasculature* are used. CT and MRI more readily depict the pulmonary arteries and veins. The pulmonary arteries arise from the main pulmonary artery trunk, while the pulmonary veins enter the left atrium and are readily distinguished on cross-sectional imaging even without intravenous contrast. Moreover, CT and MRI can accurately evaluate cardiac structure and function, particularly cardiac MRI, providing quantitative metrics to assess ventricular and valvular function.

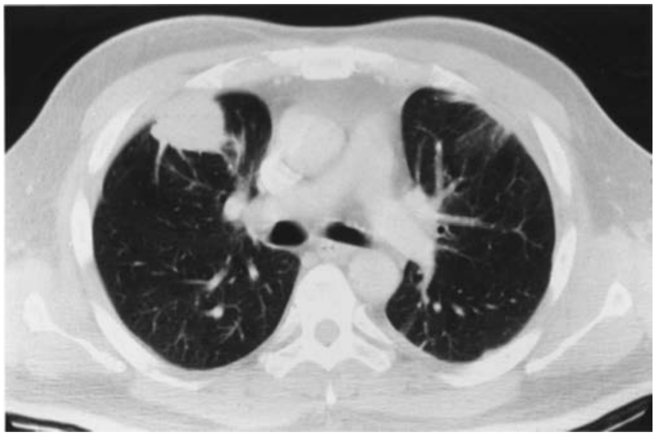

Figure 28-50 Axial CT image showing rounded atelectasis. A mass with a "tail" can be seen in the anterior segment of the right upper lobe. Pleural thickening is seen on the left side, with transpulmonary bands extending into the left upper lobe. The mass on the right represents rounded atelectasis, a finding usually associated with asbestos exposure or chronic pleural disease. The changes on the left probably represent an early stage in the development of rounded atelectasis.

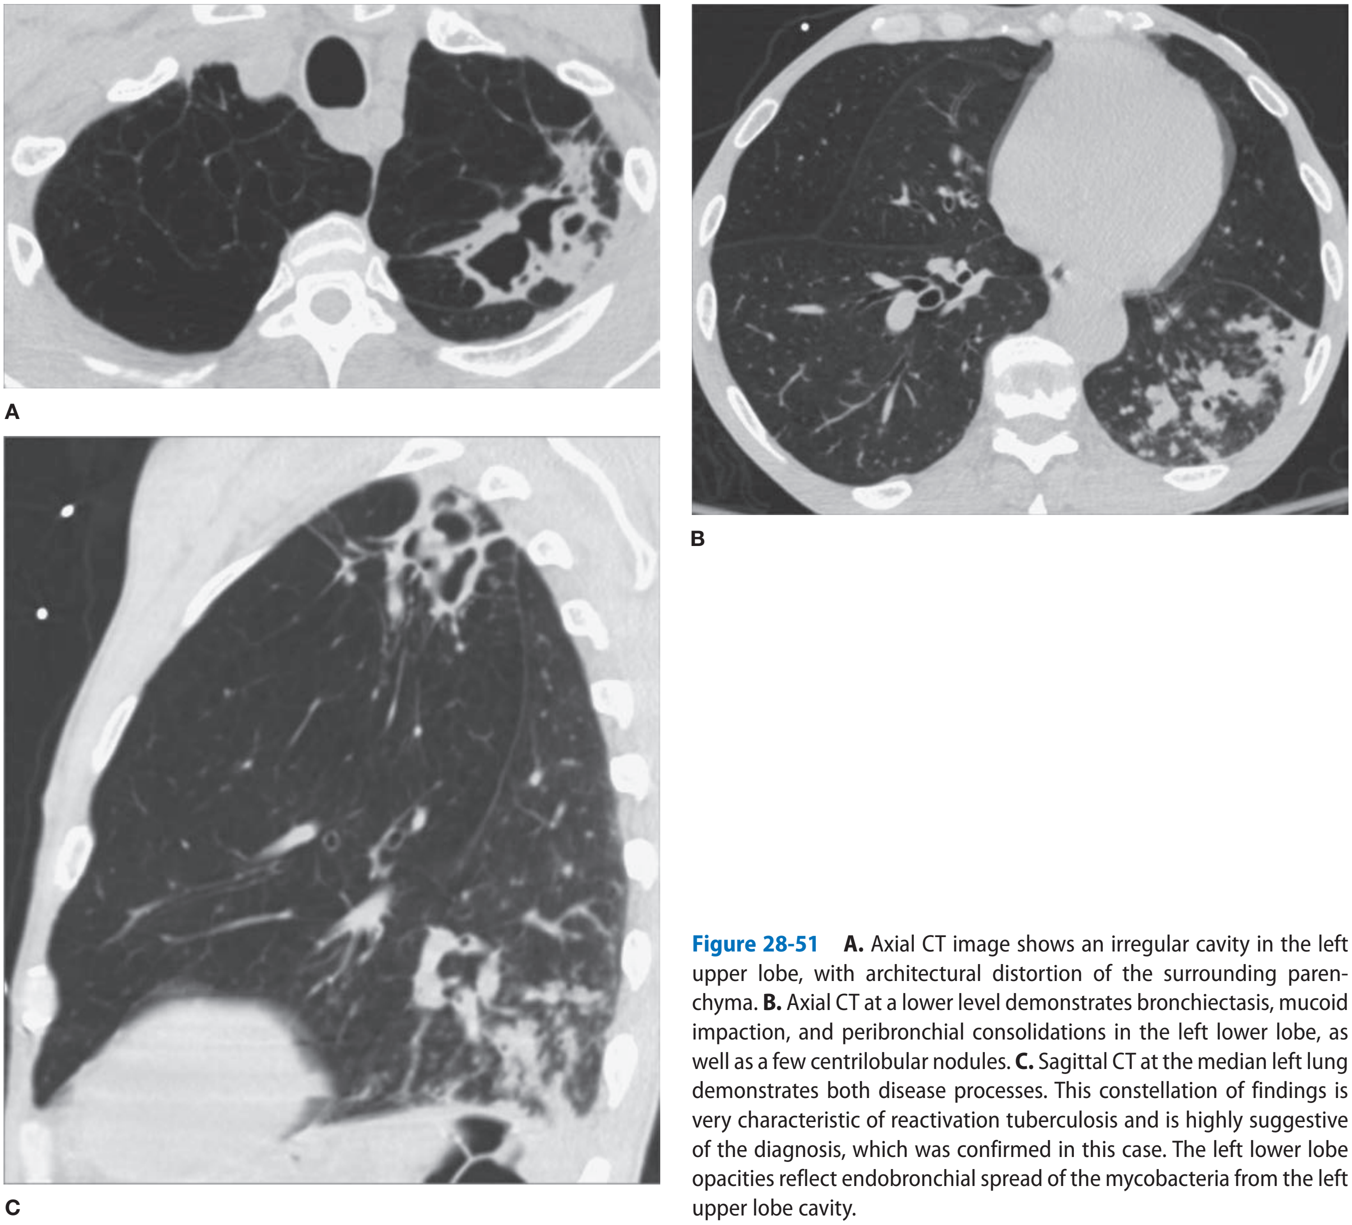

Figure 28-51 **A.** Axial CT image shows an irregular cavity in the left upper lobe, with architectural distortion of the surrounding parenchyma. **B.** Axial CT at a lower level demonstrates bronchiectasis, mucoid impaction, and peribronchial consolidations in the left lower lobe, as well as a few centrilobular nodules. **C.** Sagittal CT at the median left lung demonstrates both disease processes. This constellation of findings is very characteristic of reactivation tuberculosis and is highly suggestive of the diagnosis, which was confirmed in this case. The left lower lobe opacities reflect endobronchial spread of the mycobacteria from the left upper lobe cavity.

Congestive heart failure is a common clinical condition characterized by systolic and/or diastolic dysfunction of the left ventricle, leading to increasing diastolic filling pressure, increasing left atrial pressure, and fluid retention. Ultimately, left ventricular failure leads to right ventricular failure. The heart is almost invariably enlarged, and the central pulmonary vasculature appears prominent and indistinct. These changes are easier to recognize on PA and lateral views than on portable chest radiographs.

A rational progression of chest radiographic findings in congestive heart failure can be fully appreciated on PA and erect radiographs and is strongly correlated with increases in pulmonary capillary wedge pressure (PCWP, reflecting left atrial pressure), indicating progressive pulmonary venous congestion.

The first stage is correlated with a PCWP of 13 to 18 mm Hg and is characterized by increased width of the vascular pedicle and vascular redistribution in the erect patient; the caliber of the upper lung vessels is increased relative to the lower lung vessels (cephalization), and cardiomegaly is present.

The second stage is correlated with PCWP of 18 to 25 mm Hg and is characterized additionally by the presence of pulmonary interstitial edema—which is manifested on chest radiography as Kerley lines, thickened fissures, and peribronchial cuffing with indistinct contour of the central vessels. Kerley B lines, as previously described, represent small (1–2 cm), thin, linear opacities that are seen peripherally perpendicular to a pleural surface, reflecting edema involving interlobular septae.

Finally, the third stage is correlated with PCWP >25 mm Hg and is characterized by the additional presence of alveolar edema, manifested as fluffy (cotton-wool appearance), symmetric airspace consolidation with mid and lower lung field predominance. Pleural effusions are often present in stages II or III and may be present earlier if there is a substantial component of right ventricular dysfunction or central volume overload, such as in patients with pulmonary hypertension or superimposed chronic renal or liver disease.

Pleural effusions often accompany biventricular heart failure. However, while the pulmonary congestion usually clears rapidly in response to therapy, the pleural effusions often remain after the pulmonary vessels have returned to normal size and require a longer time to resolve. Pleural effusions in congestive heart failure may be unilateral or bilateral, although they are most often bilateral. The effusions are nearly always transudates. Therefore, the presence of

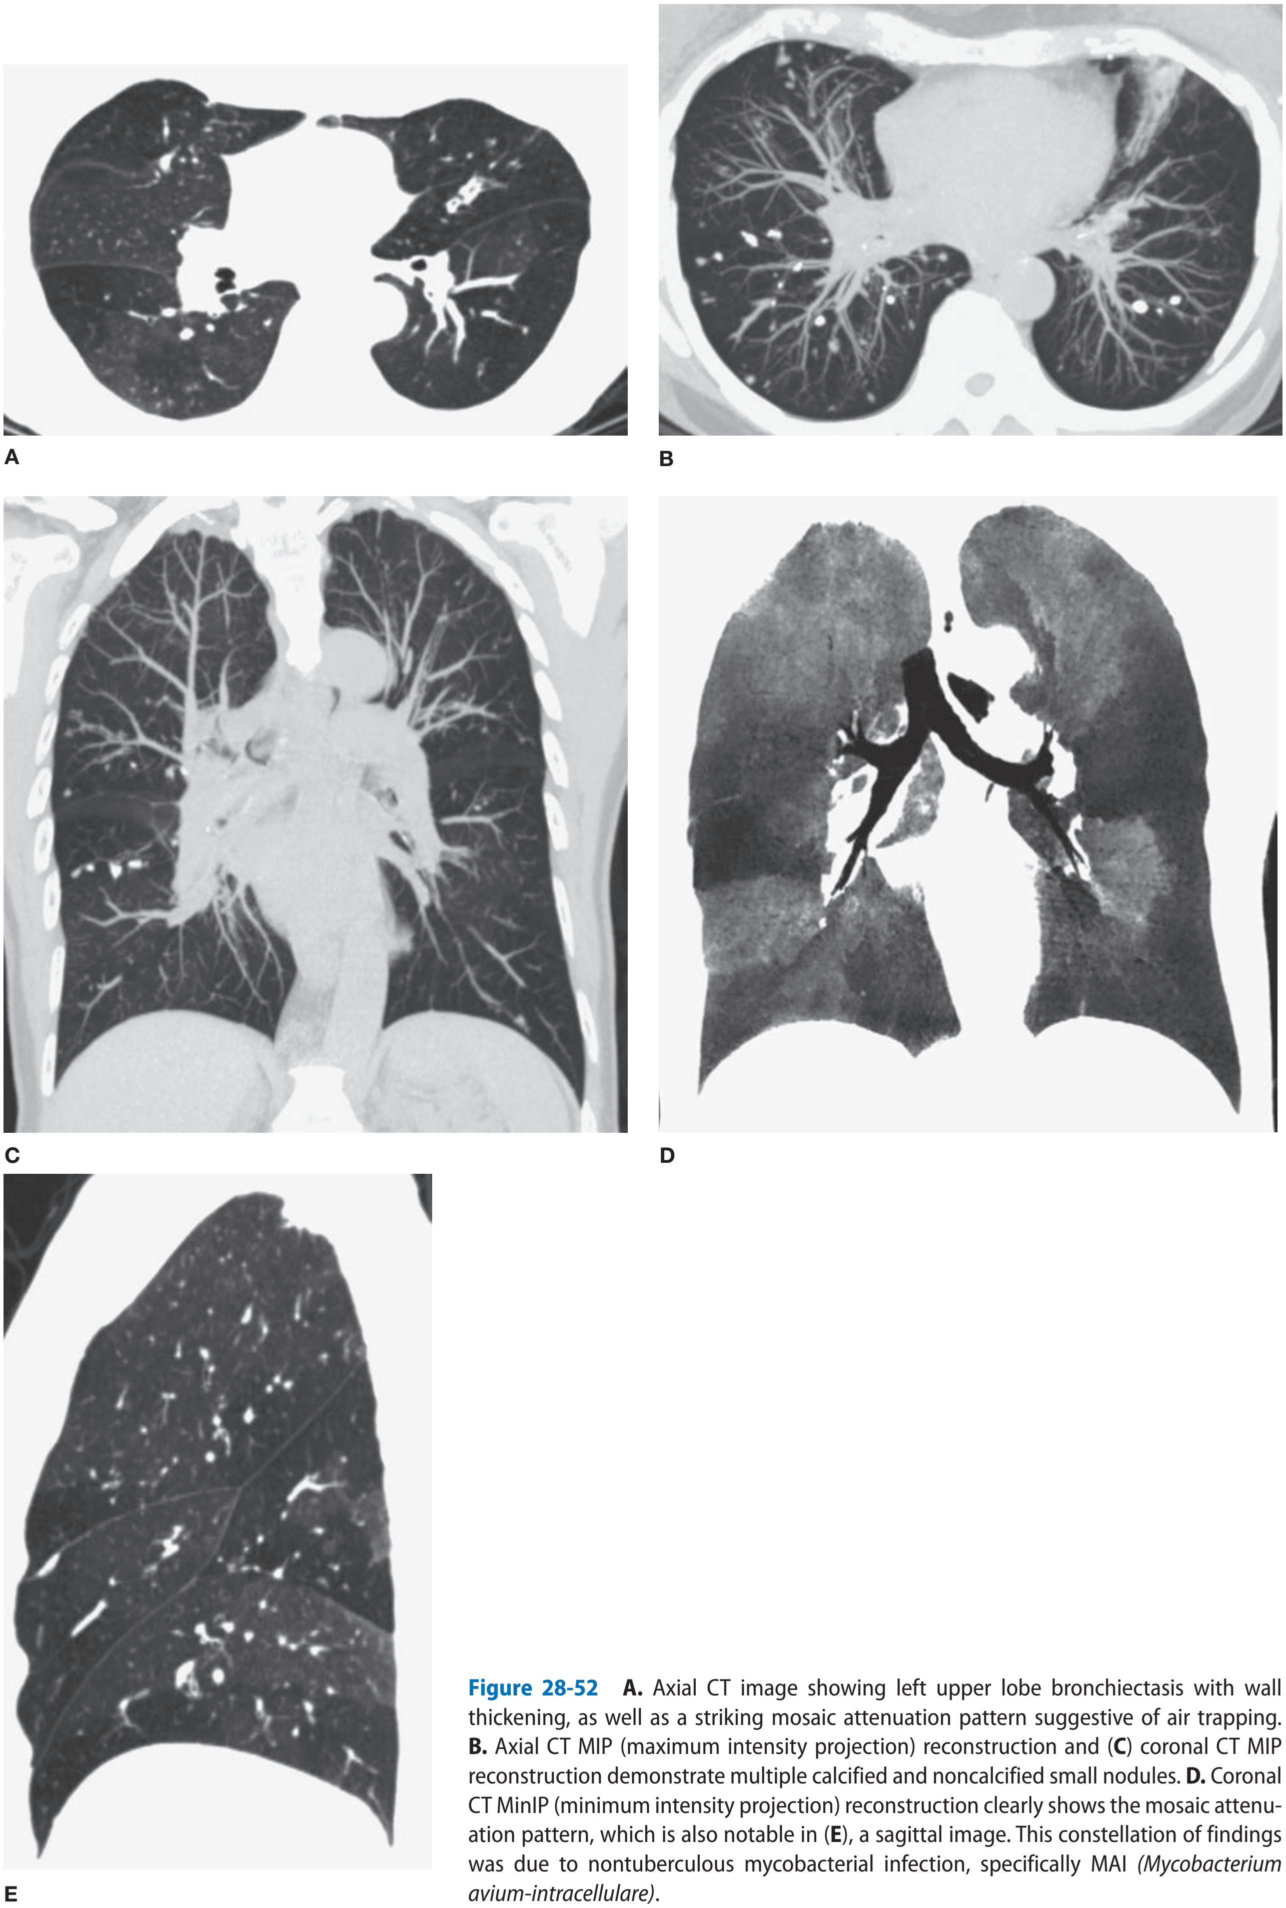

Figure 28-52 **A.** Axial CT image showing left upper lobe bronchiectasis with wall thickening, as well as a striking mosaic attenuation pattern suggestive of air trapping. **B.** Axial CT MIP (maximum intensity projection) reconstruction and (**C**) coronal CT MIP reconstruction demonstrate multiple calcified and noncalcified small nodules. **D.** Coronal CT MinIP (minimum intensity projection) reconstruction clearly shows the mosaic attenuation pattern, which is also notable in (**E**), a sagittal image. This constellation of findings was due to nontuberculous mycobacterial infection, specifically MAI *(Mycobacterium avium-intracellulare)*.

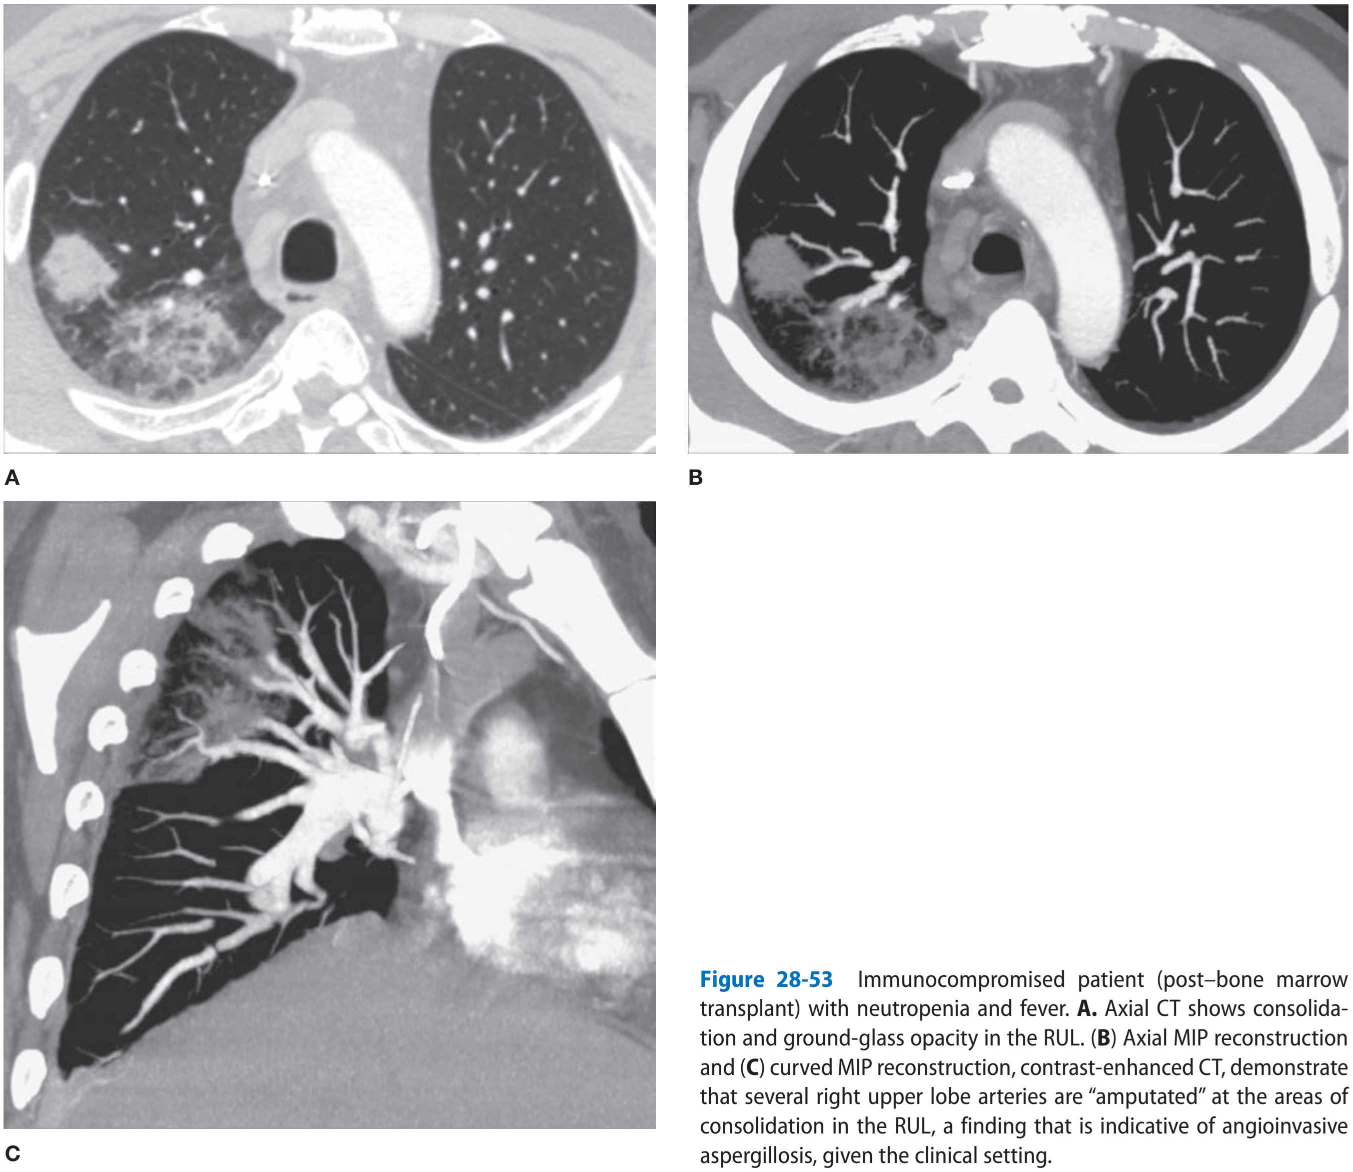

Figure 28-53 Immunocompromised patient (post–bone marrow transplant) with neutropenia and fever. **A.** Axial CT shows consolidation and ground-glass opacity in the RUL. (**B**) Axial MIP reconstruction and (**C**) curved MIP reconstruction, contrast-enhanced CT, demonstrate that several right upper lobe arteries are "amputated" at the areas of consolidation in the RUL, a finding that is indicative of angioinvasive aspergillosis, given the clinical setting.

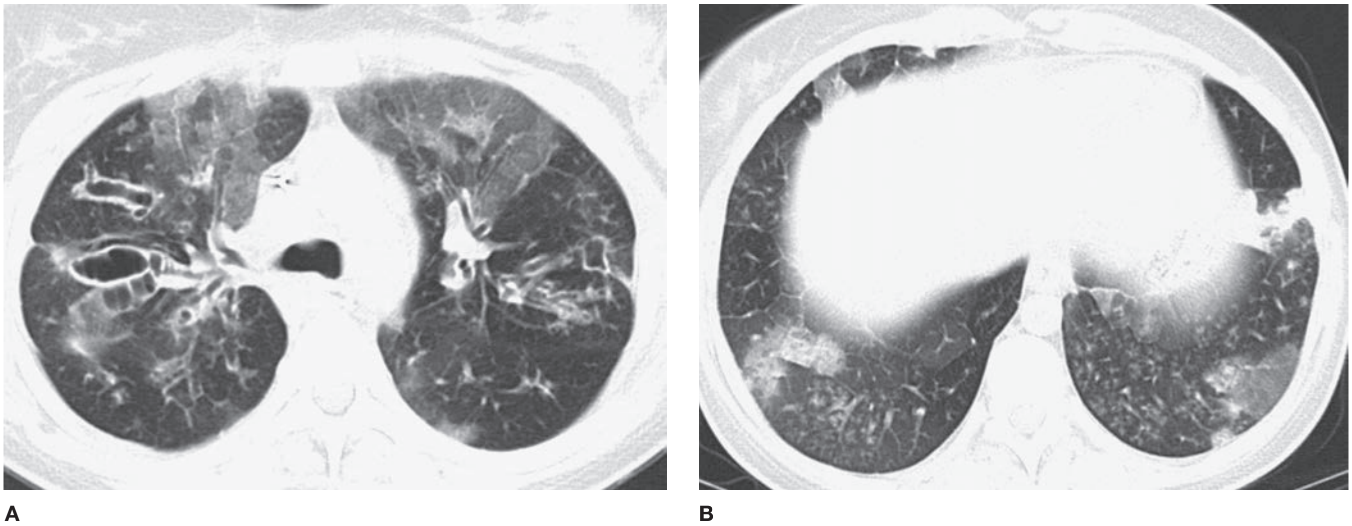

Figure 28-54 **A.** Axial CT through the level of the carina demonstrates extensive bronchiectasis. **B.** Axial CT at a lower level demonstrates multiple areas of consolidation and numerous centrilobular nodules. This patient had a diagnosis of cystic fibrosis, complicated by superinfection by *Pseudomonas aeruginosa*.

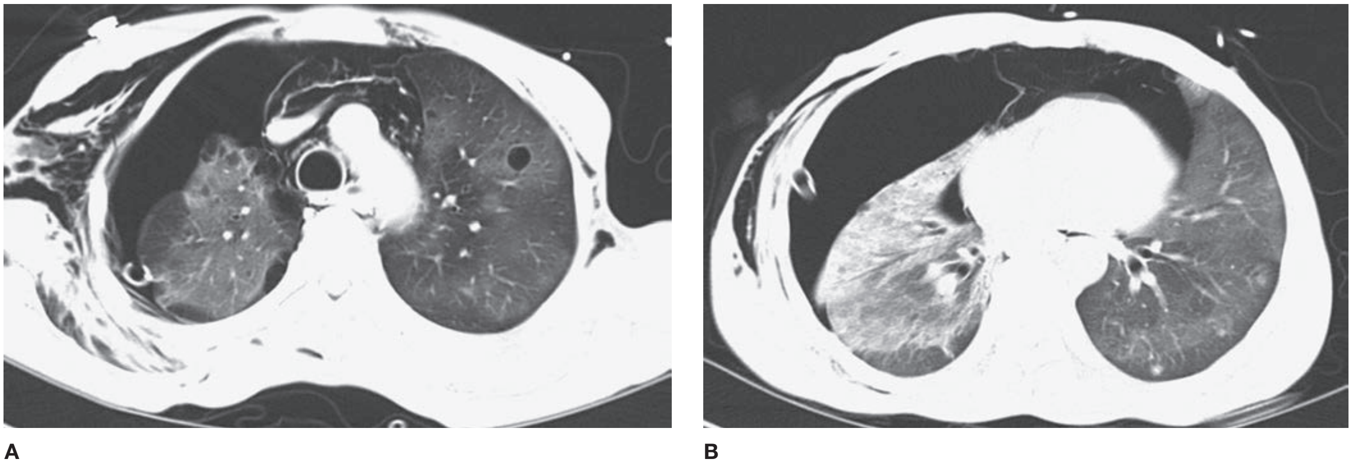

Figure 28-55 **A.** Axial CT through the upper lung fields demonstrates a large right-side pneumothorax with a chest tube partially visualized. The lung parenchyma demonstrates diffuse, but nonhomogeneous, ground-glass opacities, as well as scattered cysts. **B.** Axial CT at a lower level demonstrates diffuse ground-glass opacities, small nodules, and patchy areas of consolidation. This patient had AIDS complicated by *Pneumocystis jiroveci* pneumonia. Spontaneous pneumothorax is a known complication of this disease.

a unilateral effusion, particularly an isolated left effusion, should prompt consideration of a diagnostic thoracentesis. If the effusion is an exudate, an alternate cause, such as malignancy or infection, should be considered (Figs. 28-56 and 28-57).

CT may demonstrate the same findings and the same pattern of progression according to the degree of left heart dysfunction and PCWP increase. Nonetheless, it allows better assessment of cardiac chamber size, vascular caliber, and presence of pulmonary interstitial or alveolar edema. Nonetheless, because the combination of clinical, laboratory, and radiographic findings generally suffices for the diagnosis of congestive heart failure, CT is not routinely obtained in patients in this setting, although it is not uncommon to establish the diagnosis on CT studies performed for other reasons.

As previously discussed, pulmonary interstitial edema presents on CT as axial (peribronchovascular) and septal interstitial thickening (interlobular and intralobular); the findings are usually symmetric, smooth, and lower lung field predominant. The differential diagnosis, especially if the pattern of interstitial thickening is nodular, upper lung predominant, or asymmetric, includes sarcoidosis and lymphangitic spread of neoplasm. Pulmonary alveolar edema is demonstrated as airspace opacities (ground-glass or consolidation), with fluid-filled acinar structures; the opacities are symmetric, ill-defined, confluent, and central and lower lung field predominant. Findings of pulmonary alveolar edema often coexist with pulmonary interstitial edema, but not vice-versa. The exception is flash pulmonary edema, in which alveolar edema develops so rapidly that there is not enough time for interstitial edema to manifest. Flash pulmonary edema may occur with sudden changes in intravascular volume, such as following resuscitation in trauma patients or with sudden changes in cardiac function, as occurring with cardiac arrhythmias or myocardial infarction.

Finally, US findings in pulmonary edema include the presence of B-lines, which reflect the presence of an interstitial abnormality and in the setting of cardiogenic edema reflect extravascular lung fluid.

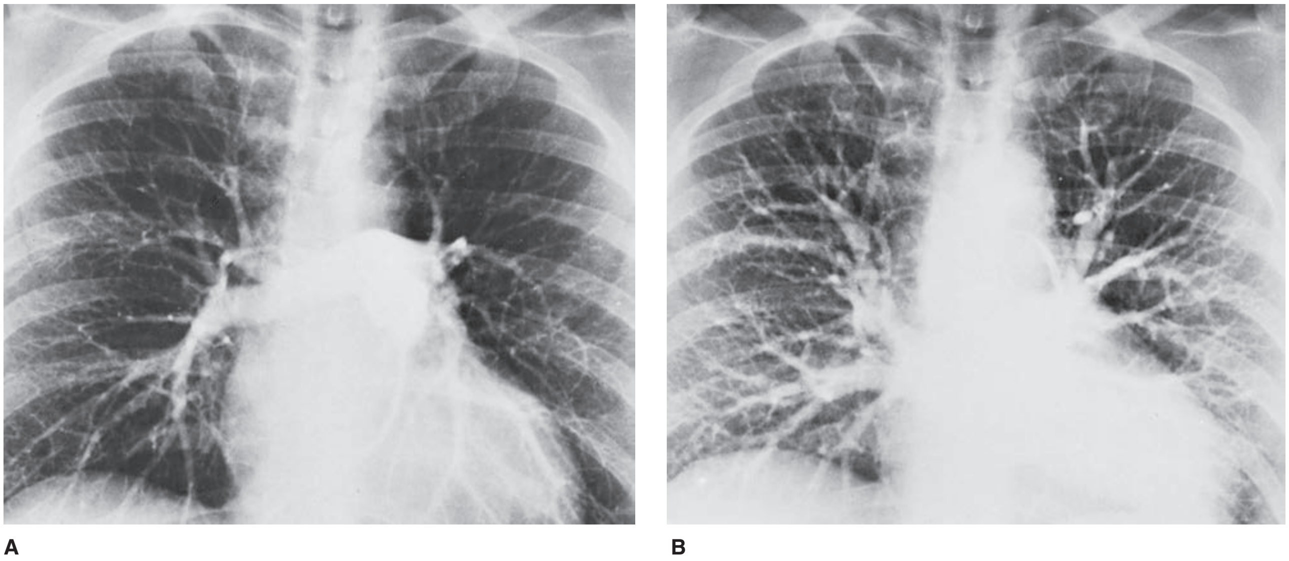

Figure 28-56 Pulmonary arteries and veins: **A.** The early phase of the pulmonary angiogram depicts the normal course and caliber of the pulmonary arteries. **B.** The late phase shows the normal course and caliber of the pulmonary veins. The veins have a more horizontal course than the arteries and enter the hila below the arteries.

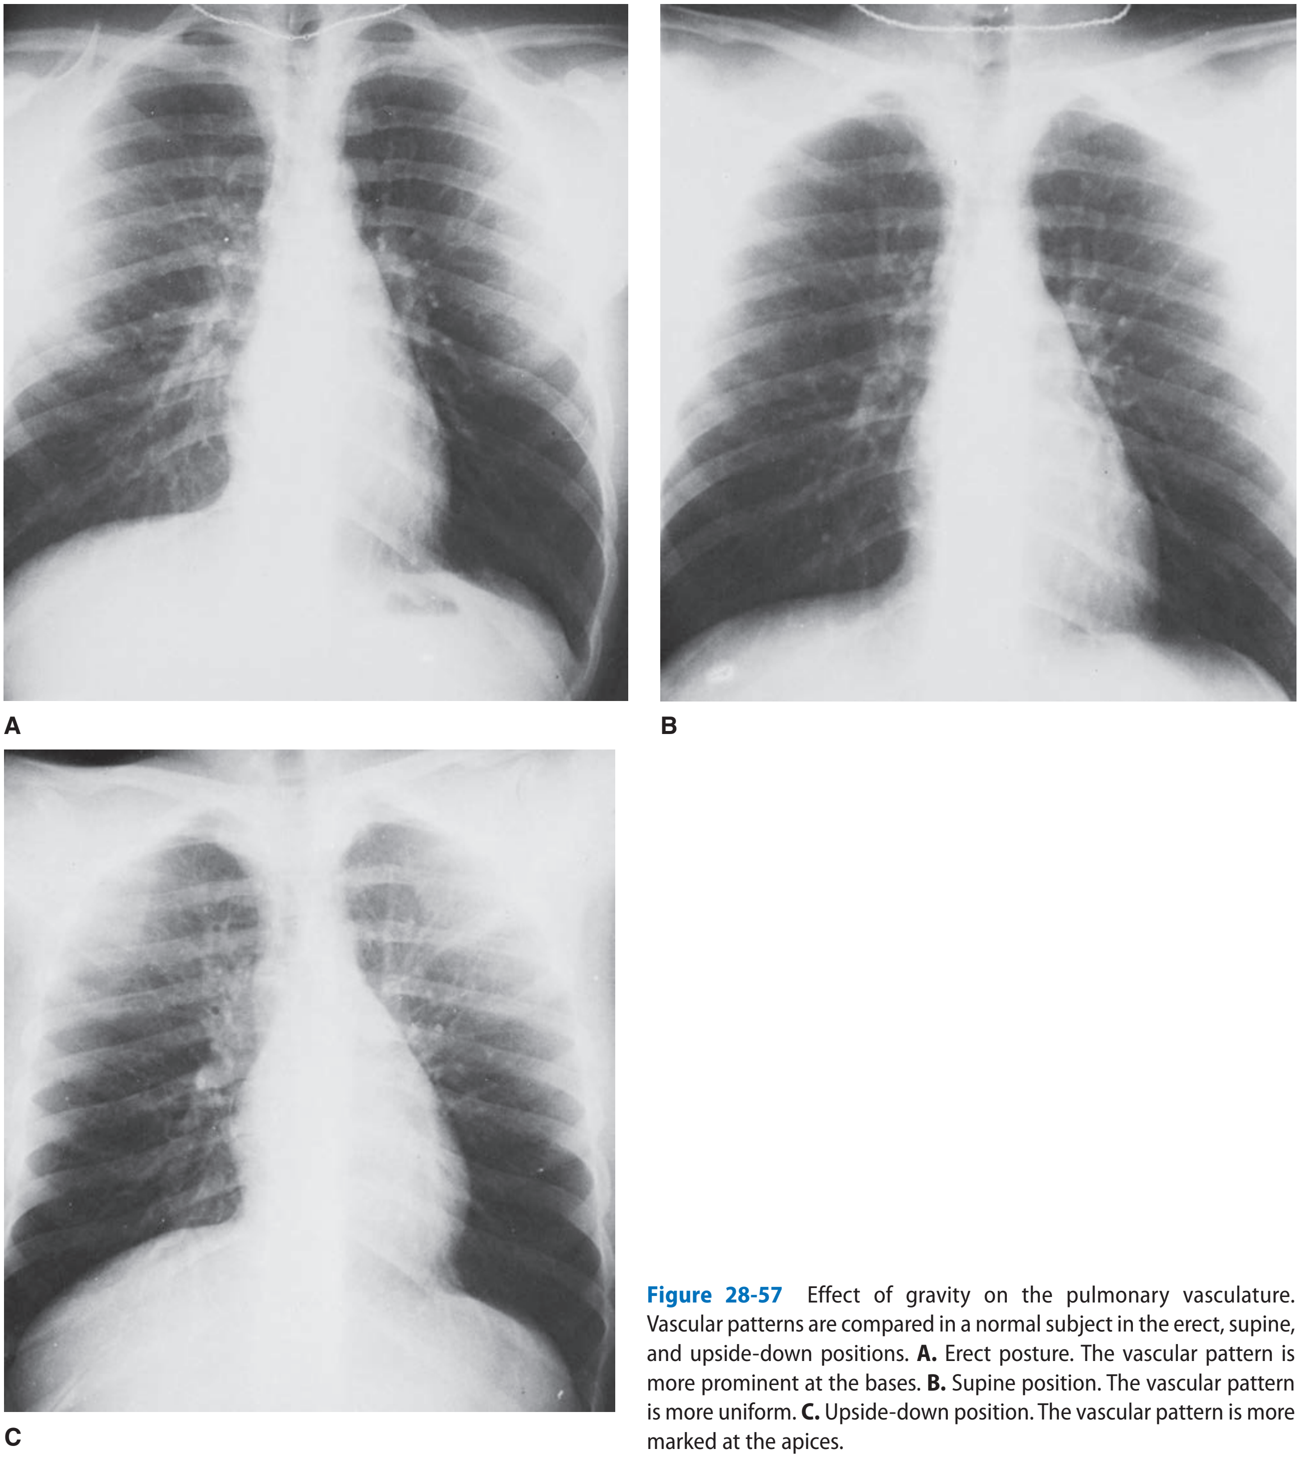

Figure 28-57 Effect of gravity on the pulmonary vasculature. Vascular patterns are compared in a normal subject in the erect, supine, and upside-down positions. **A.** Erect posture. The vascular pattern is more prominent at the bases. **B.** Supine position. The vascular pattern is more uniform. **C.** Upside-down position. The vascular pattern is more marked at the apices.

Moreover, US has high sensitivity to the presence of pleural effusion, which exceeds the sensitivity of chest radiography. Although findings are nonspecific, US can help guide therapy and monitor response to therapy in the appropriate clinical setting. Echocardiography has a well-established role in the assessment of cardiac function and, when used in combination with lung US, can help differentiate cardiogenic from noncardiogenic causes of edema.[93–95]

Pulmonary edema is the prototype of diffuse lung disease. Etiologically, it can be broadly separated into cardiogenic and noncardiogenic causes. Cardiogenic edema is caused by congestive heart failure.[96,97] Noncardiogenic edema is a manifestation of increased permeability of the pulmonary capillaries in which cardiac function is relatively preserved. Major differential diagnoses include acute hypersensitivity reactions, inhaled toxins, near-drowning, sepsis, and several processes that lead to the pathologic diagnosis of diffuse alveolar damage (DAD), most notably acute respiratory distress syndrome (ARDS).[98–102] From an imaging perspective, cardiogenic edema is more likely associated with cardiomegaly and functional impairment of the ventricles and tends to clear rapidly following administration of diuretics and drugs that optimize cardiovascular status. Noncardiogenic edema tends to resolve slowly and often requires clinical and laboratory correlation for etiologic characterization (Figs. 28-58 and 28-59). The definitions for ARDS were updated in 2011 to include the following criteria: (1) Timing: Respiratory symptoms must have begun within 1 week of a known clinical

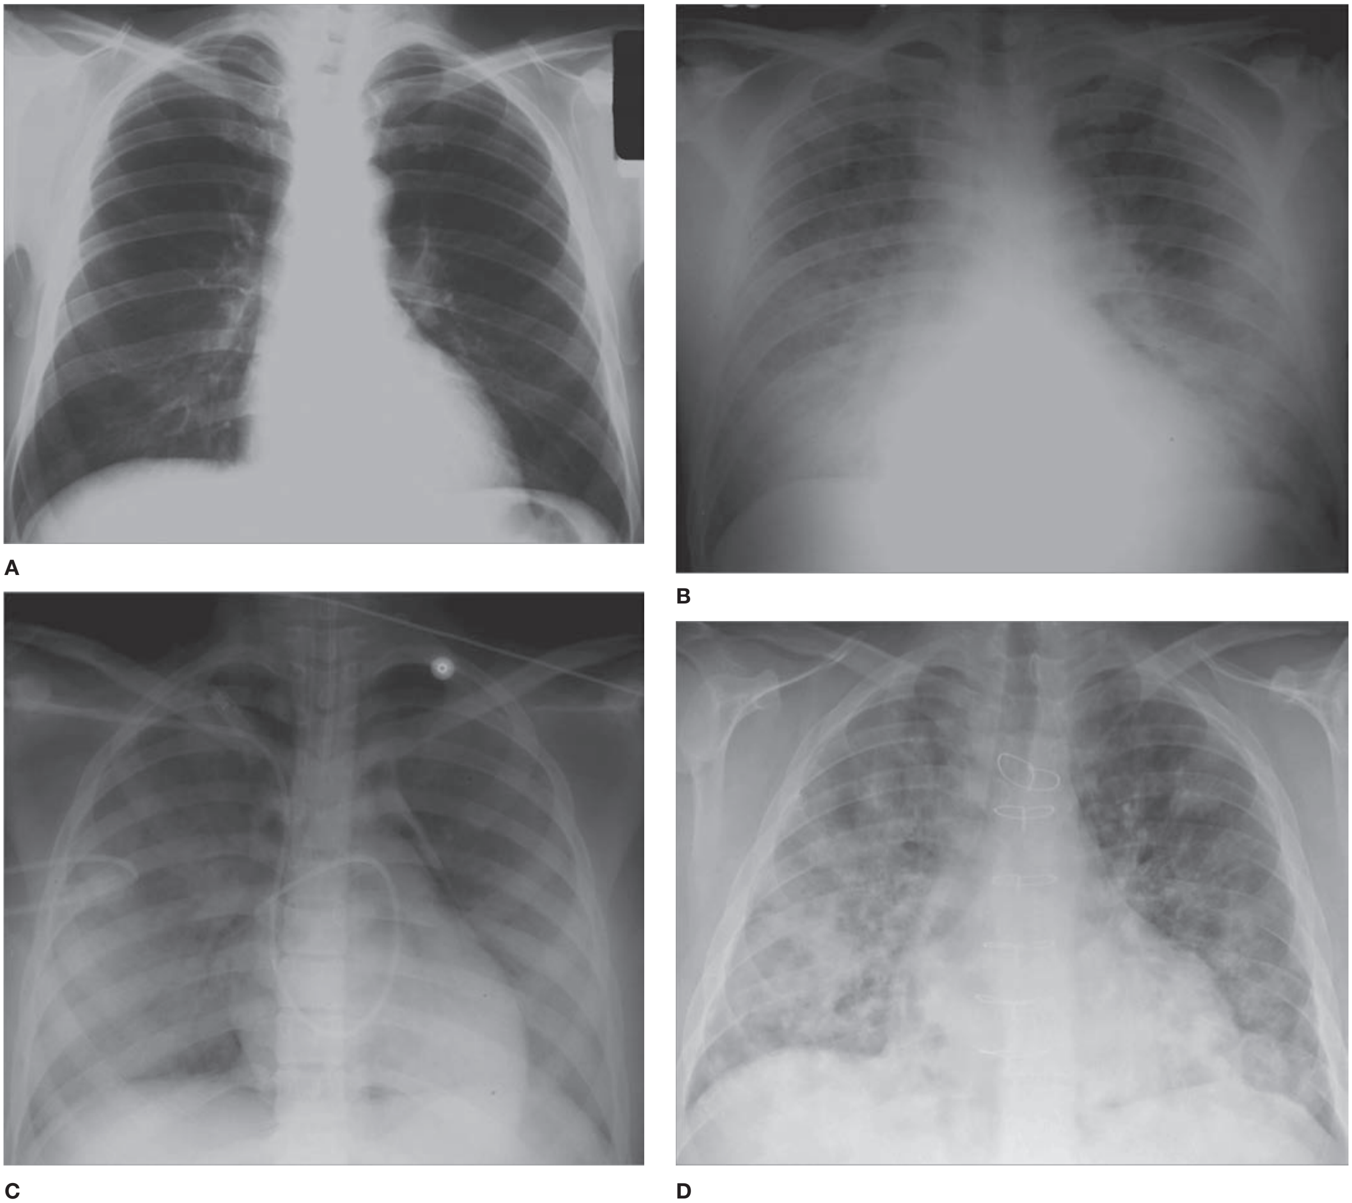

Figure 28-58 Patterns of diffuse alveolar disease. **A.** Normal PA chest radiograph, for comparison. **B.** Cardiogenic edema, with severe, symmetric, basilar-predominant airspace opacities, associated with cardiomegaly and likely small effusions. **C.** Noncardiogenic edema, with severe, symmetric, more diffuse airspace opacities; however, the cardiac size is normal and no pleural effusions are present. This patient has ARDS. **D.** Diffuse alveolar hemorrhage (DAH)—patchy, but fairly diffuse, airspace opacities are noted, with borderline heart size. This patient had systemic lupus erythematosus. Note that this pattern can be difficult to distinguish from diffuse pneumonia or pulmonary edema—clinical correlation is often needed.

insult, or the patient must have new or worsening symptoms during the past week. (2) Chest imaging: Bilateral opacities consistent with pulmonary edema must be present on a chest radiograph or CT scan, which is not fully explained by pleural effusions, lobar collapse, lung collapse, or pulmonary nodules. (3) Origin of edema: The patient's respiratory failure must not be fully explained by cardiac failure or fluid overload. An objective assessment (e.g., using echocardiography) to exclude hydrostatic pulmonary edema is required if no risk factors for ARDS are present. (4) Oxygenation: A moderate to severe impairment of oxygenation must be present, as defined by the PaO_2/FiO_2 ratio. The severity of the hypoxemia defines the severity of the ARDS, and increasing severity better correlates with patient mortality using these criteria compared with the older criteria.[103]

In the proper clinical setting, diffuse alveolar opacities represent pulmonary edema until proven otherwise. If standard therapy for congestive heart failure fails to clear the opacities, and if clinical and laboratory findings exclude noncardiogenic pulmonary edema, other diagnostic entities must be considered. The most important is a diffuse pneumonia, which can be caused by several bacterial and viral agents, including, most notably, influenza. Other differential diagnostic considerations for diffuse lung disease include diffuse alveolar hemorrhage, pulmonary alveolar proteinosis, extensive multifocal mucinous adenocarcinoma, acute hypersensitivity pneumonitis—for example, that due to drug toxicity[104]—sarcoidosis, NSIP, and desquamative interstitial pneumonia (DIP). These entities are described in Chapters 54–66 (Figs. 28-60 and 28-61).

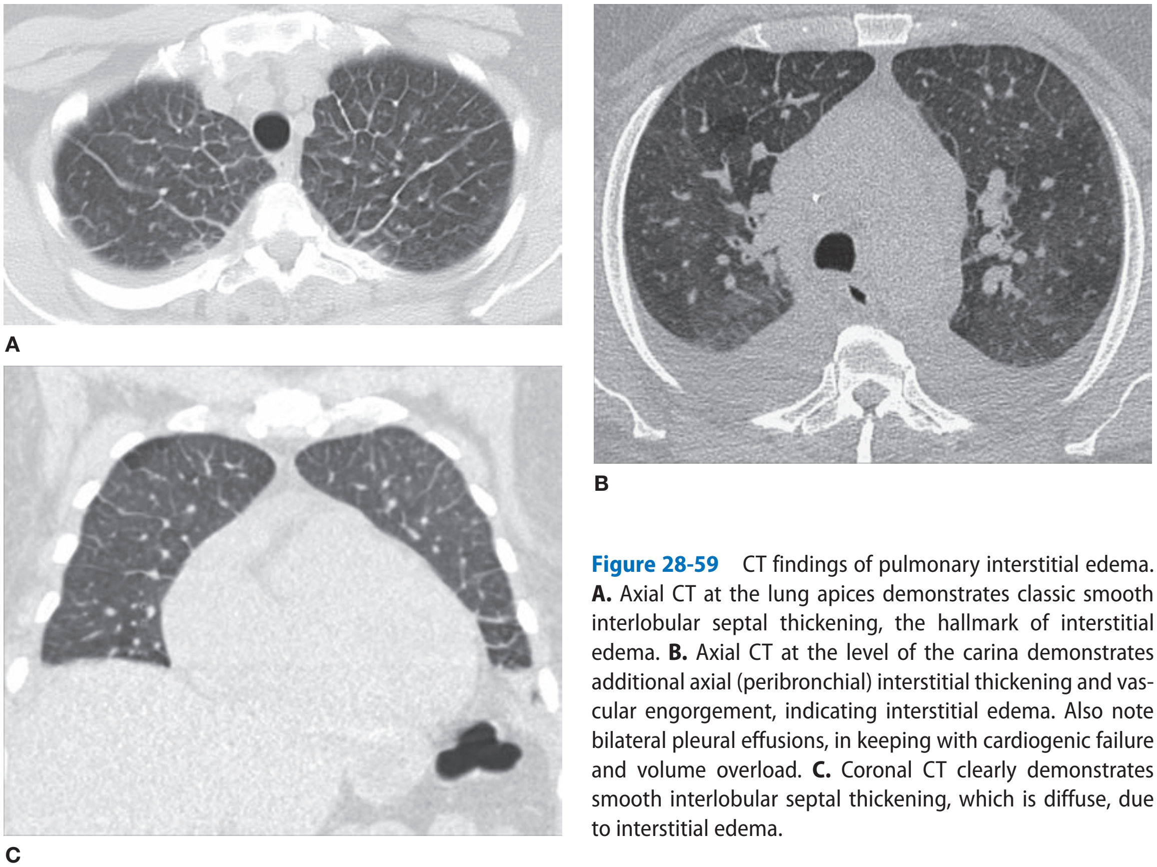

Figure 28-59 CT findings of pulmonary interstitial edema. **A.** Axial CT at the lung apices demonstrates classic smooth interlobular septal thickening, the hallmark of interstitial edema. **B.** Axial CT at the level of the carina demonstrates additional axial (peribronchial) interstitial thickening and vascular engorgement, indicating interstitial edema. Also note bilateral pleural effusions, in keeping with cardiogenic failure and volume overload. **C.** Coronal CT clearly demonstrates smooth interlobular septal thickening, which is diffuse, due to interstitial edema.

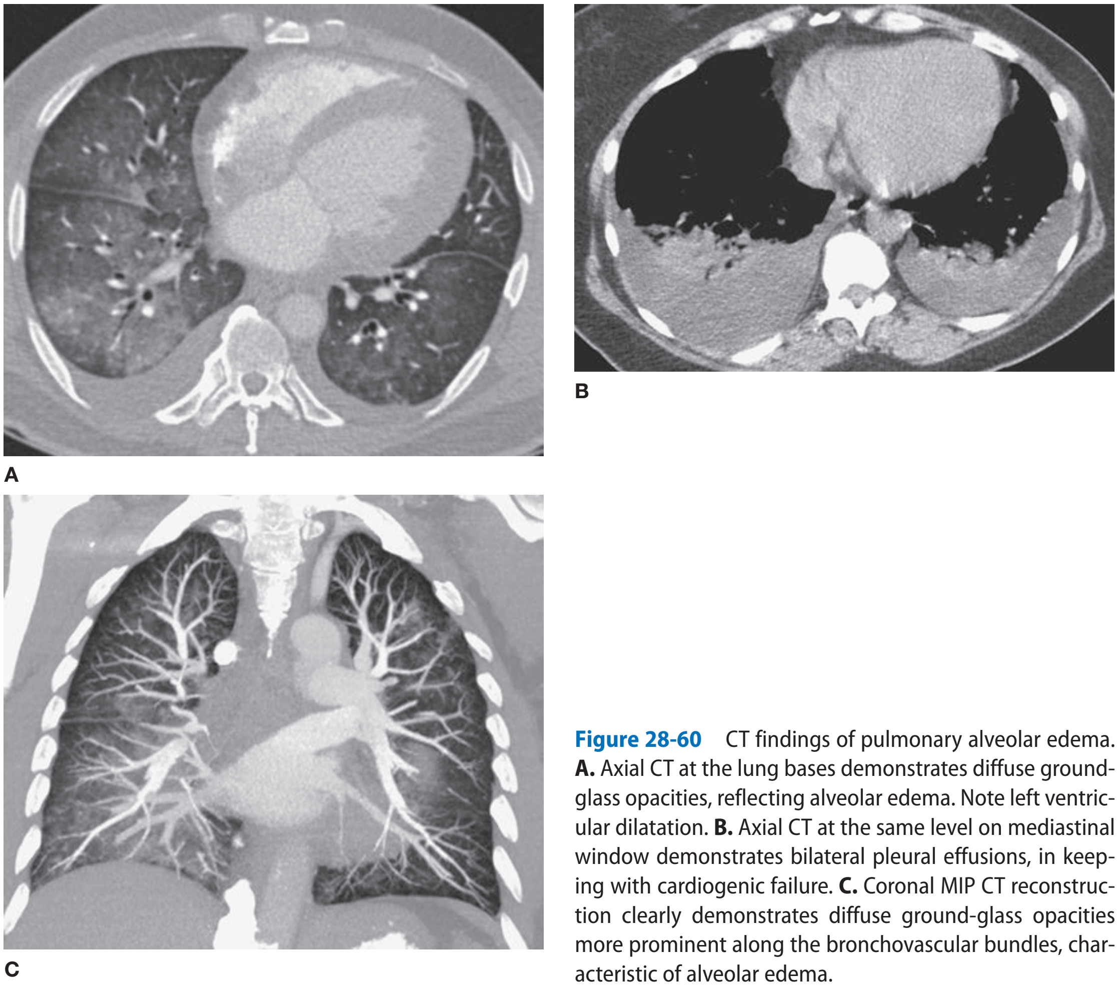

Figure 28-60 CT findings of pulmonary alveolar edema. **A.** Axial CT at the lung bases demonstrates diffuse ground-glass opacities, reflecting alveolar edema. Note left ventricular dilatation. **B.** Axial CT at the same level on mediastinal window demonstrates bilateral pleural effusions, in keeping with cardiogenic failure. **C.** Coronal MIP CT reconstruction clearly demonstrates diffuse ground-glass opacities more prominent along the bronchovascular bundles, characteristic of alveolar edema.

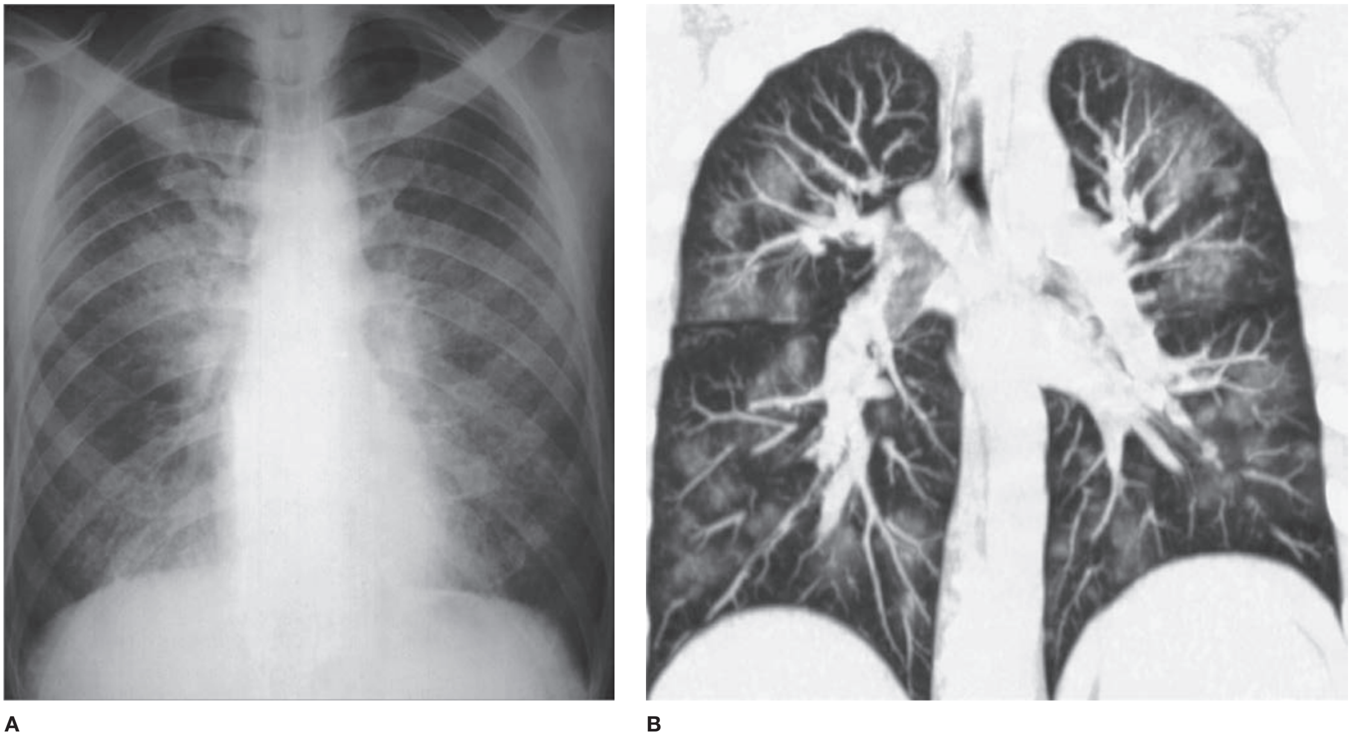

Figure 28-61 CT findings of diffuse alveolar hemorrhage (DAH). **A.** PA chest radiograph demonstrates patchy, but predominantly perihilar, alveolar opacities. **B.** Coronal MIP CT reconstruction better demonstrates the patchy, but widespread, ground-glass opacities, more prominent along the bronchovascular bundles. This patient had a diagnosis of DAH due to Goodpasture syndrome. This pattern can be indistinguishable from pulmonary edema or diffuse infection. Clinical correlation is often needed to narrow the differential diagnosis.

PULMONARY EMBOLISM AND PULMONARY HYPERTENSION

Two critically important clinical entities involving the pulmonary vasculature can be assessed using imaging: pulmonary embolism (PE) and pulmonary hypertension. Each is discussed subsequently.

Pulmonary Embolism

Contrast-enhanced, multidetector chest CT provides a powerful and readily available technique for the evaluation of PE and has become the current reference standard for the diagnosis of acute and chronic pulmonary thromboembolic disease. Not only does CT enable direct visualization of clots, it also can provide alternative diagnoses to explain symptoms in the many patients who do not prove to have PE. Moreover, CT may facilitate diagnosis of associated right heart strain when present, a finding of prognostic importance. While CT may be limited in detecting small, peripheral, subsegmental clots, particularly if the study is not of optimal quality, it has a very high negative predictive value for PE. CT may also be combined with CT venography of the pelvis and lower extremities in selected cases, when clinically indicated.

The major disadvantage of CT relative to ventilation–perfusion scanning is the breast radiation dose, which is of concern in young women and pregnant patients. The problem is further heightened by the current overutilization of CT PE studies, manifested by a yield of positive cases that is generally under 10%. Technical methods to reduce the CT radiation dose continue to be introduced. However, the best approach to radiation dose reduction is to improve the appropriate utilization of CT. Better clinical pretest assessment of risk factors for PE is required. Such assessment, using the Wells, Simplified Geneva, and PERC scores are frequently not used. Other more objective and easily implemented scoring systems have been advocated.

D-dimer measurement is a very useful screening test that carries a high negative predictive value for PE; measurement is particularly useful in the emergency room setting. A negative D-dimer in combination with a low or intermediate clinical suspicion for PE may obviate the need for CT in approximately 50% of outpatients and 20% of inpatients. Its major disadvantage, however, is its lack of specificity in conditions such as pregnancy or recent surgery, which may result in increased values.

Young patients with normal chest radiographs (and without a history of asthma or COPD) may undergo radionuclide perfusion scans as an alternative to CT; the diagnostic yield of perfusion scans in this setting is high, and the breast dose is significantly lower than with CT. More extensive use of ventilation/perfusion ($\dot{V}/\dot{Q}$) scans are limited by their poor specificity and a high rate of nondiagnostic tests, as demonstrated in the hallmark PIOPED study.[105]

Single photon-emission computed tomography (SPECT) $\dot{V}/\dot{Q}$ and SPECT with low-dose CT overcome many of the limitations of a planar $\dot{V}/\dot{Q}$ scan by introducing tomographic image acquisition, instead of only the two-dimensional views obtained using planar techniques. As a result, better characterization of the appearance and location of filling defects, as well as detection of other pathologies, are noted.[106]

Patients with coexisting symptoms and/or signs of DVT should have Doppler US of their lower extremities as the initial test.[107–109]

MRI is not considered a first-line modality for PE, as earlier studies demonstrated an unacceptably high proportion of technically inadequate or nondiagnostic scans. With continued evolution of scanning technique and MRI hardware, more recent studies and meta-analyses show promising results, including improved diagnostic capabilities and a lower number of nondiagnostic studies. Hence, MRI may be an attractive alternative to other imaging modalities, especially in younger patients and those with compromised renal function.[110,111]

The imaging workup of suspected PE in pregnancy presents several unique challenges, as both fetal and maternal breast radiation

Video 28-8 **A.** Full-color, coronal 3D VR (volume rendering) thick slab cine (anterior to posterior) emphasizing cardiovascular and pulmonary parenchymal structures and demonstrating marked ectasia of the central pulmonary arteries, compatible with pulmonary hypertension. (In this patient, mean pulmonary artery pressure was 100 mm Hg.) Also note asymmetry of arterial caliber, with relative oligemia of the left lower lobe and ectatic right upper lobe arteries, attributed to chronic thromboembolic pulmonary hypertension. **B.** Same patient. Coronal, minimum intensity projection (minIP) thick slab cine (anterior to posterior). This type of reconstruction provides excellent assessment of mosaic attenuation, which in this case is due to mosaic perfusion secondary to chronic thromboembolic pulmonary hypertension. The brighter areas of the lung parenchyma are relatively hyperperfused, whereas the darker areas are oligemic, and correlate with areas of diminished regional vascular caliber. *Video available on AccessMedicine.com.*

doses must be considered. Moreover, D-dimer is generally positive in pregnancy and, thus, not of diagnostic value. In addition, there are no useful pretest clinical risk assessment scoring systems for pregnancy. Published national guidelines recommend use of ventilation–perfusion scans in pregnant women with normal chest radiographs (and without COPD or recently active asthma) and CT in the setting of chest radiographic abnormalities that do not provide an alternative diagnosis to PE.[112,113]

Acute and chronic pulmonary thromboembolic disease can be distinguished on CT imaging by the morphology of the pulmonary arterial filling defects. Acute emboli are usually more centrally located within the vessel lumen and may be occlusive. The nonopacified pulmonary arterial branches tend to be dilated in the setting of acute thromboembolic disease. In contrast, chronic clots are more likely eccentric along the vessel wall, nonocclusive, and sometimes calcified (if long-standing). The involved vessels tend to be smaller than normal. Moreover, chronic thromboembolic disease tends to present with associated dilated central pulmonary arteries, indicating pulmonary hypertension, whereas acute emboli generally present with normal-caliber central pulmonary arteries, unless there is pre-existing pulmonary hypertension (Video 28-8A). Other findings suggesting chronic thromboembolic disease include a mosaic perfusion pattern and the presence of dilated bronchial or other systemic collateral vessels (Video 28-8B).

Given the immense functional reserve of the normal pulmonary vasculature, it is uncommon for acute PE to cause pulmonary hypertension and right ventricular dysfunction. Nonetheless, in the setting of large embolic burden, as measured by an obstruction index of the pulmonary arterial circulation of 40% or higher on helical chest CT, poor clinical outcomes are associated with right ventricular dysfunction. This situation generally only occurs with massive saddle emboli in the large proximal pulmonary arteries, or with a large number of relatively smaller emboli occluding the more distal segmental or subsegmental arteries. Chronic pulmonary thromboembolism, on the other hand, is far more prone to be associated with pulmonary hypertension, even in the absence of a substantial thromboembolic burden, due to molecular adaptation mechanisms that lead to remodeling of the pulmonary vasculature, including medial hypertrophy and in situ small vessel thrombosis.[114–116] Ventilation-perfusion lung scan is currently the preferred initial imaging test for chronic thromboembolic pulmonary hypertension (CTEPH) screening, with a normal scan essentially excluding the presence of disease.

More recently, dual-energy CT has been proposed as a method for the combined assessment of acute and chronic emboli, pulmonary vascular anatomy, pulmonary parenchymal abnormalities, and pulmonary perfusion. Pulmonary perfusion, in particular, is obtained via dual-energy CT's capacity to derive iodine maps. Identification of pulmonary perfusion defects can increase the sensitivity and specificity of CT for clot detection. Dual-energy CT has also been used for quantitative perfusion in chronic thromboembolic PE, given the strong correlation of dual-energy CT–derived perfusion parameters with subjective assessment of a mosaic attenuation pattern. Consequently, contrast-enhanced chest CT has been shown to be a useful diagnostic modality for diagnosing chronic thromboembolic pulmonary hypertension and has a comparable diagnostic performance to ventilation-perfusion scans (Figs. 28-62–28-65).[117–121]

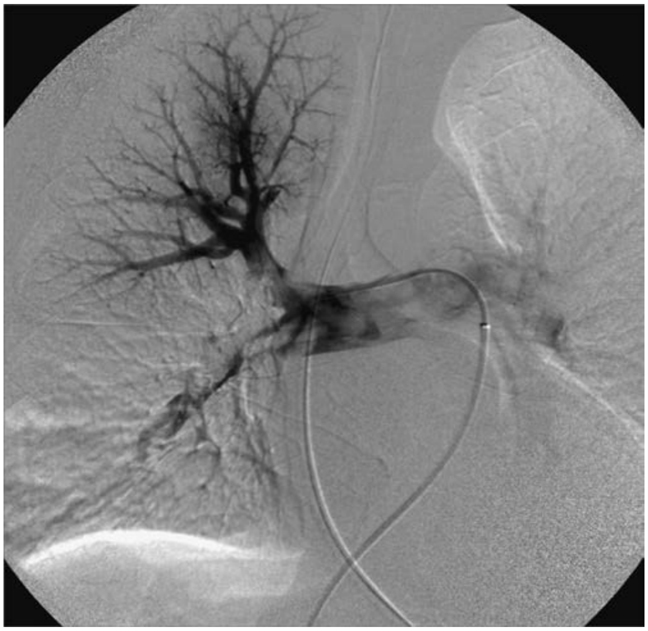

Figure 28-62 Pulmonary angiogram, arterial phase. Note normal caliber of the pulmonary arteries, with multiple filling defects in the right main, right interlobar, and proximal right upper lobar arteries, diagnostic of acute pulmonary embolism.

Pulmonary Hypertension

Because of its dual vascular supply (systemic and pulmonary, in series), the lungs effectively receive slightly greater than 100% of the cardiac output (100% via the pulmonary circulation and 1% to 2% via the systemic bronchial circulation arising from the aorta), far more than the brain, heart, liver, or kidneys (which constitute the group of highly perfused organs). In addition, the pulmonary circulation is a low-pressure, low-impedance, high-flow system that demonstrates some remarkable physiologic adaptations, such as vasoconstriction whenever there is tissue hypoxia (the opposite response of arteries elsewhere in the body, which normally vasodilate in response to hypoxia), and the ability to adapt to major changes in flow with minimal changes in pressure. Because the caliber and distribution of pulmonary vessels provide insight into the pathophysiology of the cardiopulmonary system, imaging methods can be used to study pulmonary vascular diseases.

Pulmonary blood flow is not uniform in the normal, upright human. Moreover, the blood flow pattern shifts with changes in posture, during exercise, and in a variety of heart and lung diseases. In the normal pulmonary circulation, gravity and distance from the heart are the predominant determinants of the pattern of blood flow, given that pulmonary vascular impedance is relatively uniform throughout the lungs (1/10 of average systemic vascular impedance). Assuming a normal average pulmonary arterial pressure of

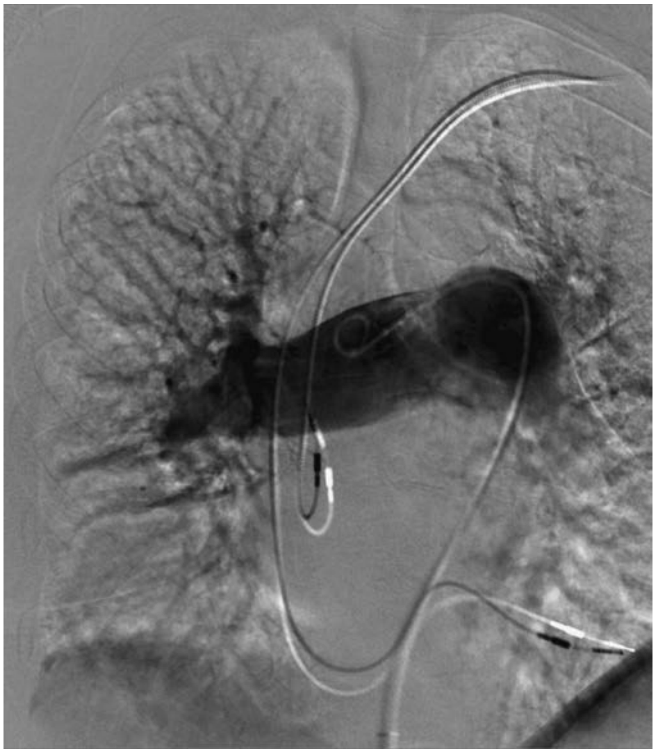

Figure 28-63 Pulmonary angiogram, arterial phase. Note marked dilatation of the pulmonary arteries, without occlusive filling defects, but with overall poor delineation of the arteries, suggesting semiocclusive defects and increased contrast transit time. The constellation of findings indicates chronic thromboembolic pulmonary hypertension (CTEPH).

15 mm Hg, in an adult patient in the erect position a gradient of 22 to 23 mm Hg exists between the apex (2–3 mm Hg) and the bases (25 mm Hg). Given that vascular impedance in the lungs is uniformly low, flow to the bases is approximately 10 times greater than flow to the apices. These differences are greatly reduced in supine position, in which there is a much smaller pressure gradient between the posterior and anterior lungs; consequently, flow is far more uniform in the supine position. In the healthy patient, exercise may increase cardiac output and pulmonary blood flow fivefold, with minimal changes in pressure due to decreased pulmonary vascular impedance. The decline in pulmonary vascular impedance is secondary to capillary recruitment and increased vascular distension.

In pathologic conditions in which pulmonary arterial or venous pressures are increased, or in which alveolar pressure is elevated, the importance of gravity as the major determinant of pulmonary flow is diminished. Furthermore, impaired gas exchange and ventilation may cause alveolar hypoxia that further interferes with pulmonary blood flow via hypoxic vasoconstriction of small arterioles.

The concept of lung "perfusion zones" is based on functional compartmentalization of the lung into three zones according to the relationships among pulmonary arterial, pulmonary venous, and alveolar pressures. In zone 1, average alveolar pressure > arterial pressure > venous pressure, and perfusion is minimal. In zone 2, average arterial pressure > alveolar pressure > venous pressure, and perfusion is pulsatile. In zone 3, average arterial pressure > venous pressure > alveolar pressure, and perfusion is continuous. Normal healthy subjects do not manifest zone 1 physiology; however, patients on mechanical ventilation with high positive end-expiratory pressure (PEEP) or patients with COPD and air trapping may develop large areas of zone 1 physiology. Moreover, heart diseases characterized by left ventricular dysfunction demonstrate increased left atrial and, consequently, increased pulmonary venous pressure. In the short term, this may cause vascular redistribution (with cephalization of the pulmonary vasculature) or pulmonary edema (if acute and more severe). In the long term, adaptation mechanisms of the pulmonary arterial circulation and right ventricle, including increased vascular impedance and right ventricular hypertrophy and dilatation, ultimately result in increased pulmonary arterial pressure; pulmonary hypertension ensues. Understanding the underlying pathophysiology is important for interpreting the imaging findings of pulmonary hypertension.

In its broadest sense, pulmonary hypertension is a pathophysiologic condition in which pulmonary hemodynamics are altered, including an increase in pulmonary vascular impedance and a consequent increase in mean pulmonary arterial pressure above 25 mm Hg (current diagnostic criteria). The pathophysiology, current WHO classification, and treatment of pulmonary hypertension are described in Chapter 72.

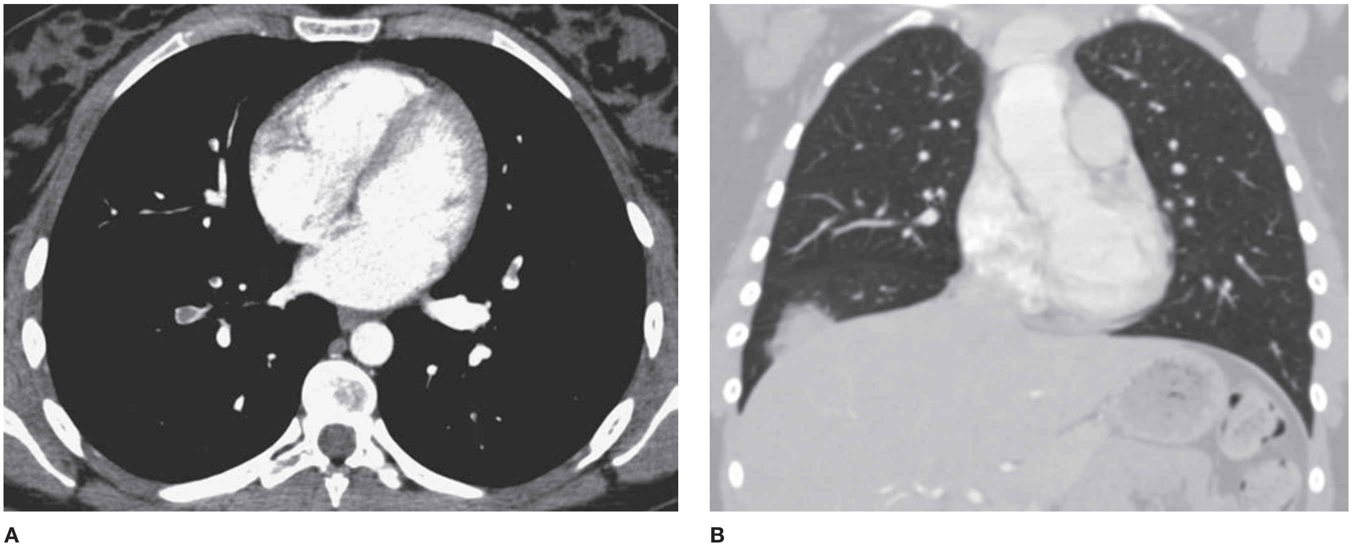

Figure 28-64 Acute pulmonary embolism. **A.** Axial CT at the lung bases demonstrates filling defects in the right lower lobe segmental arteries and left lower lobe anterior segmental artery, compatible with acute PE. **B.** Coronal CT image demonstrates a peripheral RLL consolidation, compatible with pulmonary infarct.

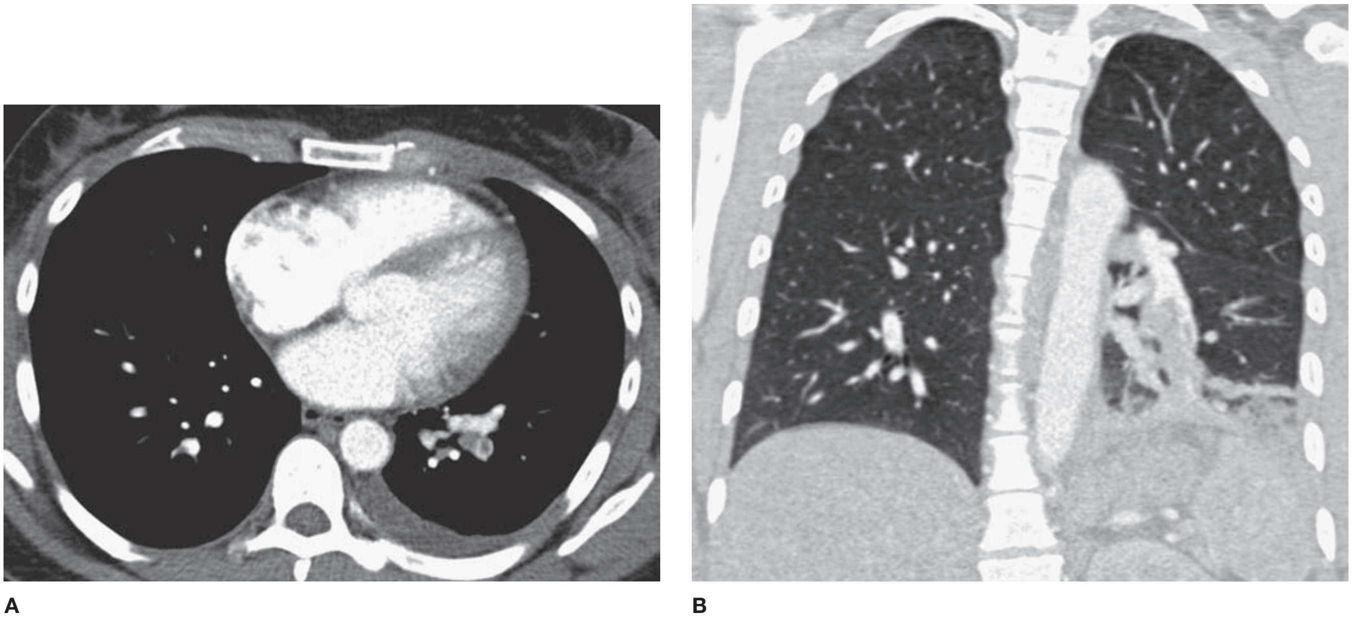

Figure 28-65 Acute pulmonary embolism. **A.** Axial CT at the lung bases demonstrates filling defects in the left lower lobe segmental arteries, compatible with acute PE. Note small left pleural effusion. **B.** Coronal CT image demonstrates a peripheral LLL consolidation, compatible with pulmonary infarct.

The reference standard for diagnosis of pulmonary hypertension is right heart catheterization, an invasive diagnostic modality that allows direct measurement of right ventricular pressure and pulmonary arterial pressure, as well as indirect measurement of pulmonary venous pressure throughout the cardiac cycle. Noninvasive imaging tests cannot measure pressure directly, although echocardiography can be used to estimate pulmonary arterial pressure via Doppler techniques that measure the velocity of the regurgitant jet through the tricuspid valve during systole. The right atrial pressure is usually assumed to be 7 to 8 mm Hg plus the central venous pressure, as estimated by physical evaluation of neck vein distention. These pressures cannot be directly measured by Doppler ultrasonography.

From a diagnostic standpoint, imaging tests may, nonetheless, provide important insight into the possible presence and potential etiology of pulmonary hypertension. The hemodynamic distinction between precapillary pulmonary hypertension (defined by mean pulmonary arterial pressure >25 mm Hg and PCWP <15 mm Hg) and postcapillary pulmonary hypertension (defined by mean pulmonary arterial pressure >25 mm Hg and PCWP >15 mm Hg) can generally be made by advanced imaging. Precapillary pulmonary hypertension includes pulmonary arterial hypertension, pulmonary hypertension due to lung parenchymal diseases, chronic thromboembolic pulmonary hypertension, and miscellaneous causes (WHO classes I, III, IV, and V). Postcapillary pulmonary hypertension includes pulmonary venous hypertension associated with left heart disease (WHO class II).

Imaging studies are important in separating pulmonary arterial hypertension from pulmonary hypertension related to pulmonary parenchymal diseases, left ventricular failure, and chronic thromboembolic pulmonary disease, since the management of these entities differs substantially.

Chest radiographs are helpful in the initial assessment of suspected pulmonary hypertension, although they are not sensitive for early diagnosis. Given their low cost and universal availability, chest radiographs can provide an assessment of cardiac size and pulmonary vasculature caliber and distribution, as well as suggest findings of congestive heart failure or diffuse lung parenchymal disease. Published studies suggest that on erect PA examinations, if PCWP is >13 but <18 mm Hg, there is usually vascular redistribution with relative hypervascularity of the upper lung fields; if between 18 and 25 mm Hg, there is also interstitial pulmonary edema; if >25 mm Hg, there is usually alveolar edema and often pleural effusions. If pulmonary hypertension is present in these clinical settings, strong consideration should be given to left ventricular failure as a causal factor.

Several radiographic findings have been described as suggestive of, but not specific for, the presence of pulmonary hypertension. These include: (1) right heart enlargement, suggested by a distance of >44 mm from the midline to the prominent right heart border on a PA film, indicating right atrial enlargement; (2) a right descending pulmonary artery (RDPA) ≥ 16 mm in diameter; (3) a left descending pulmonary artery (LDPA) ≥ 18 mm in diameter; and (4) peripheral vascular pruning on the PA film. The size of the right ventricle is better assessed on the lateral view, where filling of the usually lucent retrosternal space is indicative of enlargement.[122]

Chest CT and, increasingly, MRI have been proposed as diagnostic tests that can provide pertinent detailed information regarding the pulmonary parenchyma, cardiac anatomy and function, and the status of the pulmonary vasculature, with minimum patient risk.

Chest CT has a major role in evaluating patients with suspected pulmonary hypertension. It is the best imaging test to demonstrate lung parenchymal disease. A normal appearance of the lung parenchyma on chest CT in the setting of pulmonary hypertension effectively eliminates the possibility of COPD or ILD significantly contributing to the pulmonary hypertension and should prompt search for alternative etiologies.

Furthermore, chest CT is also useful for direct assessment of the pulmonary arteries in the setting of suspected pulmonary arterial hypertension. It has been reported that a main pulmonary artery caliber >29 mm, when measured 2 cm from the pulmonary valve, has a sensitivity of 84%, a specificity of 75%, and a positive predictive value of 97% for the presence of pulmonary arterial hypertension, as confirmed by invasive imaging. Moreover, if the main pulmonary artery has a maximum transverse diameter greater than that of the proximal ascending thoracic aorta, there is a sensitivity of 70%, specificity of 92%, and positive predictive value of 96% for the presence of pulmonary arterial hypertension. One should be mindful first to determine that the ascending aorta is not aneurysmal when performing these measurements.

An additional chest CT finding suggesting pulmonary arterial hypertension is enlargement of the segmental arteries >1.25 times the caliber of the adjacent bronchus. A combination of positive findings increases diagnostic confidence. For instance, the presence of enlarged main pulmonary artery (>29 mm) and concomitant enlargement of three out of four segmental arteries (arterial/bronchial diameter >1.25) provides a very high specificity (100%) for the diagnosis of pulmonary arterial hypertension. However, if pulmonary fibrosis or emphysema is present, the correlation between pulmonary artery dimension and severity of pulmonary hypertension is substantially weaker. In these clinical settings, a combination of findings is warranted to suggest the diagnosis.

A prospective study comparing right heart catheterization and chest CT demonstrated that CT-derived measurement of the main pulmonary artery diameter (MPAD) correlates more strongly with the presence of pulmonary hypertension in patients without ILD (MPAD >31.6 mm associated with a PPV of 90.0% and an NPV of 58.3%) than in patients with ILD (MPAD >25 mm associated with a PPV of 46.3% and an NPV of 83.8%), although in both groups the MPAD was significantly greater in patients with pulmonary hypertension than in those without. One conclusion is that pulmonary hypertension is more likely to be present even with normal-caliber pulmonary arteries if the underlying diagnosis is ILD. The presence of bronchial artery hypertrophy >1.5 mm also has been implicated in pulmonary arterial hypertension, although this sign is probably far more common in chronic pulmonary thromboembolic disease.

Several pulmonary parenchymal findings are associated with pulmonary arterial hypertension, although they are not individually sensitive or specific enough to warrant the diagnosis. The first is mosaic attenuation, which is more commonly seen in the setting of pulmonary hypertension due to chronic pulmonary thromboembolic disease, but which can also be seen in the presence of small airway disease without pulmonary hypertension, among other possibilities. Widespread tiny centrilobular ground-glass nodules also may be present, similar to those observed in hypersensitivity pneumonitis, but pathologically deemed to represent cholesterol granulomas or large plexogenic arterial lesions, which have been described in 7% to 47% of patients with pulmonary arterial hypertension.[123–125]

MRI is currently the reference standard for assessment of congenital heart diseases, as it accurately delineates structural changes, cardiac situs, intracardiac shunts, atrial–ventricular and ventriculoarterial relationships, and vascular dimensions, along with wall motion and valvular abnormalities. It is the most useful modality for assessing right ventricular anatomy and function, which is a critical prognostic determinant in pulmonary hypertension. Furthermore, contrast-enhanced MRI, through demonstration of delayed enhancement, uniquely enables detection of the presence and extent of myocardial scarring related to prior infarction, myocarditis, or infiltrative disease in the myocardium—findings that may be associated with left ventricular dysfunction and pulmonary venous hypertension. MRI, similar to Doppler echocardiography, can be used to quantitatively measure flow velocity using phase contrast imaging, allowing for estimation of arterial and intracardiac pressures. However, a major strength of MRI when compared with echocardiography is that arbitrary planes can be set without limitation by available acoustic windows, providing for greater accuracy and reproducibility. Further developments in MRI techniques will increase the clinical usefulness of this modality. In the future, it is conceivable that the combination of advanced CT and MRI techniques will be able to provide a thorough anatomic and functional assessment of the heart–lung unit in patients with suspected pulmonary hypertension, obviating the need for invasive right heart catheterization in selected patients (Figs. 28-66–28-68).[126–128]

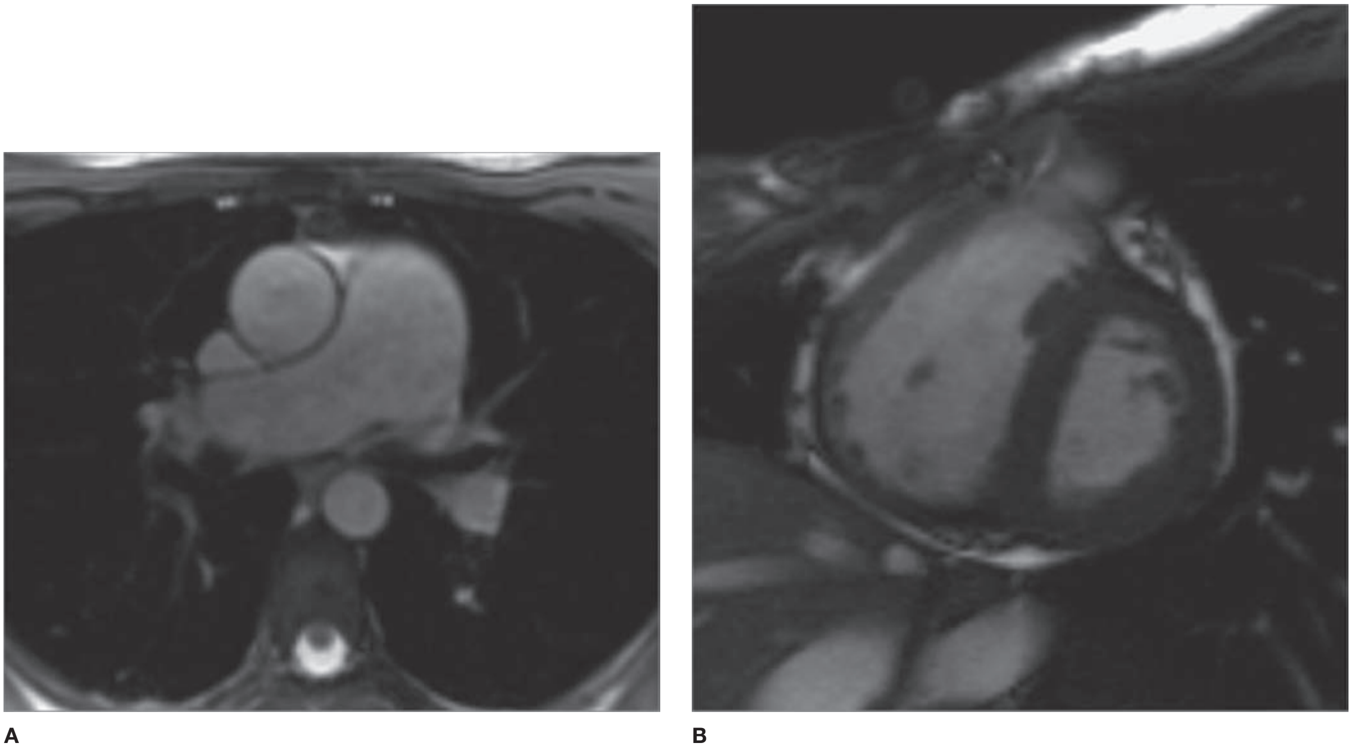

Figure 28-66 Pulmonary hypertension and right ventricular strain. **A.** Steady-state, free precession axial (SSFP) MR image ("bright blood") demonstrates dilatation of the central pulmonary arteries, with the main PA larger than the ascending aorta, compatible with pulmonary arterial hypertension. **B.** SSFP MR image, short axis of the heart, demonstrates right ventricular dilatation and straightening of the interventricular septum, indicative of right ventricular strain. The septum is normally convex toward the RV, due to normally higher LV pressure.

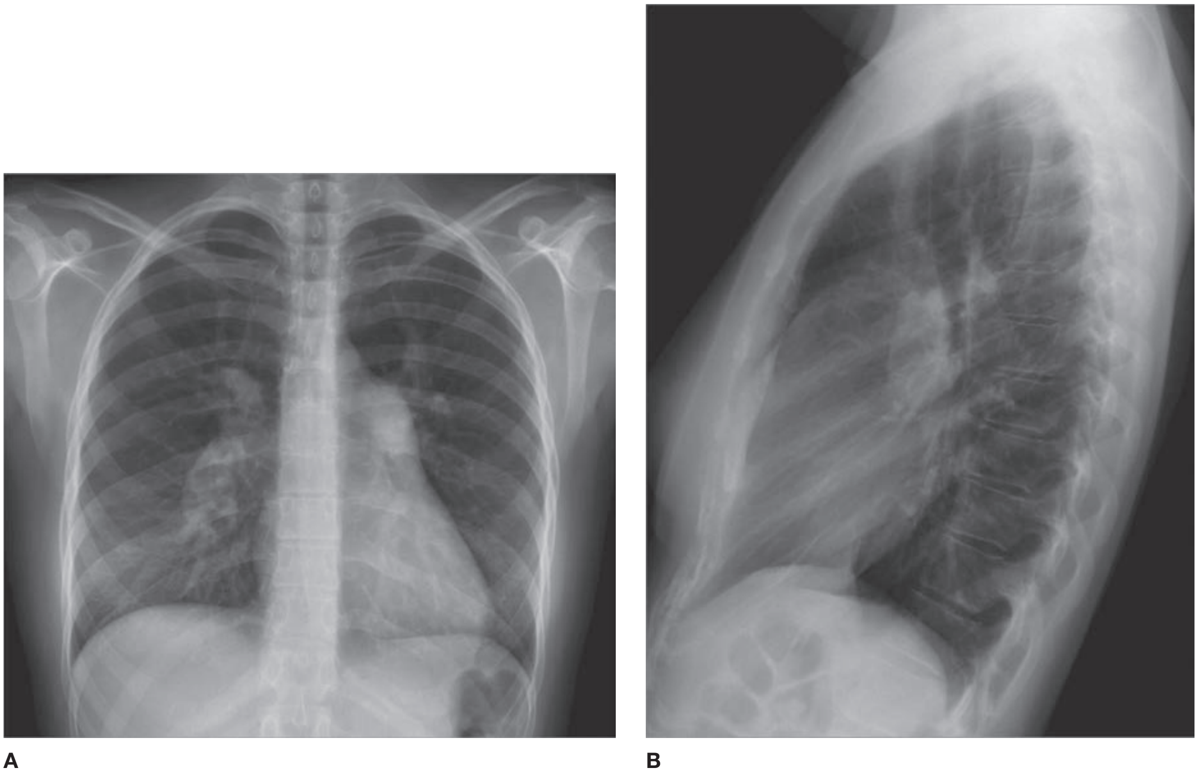

Figure 28-67 Pulmonary hypertension due to cardiac shunt. (**A**) PA, (**B**) lateral chest radiographs demonstrate moderate dilatation of the central pulmonary arteries, secondary to a long-standing uncorrected atrial septal defect (ASD).

PLEURAL, DIAPHRAGMATIC, AND CHEST WALL DISEASES

Radiographic imaging of the pleural space, diaphragm, and chest wall plays an important role in the diagnosis and evaluation of common, clinically important disorders involving these structures.

■ Pleural Diseases

Pleural pathology can be broadly classified, for imaging purposes, into three major categories: pneumothoraces; pleural effusions; and pleural thickening, nodules, or masses. These are described in the subsections that follow.

Pneumothorax

Even though generally placed within the subgroup of pleural pathology, pneumothorax, characterized as the presence of gas within the pleural cavity separating the parietal from the visceral pleura, is rarely related to a disease process of the pleura itself (see Chapter 79). Rather, it is associated with pulmonary or chest wall lesions. Nonetheless, pneumothorax

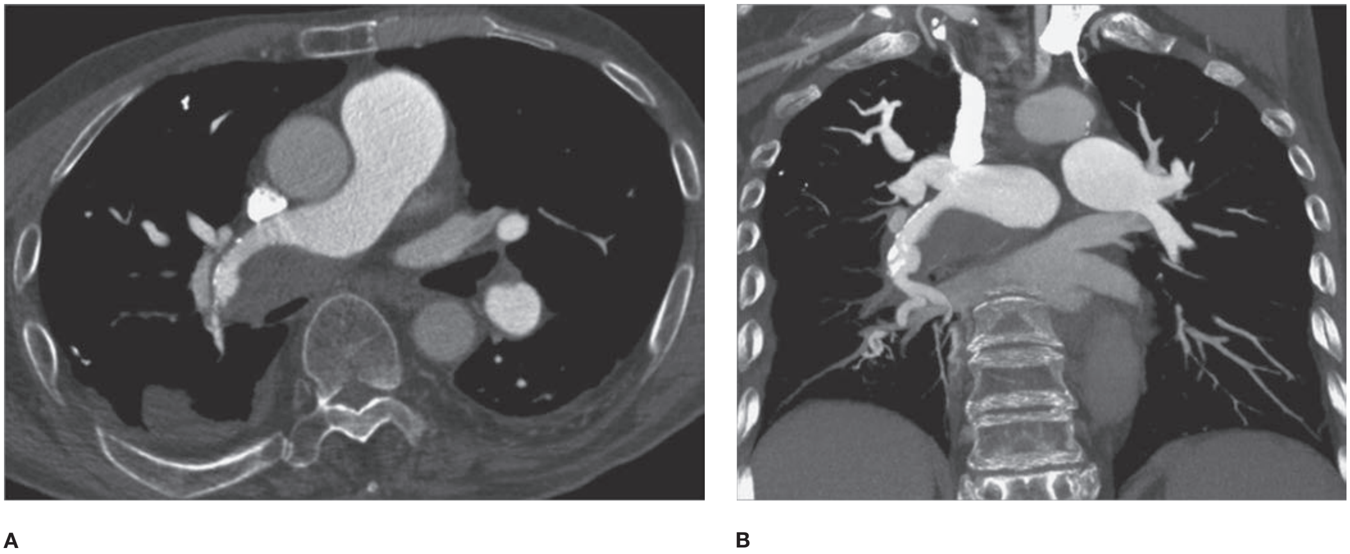

Figure 28-68 Chronic thromboembolic pulmonary hypertension (CTEPH): (**A**) axial CT image and (**B**) coronal MIP CT image demonstrating marked dilatation of the central pulmonary arteries, partially occlusive filling defect in the right main pulmonary artery, and tortuosity of the pulmonary arteries, with asymmetric vascular caliber. The constellation of findings reflects CTEPH.

is a very important clinical diagnosis, since it can lead to substantial morbidity or mortality if undetected or not properly treated.

Imaging is generally extremely accurate in the diagnosis of pneumothorax. The only exception is a portable chest radiograph obtained in a supine position, which is relatively insensitive for detection of small pneumothoraces. In this scenario, a pneumothorax should be suspected if there is increased lucency in the least dependent portion of the hemithorax (the anterolateral costophrenic angle in supine position), known as the "deep sulcus sign." This finding should prompt a lateral decubitus film, with the patient positioned with the suspected pneumothorax in the nondependent side; findings include a sharply marginated lucency along the lateral nondependent hemithorax.

On the other hand, erect PA radiographs are very sensitive and can detect even very small pneumothoraces, which are identified as crescentic-shaped lucencies lateral and superior to the apex of the lung and delineated from the lung parenchyma by a thin visceral pleural line. If there is doubt regarding the presence of a very small pneumothorax, an expiratory view may help by increasing the conspicuity of the pneumothorax, as the lung volumes will be reduced while the pneumothorax volume remains constant, resulting in an increase in the percent volume of the hemithorax occupied by the pneumothorax. In addition, lung parenchymal attenuation will be slightly increased relative to the pneumothorax.

Thoracic ultrasound (see Chapter 29), especially as a bedside study performed in the emergency department or ICU, has a reported higher sensitivity, and similar specificity, as chest radiography for detection of pneumothorax. A combination of lack of pleural movement and presence of a "lung point" (where parietal and visceral pleura split and lung parenchyma separates from the chest wall) have been described as the most specific findings for diagnosis.[129]

Finally, CT is the most accurate modality for detecting pneumothorax and can demonstrate even minuscule pneumothoraces (<1%) that cannot be detected by standard radiographic techniques.

Special cases include tension and loculated pneumothoraces. Tension pneumothorax is a critical diagnosis that requires emergent treatment. A tension pneumothorax manifests on imaging as substantial lung collapse, contralateral mediastinal shift, and downward ipsilateral diaphragmatic displacement. It is generally associated with respiratory and cardiovascular compromise and requires prompt decompression. Loculated pneumothorax occurs when there are inflammatory or neoplastic adhesions between the parietal and visceral pleura, causing gas to accumulate in the pleural space in unusual locations and geometric configurations that do not respect gravitational gradients.

Imaging can also be performed to monitor a pneumothorax, for example, to decide if and when to place a chest tube, and also to investigate the etiology. Most pneumothoraces are either traumatic (in the setting of rib fractures or pulmonary lacerations) or iatrogenic (in the setting of pulmonary, mediastinal, or chest wall interventional procedures, which may be percutaneous, bronchoscopic, or surgical). CT is the best imaging modality to demonstrate rib fractures and pulmonary lacerations. Occasionally, a patient presents with a spontaneous pneumothorax. Most often these are related to rupture of pulmonary blebs or bullae, which may occur in patients with COPD or cystic lung diseases; in some cases, no specific cause can be demonstrated.[130]

A chronic pneumothorax usually occurs in association with pleural effusion, resulting in a hydropneumothorax. Hydropneumothoraces are generally associated with surgical procedures, malignancy, or severe infections, such as empyema. A chronic pneumothorax strongly suggests the presence of a bronchopleural fistula, as gas-forming infection in the pleural space is rare (Figs. 28-69 and 28-70).[131]

Pleural Effusions

Fluid in the pleural cavity appears radiographically as a homogeneous opacity that generally occupies a dependent position. A small pleural effusion that is barely perceptible or is overlooked on the PA view is often readily apparent on the lateral radiograph as blunting of the posterior costophrenic sulcus. The best non-CT radiographic study for demonstrating small quantities of pleural fluid is the lateral decubitus view, with the suspected pleural effusion on the dependent side. Using this technique, as little as 25 mL of fluid can be detected. Larger pleural effusions usually blunt the lateral costophrenic sulcus on the PA radiograph as well.

US is highly sensitive to the presence of pleural effusions and can identify as little as 5 mL of free pleural fluid; the technique is also useful in assessing the fluid for degree of complexity (i.e., the presence of septations and loculations).[132]

Occasionally, pleural fluid remains between the diaphragm and the lung, that is, infra-pulmonary or subpulmonic, displacing the lung upward so that the lateral costophrenic angle remains sharp. The presence of a subpulmonic accumulation of fluid should be suspected if the diaphragm appears elevated, particularly along its lateral aspect on the frontal radiograph; if the costophrenic sulcus is blunted posteriorly; or if the gastric gas bubble is separated from the dome of the apparent left hemidiaphragm by more than a few millimeters. (The last finding is frequently normal, however.) CT is especially sensitive in identifying even the smallest of pleural effusions, which may be undetectable on chest radiographs. In the intensive care unit, where many portable radiographs are obtained in supine patients, CT imaging is particularly helpful in the diagnosis of pleural effusions, often revealing sizable effusions that are unsuspected.

Pleural effusions can be classified into two major categories: transudates and exudates. Transudates are characterized by low protein concentration relative to the plasma, and very low cellularity; exudates are characterized by higher protein concentration and cellularity, as discussed in detail elsewhere (Chapters 76 and 77). Transudative pleural effusions are commonly caused by congestive heart failure, volume overload in the setting of renal dysfunction, or ascites in the setting of hepatic failure. Rarely, they are due to connective tissue disease or metastatic neoplasm. Broad causes of exudative effusions include parapneumonic collections, pulmonary infarction, malignancy (metastatic or due to primary pleural neoplasms), connective tissue disorders, subdiaphragmatic inflammatory processes, and infections (including empyema). Obtaining a specific diagnosis usually requires extensive evaluation that includes CT or MRI, thoracentesis, and, possibly, pleural biopsy (Fig. 28-71).

Imaging modalities, particularly CT, may suggest, but not confirm, that an effusion is more likely a transudate or an exudate, thereby guiding patient management. Most transudates are bilateral, simple, non-loculated effusions occurring in dependent locations. Many exudates are unilateral, loculated effusions. A loculated effusion usually conforms to an unusual shape, commonly ovoid or with geometric edges, and sometimes along the fissures. Loculated effusions may resemble pulmonary masses on chest radiographs, although the pleural location can be readily ascertained on CT. The differential diagnosis of pleural effusions is one scenario in which US can be used to provide additional information beyond CT. For example, US may demonstrate internal septations within an effusion, a finding that can be difficult to demonstrate using CT and that is highly associated with exudative effusions. Furthermore, US can be used therapeutically to provide real-time guidance for thoracentesis and chest tube placement.[133–135] Conversely, US may occasionally fail to detect exudative pleural effusions, including empyemas, which are echogenic, and which are readily detected by CT.

Pleural Thickening, Nodules, and Masses

Pleural diseases that cause diffuse thickening or localized nodularity may be separated into three broad etiologic categories: inflammatory, infectious, and neoplastic (both benign and malignant). Specific subgroups that are commonly encountered, but rarely clinically relevant, include apical pleural thickening (apical capping),

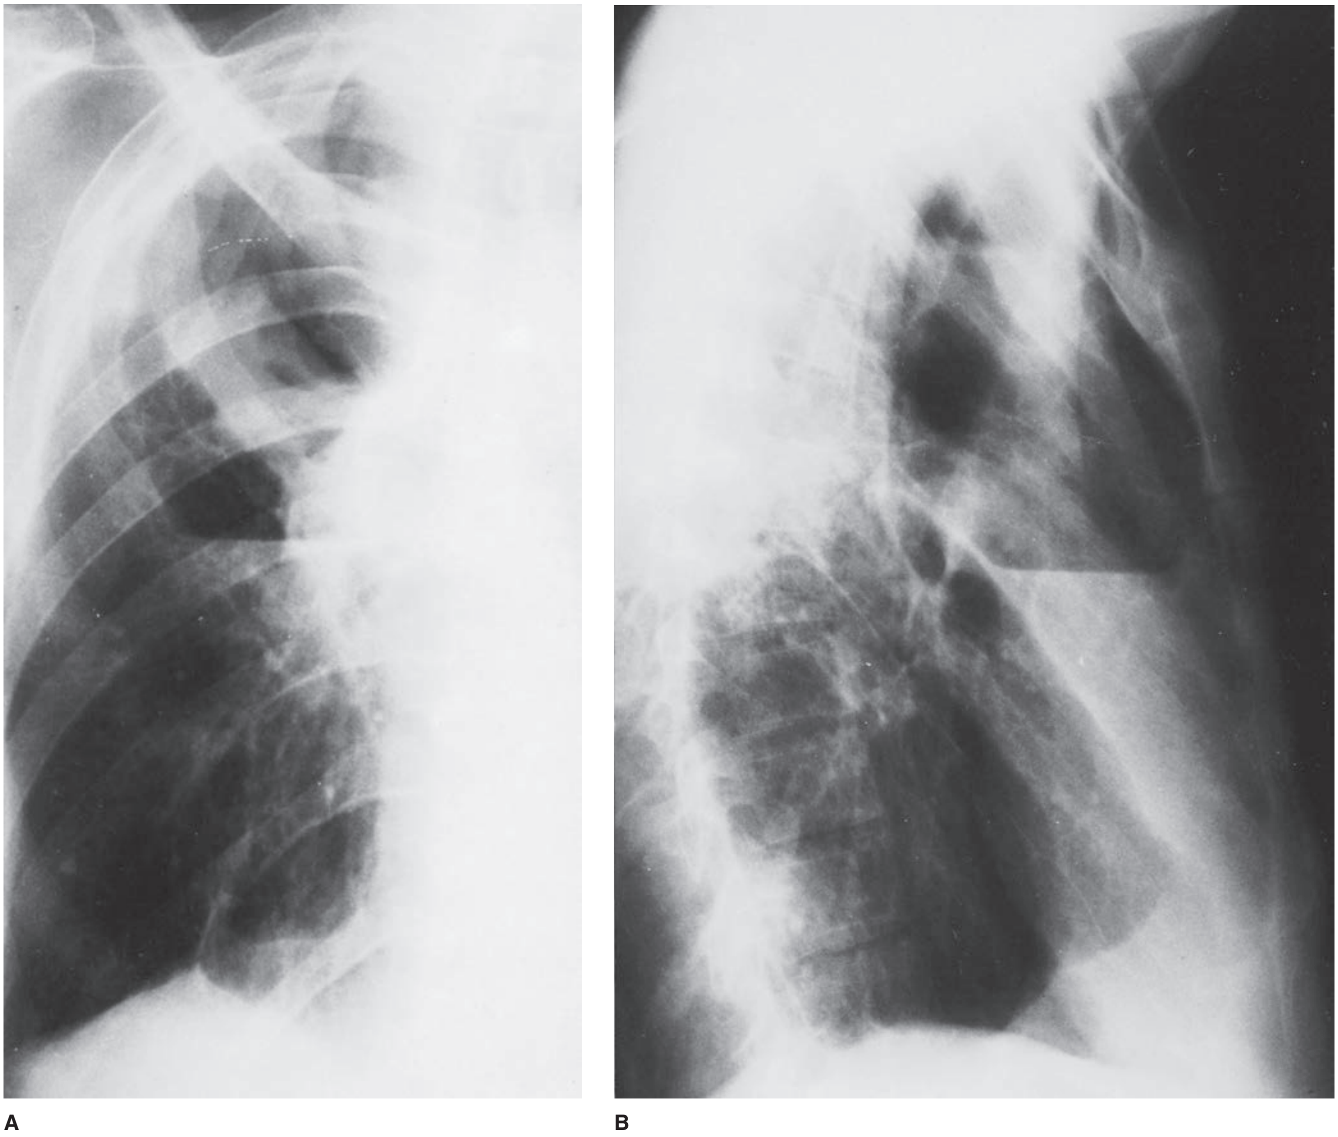

Figure 28-69 Hydropneumothorax. **A.** PA view. A distinct air–fluid level is seen overlying the right hilus. **B.** Lateral view. The fluid and air are anterior to the hilus. The findings are difficult to differentiate from a lung cavity, but the very thin edge suggests localization in the pleural space. This was a hydropneumothorax and was secondary to a postoperative bronchopleural fistula.

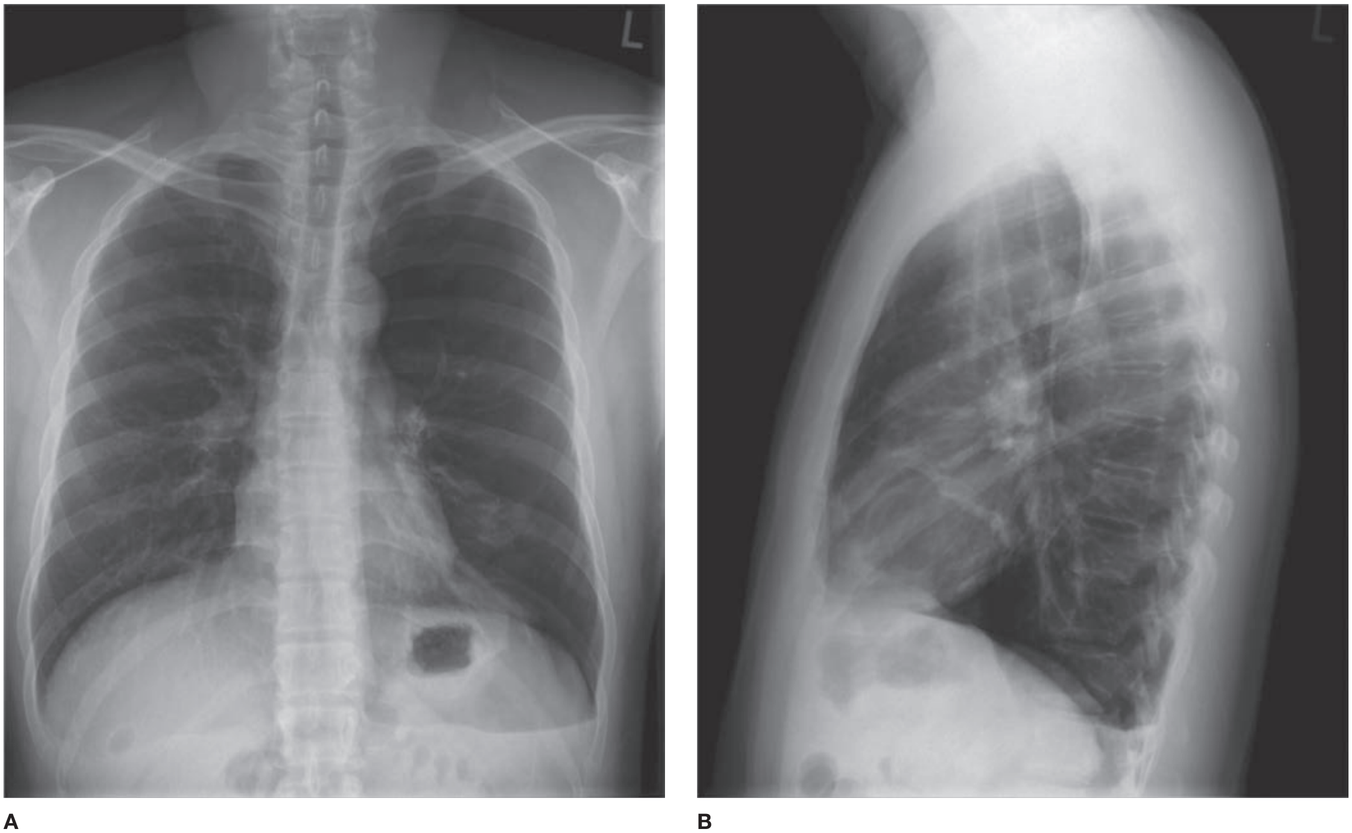
which is usually bilateral and age-related and usually idiopathic (attributed to age-related ischemic changes); however, apical capping may potentially be associated with sequelae of granulomatous infections, particularly if accompanied by apical parenchymal scarring. Blunting of the lateral costophrenic angle on the PA view with sparing the posterior costophrenic angle on the lateral may be attributed to post-inflammatory pleural thickening. Radiographic follow-up is helpful in excluding a focal mass. Multifocal pleural plaques, which are smoothly marginated, localized areas of pleural thickening, and which are often associated with calcifications, are common late manifestations of prior asbestos exposure. Frequently, they are the sole imaging manifestation of past asbestos exposure. CT is the optimal modality for their detection and characterization.

Diffuse pleural thickening involving both hemithoraces is more likely of inflammatory etiology, although bilateral pleural metastases can definitely occur and should be considered. Smooth pleural thickening measuring <5 mm in thickness with sparing of the mediastinal pleura is more suggestive of benign etiology. Unilateral, extensive pleural thickening is more suspicious for a malignant etiology, either pleural metastases or primary malignancy, such as pleural mesothelioma. Nodular thickening of the mediastinal pleura and involvement of the interlobar fissures are particularly correlated with a malignant etiology; as a rule, the more nodular the pleural thickening appears, the more likely a malignant process is its cause. The differential diagnosis includes empyema, particularly tuberculous empyema, which may be indistinguishable from mesothelioma based on imaging appearance. Imaging cannot distinguish mesothelioma, pleural metastases, and tuberculous empyema; tissue sampling and correlation with other clinical and laboratory findings are required.[136–139]

A special case to consider is extensive pleural thickening associated with calcifications and diminished volume of the adjacent lung parenchyma—a fibrothorax. Most fibrothoraces reflect sequelae of prior substantial pleural inflammation caused by empyema or hemothorax, and their clinical significance is due to their potential to impair chest wall mechanics and restrict lung expansion.

A localized pleural nodule suggests a benign pleural neoplasm, such as a solitary fibrous tumor of the pleura or lipoma. The nodule may be difficult to distinguish from a localized area of pleural thickening, but generally it is larger and more symmetric in contour. On CT, these nodules usually have a characteristic appearance: Their



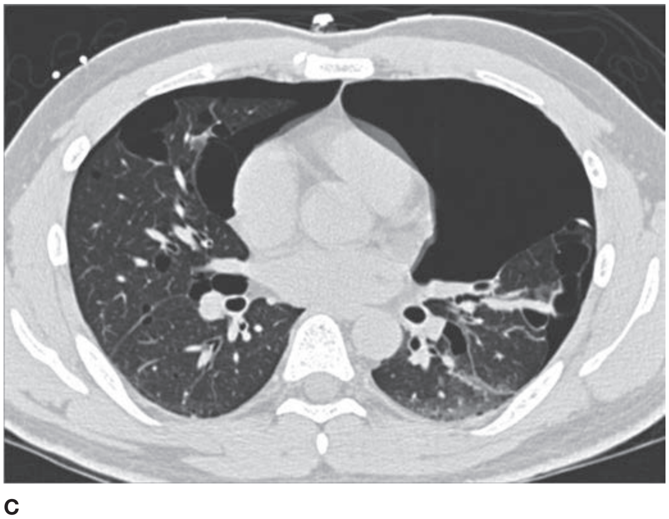


Figure 28-70 Bilateral pneumothoraces. (**A**) PA and (**B**) lateral chest radiographs demonstrate bilateral pneumothoraces, approximately 20% on the right and 40% on the left. The patient presented with spontaneous pneumothoraces. **C.** Axial CT at the lung bases confirms bilateral pneumothoraces and also indicates the etiology, demonstrating multiple pulmonary cysts. The patient was found to have Birt–Hogg–Dubé syndrome, a genetic disease that causes pulmonary cysts and predisposes the patient to recurrent spontaneous pneumothorax.

shape is ovoid with their largest diameter parallel to the chest wall, and their edges are flat and tapering. The appearance is similar to the extrapleural sign on chest radiographs, which is defined as a shadow that has smooth margins, has tapering edges with obtuse angles with the chest wall, and is generally seen well in only one of the two standard views of the chest. Occasionally, a peripheral nerve sheath tumor (e.g., schwannoma or neurofibroma) arising from an intercostal nerve may mimic a pleural nodule. These lesions, however, tend to cause indentation of adjacent ribs due to long-standing mass effect, helping to suggest the diagnosis.

Rarely, solitary or multiple pleural nodules without associated effusion may represent a malignant process; the classic example is the so-called "drop" metastases from thymic neoplasms.

DIAPHRAGMATIC DISEASES

Diaphragmatic evaluation can be performed initially via chest radiographs, ideally PA and lateral views. The normal hemidiaphragm has smooth contours and gentle curvature, with its dome near its center and no focal protrusions, with the left hemidiaphragm slightly lower than the right. The most common diaphragmatic abnormality is an eventration, in which there is focal weakness of the muscle, correlated with focal protrusion or bulge. Diaphragmatic paralysis should be suspected when an entire hemidiaphragm is elevated, typically >2 cm in comparison to the normal side. To confirm diaphragmatic paralysis, the standard test is a fluoroscopic dynamic evaluation ("sniff test"), in which the patient is imaged during shallow breathing, deep breathing, and forceful inspiration ("sniff"). The normal hemidiaphragm moves downward with the sniff maneuver, while a paralyzed hemidiaphragm will demonstrate paradoxical upward motion.

Diaphragmatic hernias can be classified into three broad categories: hiatal, congenital, and traumatic. Hiatal hernias occurring through the centrally placed esophageal hiatus are the most common, and usually contain a portion of the stomach, although very large

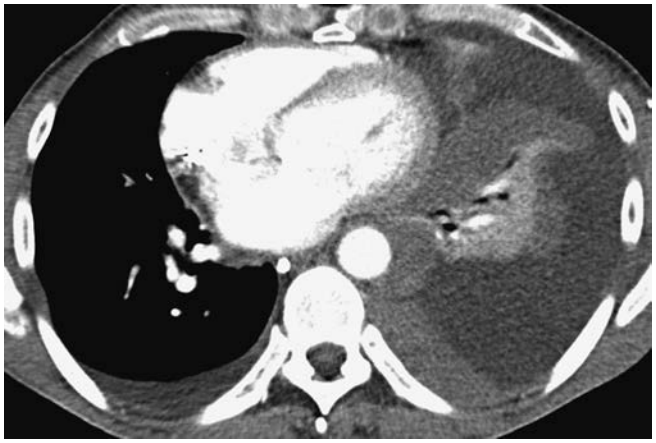

Figure 28-71 Malignant pleural effusion. Axial CT image demonstrates bilateral pleural effusions. The left effusion is associated with enhancing pleural masses, better visualized at the posterior medial costophrenic angle and adjacent to the descending thoracic aorta. This is characteristic of a malignant effusion. The patient was later diagnosed with mesothelioma.

hernias can contain small or large bowel loops as well. Congenital hernias are usually through the paired foramina of Morgagni (anterior and medial) or the paired foramina of Bochdalek (posterior and central). The latter are more frequent and are usually small, incidental hernias containing fat. When large, these congenital hernias can contain viscera, either bowel loops (Morgagni) or retroperitoneal structures such as the kidney (Bochdalek), but these are virtually always diagnosed in infancy. Traumatic hernias should be suspected in patients who had blunt trauma and present with a newly elevated hemidiaphragm. These are more common on the left, as the liver usually prevents herniation on the right except in very large defects. Traumatic diaphragmatic ruptures may occur in the setting of trauma without detectable herniation, and the actual herniation of abdominal viscera into the thorax may occur days, months, or even years later. Inquiry regarding a history of remote trauma is thus important in the evaluation of diaphragmatic hernias. Multiplanar coronal and sagittal CT or MRI images allow accurate assessment of diaphragmatic contour abnormalities and are the reference standard for the diagnosis of diaphragmatic rupture. MRI offers the additional advantage of functional assessment, with fast-gradient echo cine sequences optimally demonstrating diaphragmatic motion (Figs. 28-72 and 28-73).[140–144]

CHEST WALL MASSES

Chest wall masses may extend into the pleura and cause pleural nodularity or masses. These are very difficult to detect radiographically unless they cause bone destruction or substantial mass effect. US plays an important role in detection and characterization of superficial lesions, especially by differentiating cystic from noncystic lesions, as well as by assisting performance of percutaneous biopsies. CT or MRI provide a more comprehensive assessment. CT excels in assessment of lung and osseous structure involvement, while MRI offers superior contrast resolution of soft-tissue tumors, hematomas, and abscesses. Tissue sampling is generally necessary for accurate diagnosis. The differential diagnosis of chest wall masses includes soft-tissue infection (e.g., cellulitis, phlegmon, abscess), which is generally associated with trauma and surgical procedures; hematoma, also often associated with trauma or surgical procedures; extension of infection arising from the lung, the classic example of which is actinomycosis; and rarely, neoplasms, such as soft-tissue sarcomas, lymphomas, metastatic disease, and malignant nerve sheath tumors.[145,146]

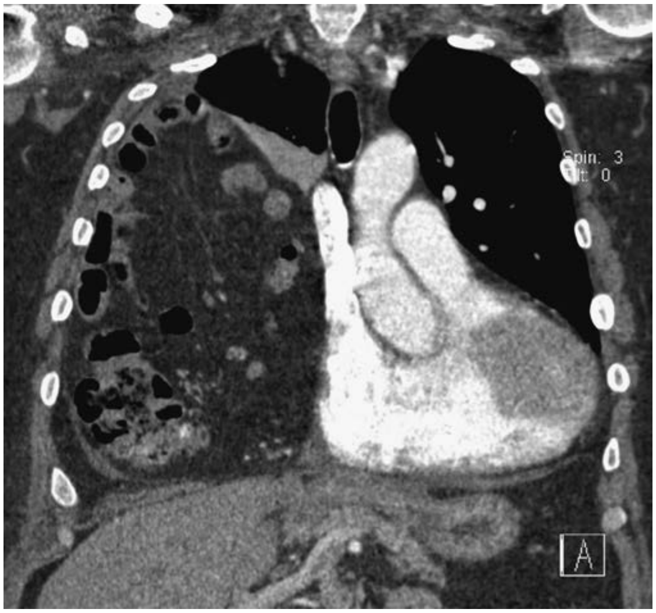

Figure 28-72 Diaphragmatic hernia. Coronal CT image demonstrates a wide defect in the right hemidiaphragm. The right lung is nearly completely collapsed, and the right hemithorax is nearly completely occupied by small and large bowel loops with associated mesenteric fat. This is diagnostic of diaphragmatic hernia, in this case due to blunt trauma to the abdomen.

MEDIASTINAL DISEASES

Mediastinal diseases encompass multiple systems, organs, and a vast array of differential diagnoses. Before discussing mediastinal diseases, it is necessary to define the contents of the mediastinum and its boundaries.

The anatomic delineations of "compartments" of the mediastinum are not defined consistently throughout the medical literature. For radiographic diagnosis, a simple classification has been employed: (1) The *anterior compartment*, which extends from the sternum anteriorly to the heart, aorta, and brachiocephalic vessels posteriorly, comprises only the thymus, fat tissue, and a few lymph nodes. (2) The *middle* or *visceral compartment* contains the heart,

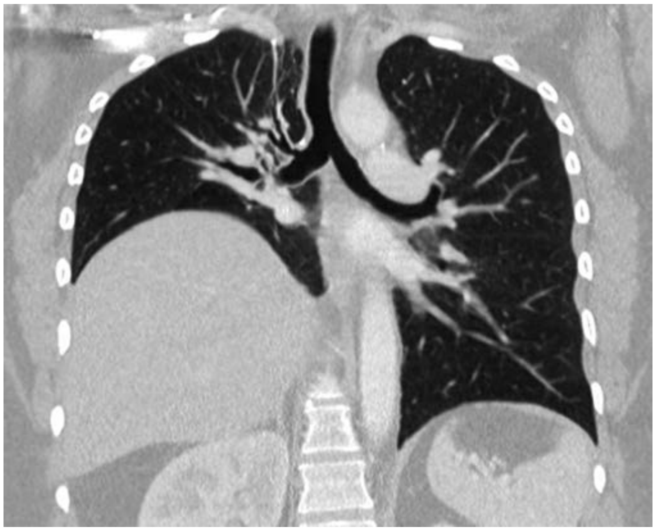

Figure 28-73 Diaphragmatic paralysis. Coronal CT image shows marked elevation of the right hemidiaphragm. Fluoroscopic examination confirmed a paralyzed right hemidiaphragm.

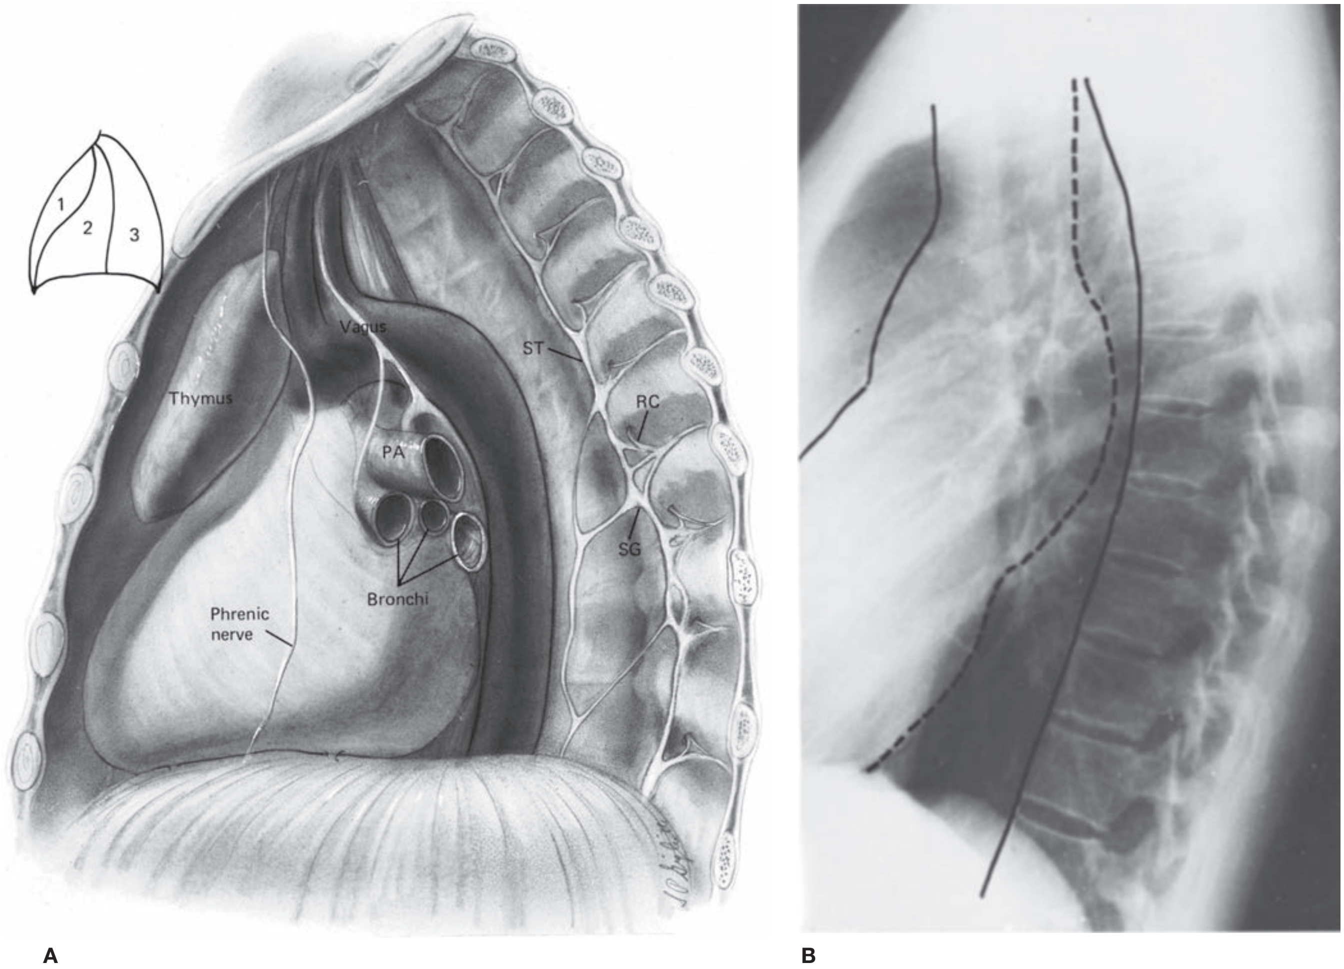

FIGURE 28-74 Compartments of the mediastinum: **A.** Anatomic view of the compartments of the mediastinum. The subdivisions (1, anterior; 2, middle; 3, posterior) in the small schematic *(top left)* correspond to those designated by the *solid black lines* in **B.** PA, pulmonary artery; RC, ramus communicans; SG, sympathetic ganglion; ST; sympathetic trunk. **B.** Radiographic division of the mediastinum. The *closed lines* delineate the anterior, middle, and posterior compartments. The *dashed line* represents the division of the middle and posterior mediastinum that is conventionally used by anatomists. ***(A:** Reproduced with permission from Fishman AP: Pulmonary Diseases and Disorders. New York, NY: McGraw Hill; 1980.)*

great vessels, trachea and its branches, esophagus, and descending aorta. It extends from the posterior border of the anterior compartment to the anterior border of the vertebral column. These boundaries differ from the anatomist's classification, which relegates portions of the esophagus and the descending aorta to the posterior mediastinum. (3) The *posterior compartment* contains the vertebrae and paravertebral sulci.

More recently, the International Thymic Malignancy Interest Group (ITMIG) has introduced a classification system based on CT anatomy, in which the mediastinum is also considered to have three compartments, with the thoracic inlet forming the superior border and the diaphragm representing the inferior border. These compartments are known as the perivascular, visceral, and paravertebral compartments. This classification scheme offers a more accurate approach to anatomic characterization of pathology (Figs. 28-74 and 28-75).[147,148]

This section focuses on diseases of the lymph nodes and thymus. Cardiac and systemic vascular diseases are beyond the scope of this textbook and will be mentioned only briefly. Pulmonary vascular diseases have been described previously. Esophageal diseases and spinal or paraspinal diseases are briefly discussed (Fig. 28-76).

Before a discussion on mediastinal neoplasms, it is important to emphasize the role of CT for evaluation of suspected mediastinal infections in the postoperative patient.

Mediastinitis is a catastrophic complication of multiple types of cardiothoracic surgeries and, if unrecognized and not treated aggressively, often leads to a fatal outcome. In the immediate postoperative period, after cardiac, central vascular, major pulmonary, or esophageal surgery, the presence of a small amount of gas and fluid in the mediastinum is an expected occurrence. The findings tend to subside within hours or a few days. While there is no absolute rule to apply to the time frame over which a pneumomediastinum or mediastinal fluid collection becomes clearly pathologic, some general guidelines are helpful in guiding management decisions: (1) It is expected that any postoperative fluid or gas collection will decrease in size over time, and any increase in size is suspicious for an evolving mediastinitis. (2) Large fluid and gas collections (those measuring >2 cm in the smallest diameter) are almost always pathologic. (3) Any persistent mediastinal fluid or gas collection >1 week following surgery is suspicious, and the index of suspicion rises if the patient is clinically worsening, if there are laboratory signs to support infection (e.g., leukocytosis with a left shift), and if there are CT features suggesting active inflammation, such as rim enhancement in the boundaries of the collection. Any of these findings should prompt aggressive management with percutaneous or surgical drainage of the collection and institution of broad-spectrum antibiotics.

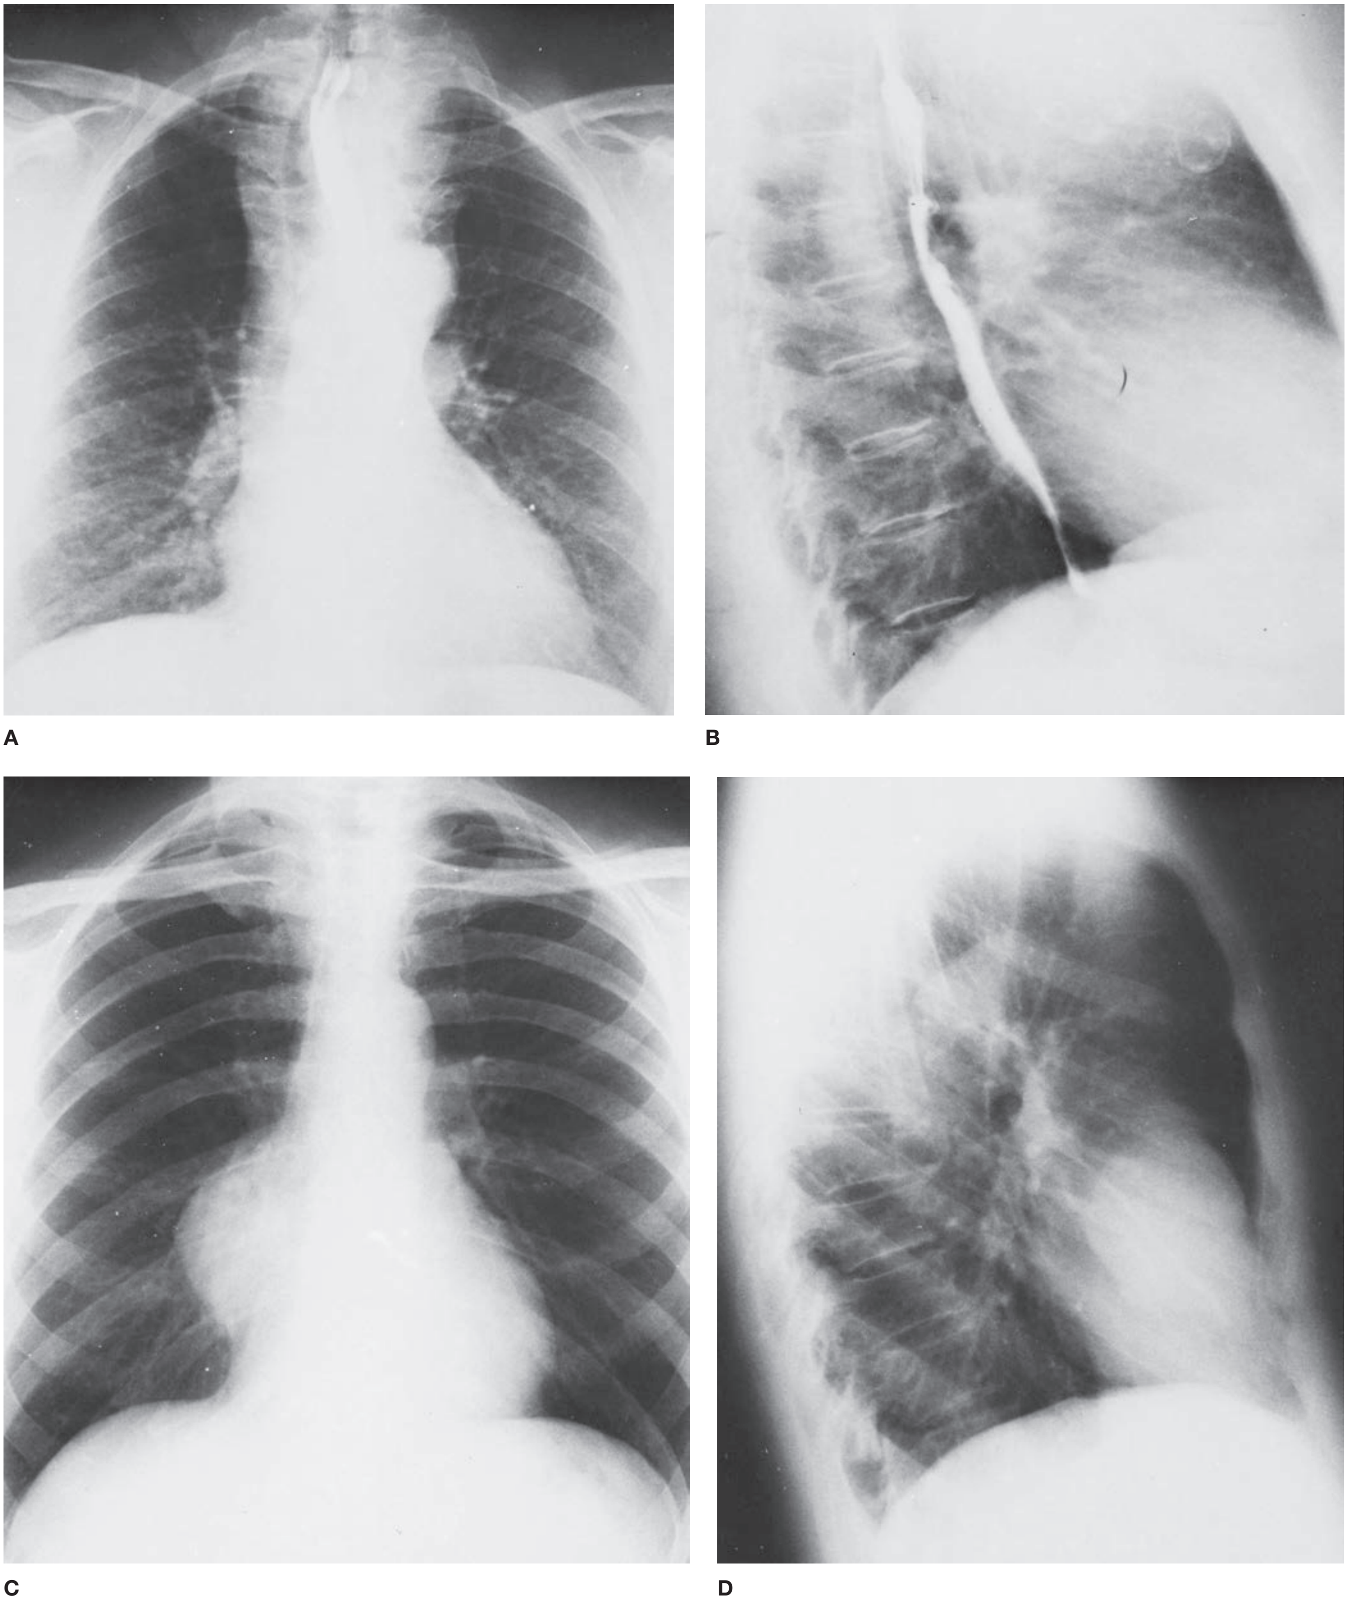

Figure 28-75 Radiographic spectrum of mediastinal masses: Substernal thyroid. **A.** PA view. A large mass in the neck extends below the clavicle. The trachea and esophagus are displaced to the right. **B.** Lateral view. The trachea and esophagus are also displaced posteriorly. Several calcifications are present within the mass. **C.** PA view. A discrete mass (thymoma) lies along the right heart border. **D.** Lateral view. The mass also overlies the anterior portion of the cardiac shadow. Despite being radiographically well circumscribed, the mass may be either invasive or noninvasive thymoma. CT is required for further characterization.

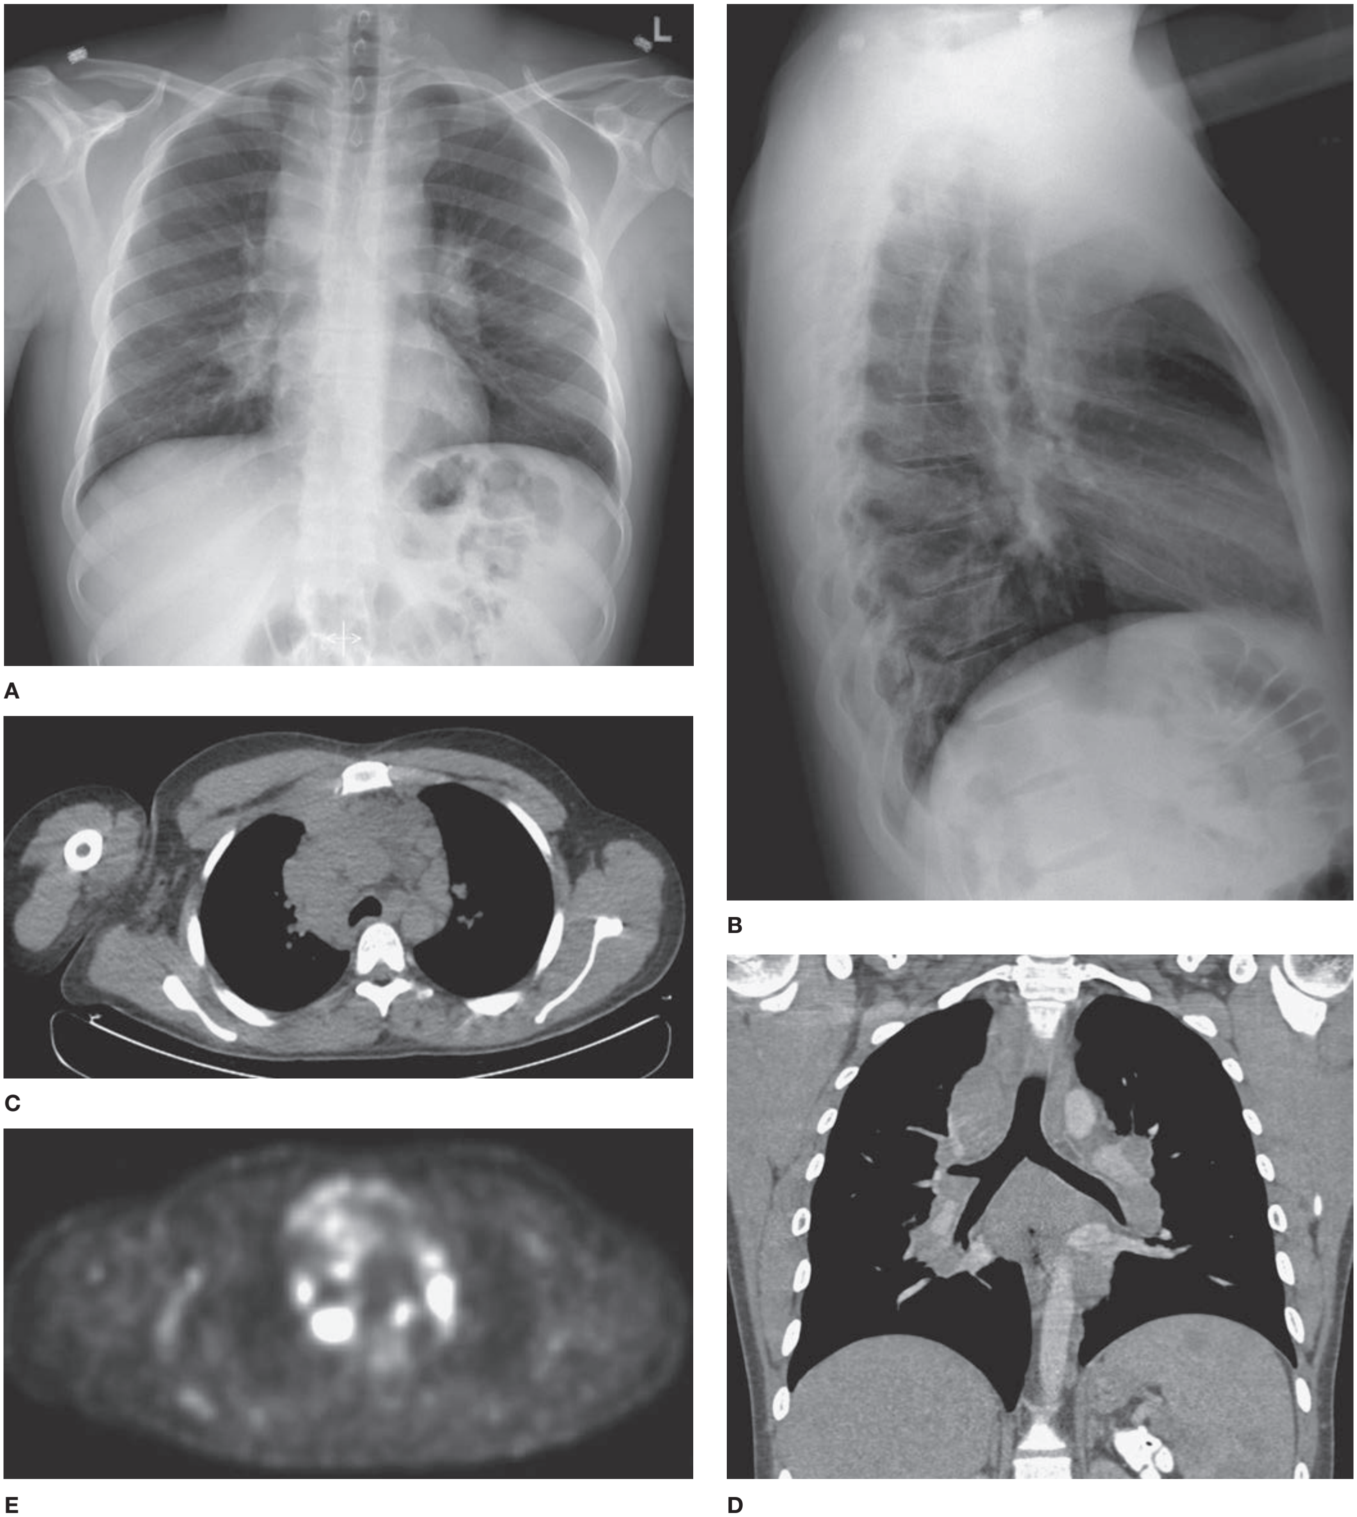

Figure 28-76 Lymphadenopathy: (**A**) PA and (**B**) lateral chest radiographs demonstrate marked widening of the bilateral paratracheal stripes and mild prominence of the bilateral pulmonary hila, compatible with mediastinal and hilar lymphadenopathy. (**C**) Axial noncontrast CT and (**D**) Coronal contrast-enhanced CT better demonstrate the extent of mediastinal and hilar lymphadenopathy. Pathology confirmed a large B cell lymphoma. **E.** Axial FDG-PET at the level of the upper lung fields demonstrates increased glucose uptake within the enlarged mediastinal lymph nodes, indicative of increased metabolic activity. This study can be performed to monitor treatment response.

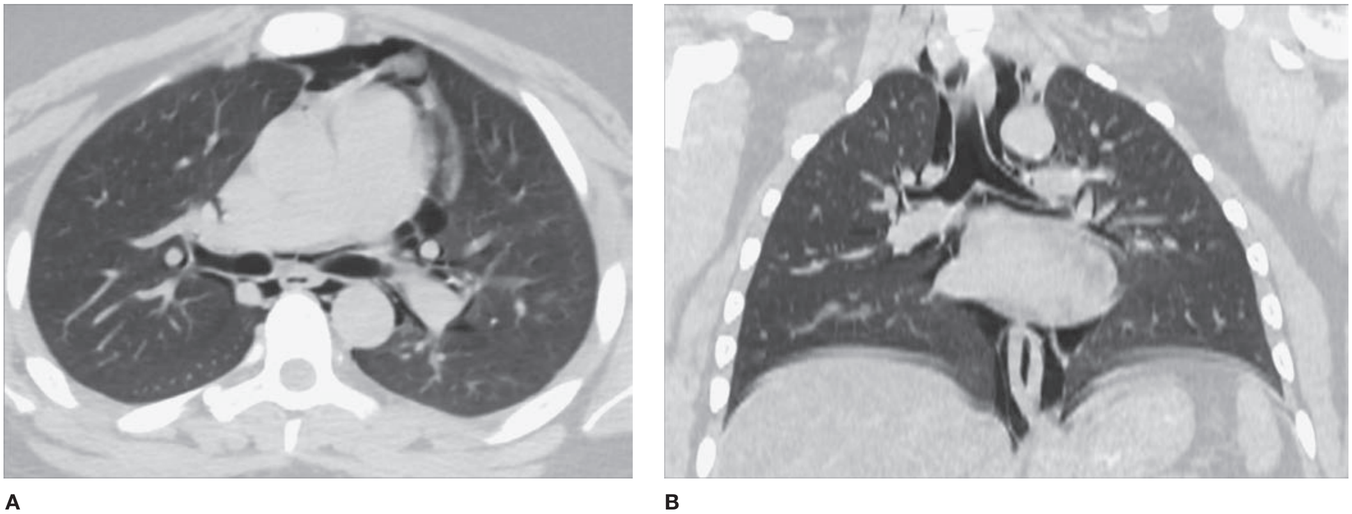

Figure 28-77 Pneumomediastinum. **A.** Axial CT at the level of the mainstem bronchi demonstrates gas within the anterior, middle, and posterior mediastinal compartments, compatible with pneumomediastinum. **B.** Coronal CT demonstrates the full extent of the pneumomediastinum. Note absence of pneumothorax. There is also subtle pulmonary interstitial emphysema, denoted by linear lucencies parallel to the proximal airways. This patient had barotrauma related to a severe asthma exacerbation.

A spontaneous pneumomediastinum has different clinical implications, as it may be a sign of an ominous condition, such as esophageal perforation (which warrants urgent surgical treatment), or a relatively benign condition when associated with barotrauma and tear of the distal airways or acini. Clinical correlation and careful clinical observation are very important to distinguish these etiologies (Fig. 28-77).[149,150]

The classic differential diagnosis of masses in the anterior compartment includes enlarged lymph nodes, substernal goiter or thyroid neoplasm, thymic hyperplasia and thymic neoplasms, and germ cell neoplasms. Distinction among these can be made on the basis of the patient's age and clinical presentation, their position within the anterior mediastinum, and the appearance on CT or MRI.

Thyroid masses invariably lie high in the anterior or middle mediastinum and often displace or compress the trachea and esophagus. On CT, the thyroid has characteristic high attenuation on unenhanced images due to its iodine content, and multinodular goiter often presents with a very heterogeneous texture containing cystic and calcified opacities within a background of dense thyroid parenchyma. Ultimately, any high anterior mediastinal mass with these imaging characteristics and unequivocal contiguity with the thyroid gland on CT or MRI is deemed to represent a thyroid neoplasm or multinodular goiter, until proved otherwise.[151]

If an anterior mediastinal mass does not arise from the thyroid, the differential diagnosis of germ cell neoplasm, thymoma, and lymphoma can be challenging using imaging; tissue sampling is almost always necessary. Nonetheless, some clinical and imaging features may suggest a specific diagnosis. For example, germ cell neoplasms tend to occur in younger patients and are often heterogeneous—in particular, CT demonstration of fat and calcification within an anterior mediastinal mass is diagnostic of a teratoma.[152] Teratomas may also contain cystic components. Thymic hyperplasia or neoplasms tend to conform to the triangular shape of the thymus (particularly benign thymomas, although invasive thymomas and thymic carcinomas may have a more irregular configuration). Thymomas tend to occur in older patients and may be associated with the diagnosis of myasthenia gravis. Because of the presence of intracellular lipids in the normal thymus, thymic hyperplasia can be distinguished from thymomas and infiltration by lymphoma using proton chemical-shift MRI; signal loss is noted in out-of-phase sequences (Fig. 28-78).

Noncomplex thymic cysts measure fluid attenuation and are smoothly marginated with thin walls and no internal IV enhancement or solid components on CT. MRI offers superior contrast resolution and confident characterization of complex cystic thymic lesions, which can appear of soft tissue density on CT due to proteinaceous or hemorrhagic component.

The histologic classification of thymic epithelial tumors was updated in 2015 by the World Health Organization (WHO). In addition, a TNM/AJCC classification was published in 2017, establishing a staging system for thymic neoplasms (including thymoma, thymic carcinoma, thymic neuroendocrine tumors, and combined thymic carcinoma). Several imaging features were suggested to better characterize and stage thymic malignancy. On CT and MRI, the presence of lobulated or irregular contours, as well as cystic or necrotic areas within the tumor, was found useful in differentiating early from advanced disease. Advanced imaging techniques utilizing perfusion characteristics on MRI and dual-energy CT, as well as iodine content on dual-energy CT and diffusion-weighted MRI sequences, enable differentiation of low- and high-grade neoplasms.[153,154]

Finally, lymphomas occur over a wide age range (with Hodgkin disease having a bimodal distribution) and are generally homogeneous on CT and MRI, unless previously treated (Figs. 28-79 and 28-80).[155,156]

In cases where imaging does not provide a definitive diagnosis, tissue sampling should be considered. Surgical biopsies offer the highest accuracy (approaching 100%) but are also associated with a significant complication rate (approaching 15%). If visible by US, a guided percutaneous biopsy has been shown to be a safe and efficient method to obtain tissue, and it has a reported accuracy of >90%. Furthermore, reported complication rates are lower compared with CT-guided biopsies. CT provides better visualization of deeper compartments, with an approximate reported overall accuracy of 90%. It is the most common method of image-guided biopsy in most institutions.[157–159]

Lymphadenopathy in the thorax has an extremely broad differential diagnosis, and its presence is best assessed using CT or MRI. Anatomically, the largest lymph nodal chains in the thorax can be divided into axillary, supraclavicular (which includes lower cervical chains), mediastinal, and bilateral hilar chains. Smaller chains include internal thoracic (mammary), anterior cardiophrenic (or paracardiac), and retrocrural. Mediastinal lymph node stations are further subdivided into prevascular, paratracheal (upper and lower,

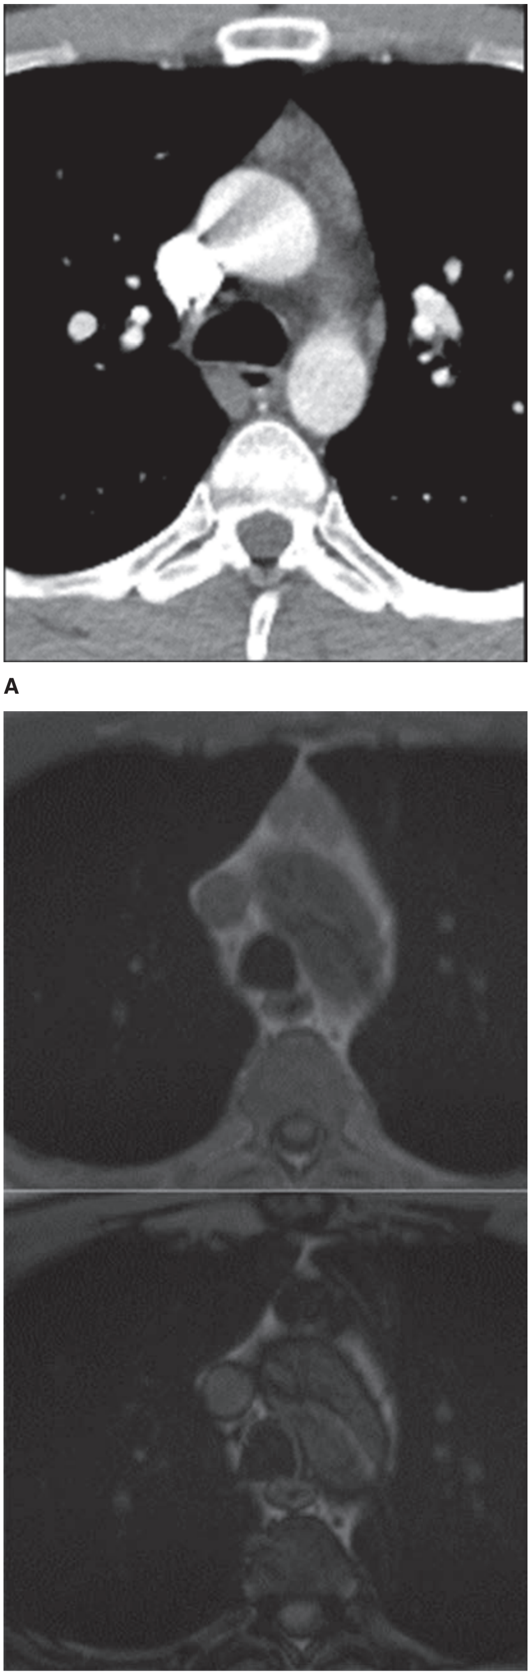

Figure 28-78 MRI allows confident diagnosis of an indeterminate anterior mediastinal lesion identified on axial CT image (**A**) using chemical shift MRI sequence (**B**). The lesion had an intermediate intensity on the in-phase MRI image (upper image) with subsequent >20% loss of intensity on the out-of-phase image (lower image) consistent with intracellular fat found in benign thymic hyperplasia.

right and left), subaortic (or AP window), subcarinal, para-aortic, and paraesophageal.

A normal lymph node on CT or MRI has an ovoid, reniform shape ("kidney shape") and a fatty hilum and measures <1 cm in its smallest diameter. An abnormal lymph node is frequently rounded, loses the delineation of the hilum, and measures >1 cm in its smallest diameter. It is important to emphasize that early neoplastic or infectious disease may be associated with "normal" lymph nodes on CT or MRI, but "abnormal" lymph nodes on CT or MRI are virtually never normal from a pathologic standpoint, even if the diagnosis is not clinically significant.

From an imaging perspective, establishing the etiology of mediastinal lymphadenopathy implies assessing the size, configuration, number, and location of the enlarged lymph nodes. Enhancement patterns on CT or MRI have a limited role, and FDG uptake on PET/CT may identify pathologic lymph nodes that do not meet pathologic size criteria on CT or MRI. The presence of calcification is also an important sign in narrowing the differential diagnosis.

The following guidelines should be utilized in the general assessment of mediastinal and thoracic lymphadenopathy.[160–162]

Very large (measuring >2–3 cm), confluent, conglomerate lymphadenopathy is malignant until proven otherwise. Considerations include nodal metastasis and lymphoma, particularly high-grade, large B cell lymphomas or Hodgkin disease. An anterior mediastinal, prevascular location favors lymphoma. Distribution of disease may help elucidate the origin of the primary neoplasm, in case the diagnosis is not obvious or previously established if one is cognizant of the typical lymphatic drainage pathways. For example, lung carcinomas present more frequently with ipsilateral hilar, subcarinal, and paratracheal lymphadenopathy; head and neck squamous cell carcinomas more often involve supraclavicular lymph nodes; breast carcinomas frequently involve ipsilateral axillary and internal thoracic lymph nodes; hepatocellular carcinomas usually involve anterior cardiophrenic lymph nodes (paracardiac nodes).

An increased number of nodes in disseminated lymphadenopathy, symmetric distribution involving multiple nodal stations, and moderately or substantially enlarged nodes suggest a low-grade lymphoproliferative disease, particularly chronic lymphocytic leukemia/small lymphocytic lymphomas (CLL/SLL). Note that early disease may present with only mildly enlarged lymph nodes.

Mild or moderately enlarged lymph nodes with a bilateral hilar and lower paratracheal distribution suggest the diagnosis of sarcoidosis.

Mild, bilateral, predominantly axillary lymphadenopathy can be seen in the setting of connective tissue diseases, such as systemic lupus erythematosus.

Mild disseminated lymphadenopathy can be seen in systemic infections, particularly "mono-like" syndromes caused by mononucleosis, CMV, and related infections.

Necrotizing lymphadenopathy may be seen in the setting of infectious lymphadenitis (particularly mycobacterial) but is also commonly seen in nodal metastasis.

Coarsely calcified lymph nodes, particularly mediastinal and hilar, suggest sequelae of granulomatous inflammation, including sarcoidosis and mycobacterial or fungal infection; however, treated malignancy and pneumoconiosis also should be considered in the differential diagnosis in the proper clinical setting.

Mild lymphadenopathy can be ascribed to a "reactive" etiology, including prior infections, congestive heart failure, or ILDs. Reactive lymphadenopathy is a diagnosis of exclusion.

Additional structures of the middle mediastinal compartment are the heart and central vessels. Aortic or aortic branch aneurysms can be suggested on chest radiographs by the presence of mediastinal widening and prominence of the aortic contours. Diagnostic confirmation and full characterization require CT or MRI, typically with intravenous contrast. Duplication cysts of the foregut may arise

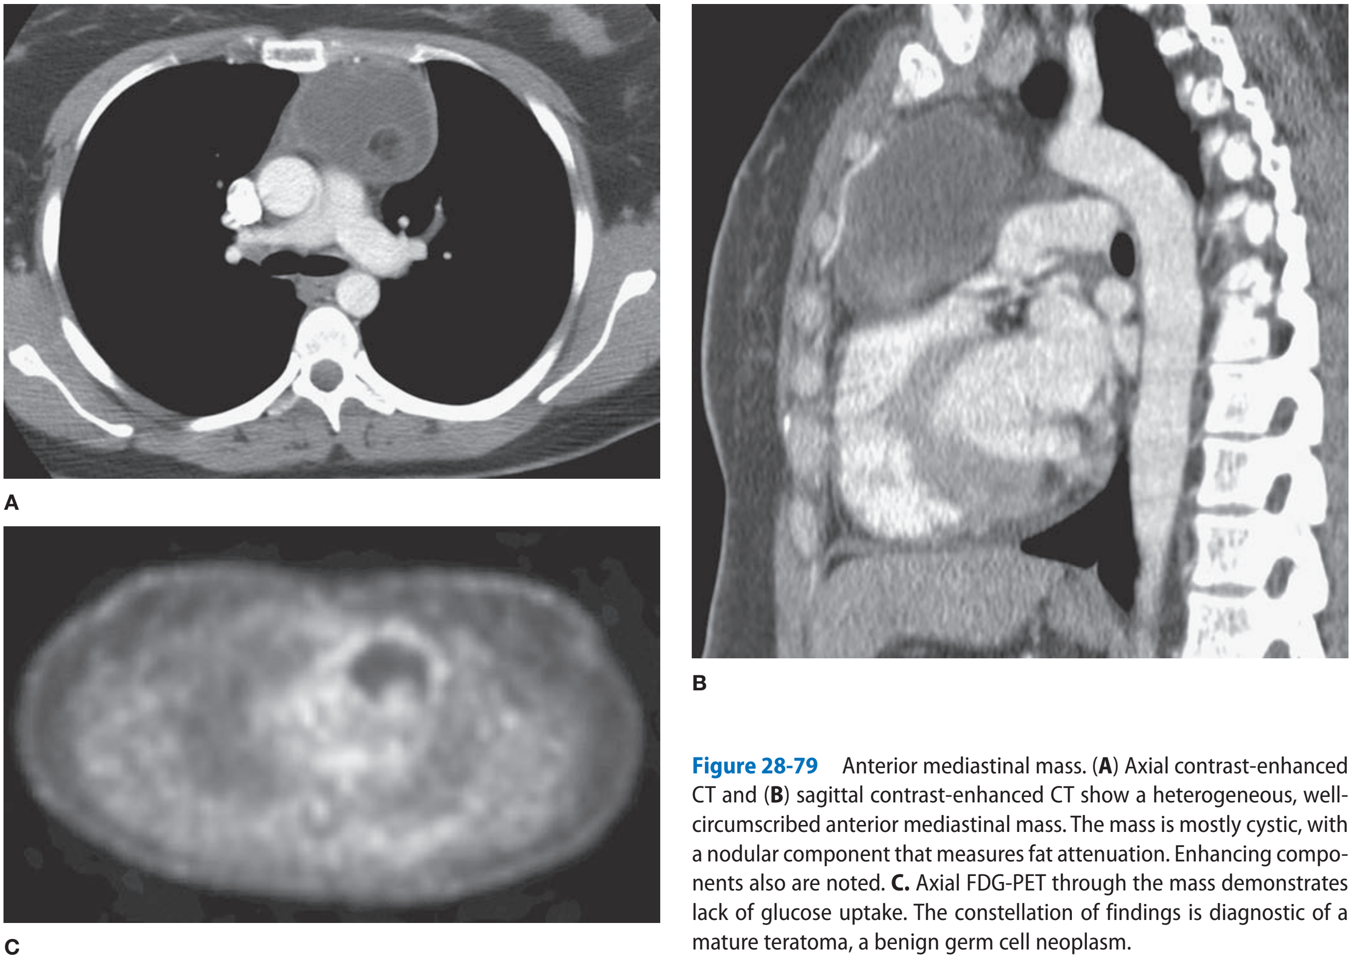

Figure 28-79 Anterior mediastinal mass. (**A**) Axial contrast-enhanced CT and (**B**) sagittal contrast-enhanced CT show a heterogeneous, well-circumscribed anterior mediastinal mass. The mass is mostly cystic, with a nodular component that measures fat attenuation. Enhancing components also are noted. **C.** Axial FDG-PET through the mass demonstrates lack of glucose uptake. The constellation of findings is diagnostic of a mature teratoma, a benign germ cell neoplasm.

from the esophagus or tracheobronchial tree and are also common in the middle compartment. These localized masses are smooth and well circumscribed; generally, they do not contain air, and their attenuation is low on CT (generally of simple fluid density) without contrast enhancement. However, duplication cysts containing highly proteinaceous fluid may have CT densities comparable to soft tissue, thus mimicking solid masses. As indicated earlier, MRI is useful in characterizing proteinaceous fluid and, thus, may be diagnostic in these cases. Bronchogenic cysts commonly occur at the tracheal carina or paratracheal region, whereas esophageal duplication cysts are characteristically located near the distal esophagus. However, esophageal and bronchogenic cysts may occur anywhere within the middle compartment.

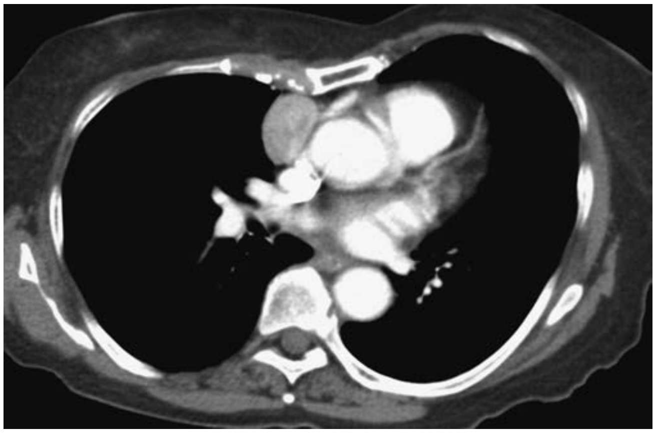

Figure 28-80 Anterior mediastinal mass. Axial contrast-enhanced CT demonstrates a homogeneous, enhancing, well-circumscribed anterior mediastinal mass along the anterior right heart border. Pathology confirmed a thymoma.

A dilated (patulous) esophagus is sometimes seen on the chest radiograph as a long tubular mass in the middle compartment and is readily identified by CT. The significance of a patulous esophagus is its association with dysmotility disorders, such as achalasia, CREST syndrome, and presbyesophagus. Neoplasms of the esophagus or trachea may also present as more localized mediastinal masses by chest radiograph; usually, CT is required for recognition. Early esophageal neoplasms may involve primarily the mucosa and may not be well seen on the CT, even if clearly demonstrated on a barium swallow study or endoscopy. Hiatal hernias are readily diagnosed using CT. The presence of esophageal wall thickening is usually clinically relevant. Smooth and concentric wall thickening favors esophagitis, particularly reflux esophagitis; irregular and eccentric wall thickening is concerning for esophageal carcinoma.[163]

In the posterior (paraspinal) compartment, the most common radiographic abnormalities are neurogenic neoplasms. However, neoplasms or infections of the vertebral column may also present as masses in the posterior compartment. CT or MRI usually distinguishes between a neurogenic neoplasm, which is unilateral and paraspinal in location, and lesions that erode or destroy the vertebrae and are generally present on both sides of the vertebral column. MRI is the best modality to diagnose a neurogenic neoplasm (Figs. 28-81 and 28-82).[164,165] Other considerations in the posterior compartment include paraspinal hematoma in the setting of trauma, and rarely, extramedullary hematopoiesis in patients with hemoglobinopathies, myeloproliferative disorders, or bone marrow infiltration.

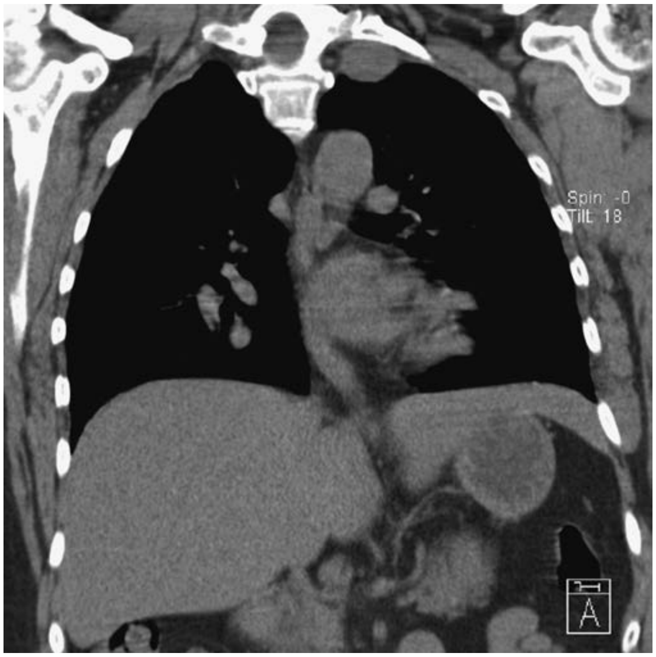

Figure 28-81 Posterior mediastinal mass. Coronal noncontrast CT shows a homogeneous, well-circumscribed posterior mediastinal mass in the left superior sulcus medially. Note absence of aggressive features by CT. Pathology confirmed a neurogenic neoplasm (schwannoma).

OUTLOOK FOR THE FUTURE

This chapter provides a modern, evidence-based overview of the wide scope and central role imaging plays in the diagnosis and management of thoracic diseases. Currently, it is inconceivable to imagine practicing thoracic medicine and surgery without the constant support of radiologist consultants and their armamentarium of basic and advanced imaging modalities.

Predicting the long-term future is most often a futile endeavor. However, there are clear trends that allow us to attempt to forecast likely innovations and changes in the field of thoracic imaging over the next decade.

The most important trend is demonstrating that imaging-based diagnostic and therapeutic approaches are beneficial to patient care, improving morbidity and mortality, while decreasing the overall cost of care. This trend is imposed by the current global economic environment and the mandate to increase the efficiency of healthcare systems by diminishing waste and redundancy and eliminating procedures that do not positively impact patient outcomes. Future clinical trials will emphasize what imaging can offer to empower practitioners to diagnose thoracic diseases earlier, faster, and in a less invasive manner. In addition, studies will address delivery of therapeutic approaches that will be more effective and less costly and contribute to better patient outcomes and quality of life.

The introduction of artificial intelligence (AI) has heavily influenced research trends in radiology in the last decade. Early clinical applications of AI in imaging generally, and thoracic imaging specifically, have already been implemented across the globe. Efforts have been made to develop automatic and semiautomatic methods to detect and characterize imaging pathology. In addition, the building of predictive imaging tools to streamline patient care using deep learning have resulted in early detection of pulmonary nodules and interstitial lung disease on CT, or pneumothorax on chest radiography. The evolving field of radiomics offers the possibility of identifying imaging features not visible to the human eye, and using them to predict treatment response in lung cancer or assessment of the aggressiveness of subsolid pulmonary nodules noted on CT. The field of AI will likely continue to evolve and become a useful tool in the radiologist's toolbox in improving patient care and outcomes.[166,167]

Another important trend is combining functional and anatomic information within a single imaging modality. PET/CT already offers this capability by coupling anatomic and metabolic imaging. CT, when performed with 4D cine sequences, may provide insight into chest wall, central airway, and lung mechanics, and may detect air trapping related to small airway disease. Dual-energy CT can provide further insight regarding perfusion dynamics and material characterization of lesions. It is likely that with continuous advancement of MRI hardware and sequences, MRI will finally become an integral part of imaging of lung parenchyma, noting that improving quality of DWI sequences will likely contribute to functional assessment of mediastinal and lung pathology.

We expect that increasing availability of hand-held US devices will impact the way patients are evaluated, particularly in the emergency department, where US may possibly surpass chest radiography as the main imaging tool for certain situations, e.g., evaluation

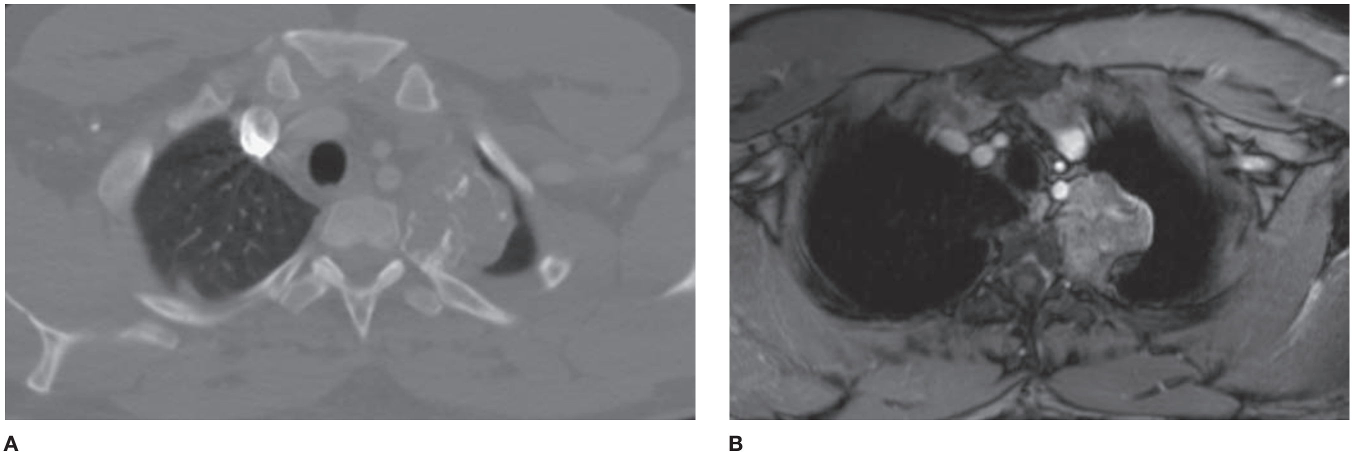

Figure 28-82 Posterior mediastinal mass. **A.** Axial noncontrast CT demonstrates a large left posterior mediastinal mass that appears to arise from the left posterior second rib, which demonstrates expansion and cortical destruction. Note irregular calcifications within the mass. **B.** Axial T1-weighted postcontrast MR shows moderate enhancement throughout the lesion. The constellation of findings suggests a primary bone neoplasm with chondroid differentiation. Pathology confirmed a chondrosarcoma.

of pleural pathology and detection of peripheral parenchymal lung disease.

Thoracic oncology will greatly benefit from new molecular imaging agents that target important cellular and subcellular biochemical pathways associated with carcinogenesis. Furthermore, molecular imaging will allow in vivo real-time assessment of the genetic and epigenetic processes underlying a number of pathologic conditions in the heart, lungs, and mediastinum, leading to more targeted, individualized, and, ultimately, effective therapeutics.

Quantitative imaging will be another trend that aims to provide a much better assessment of disease severity, particularly for diffuse lung diseases, such as COPD and ILD. Instead of simply reporting the presence of a specific disease and, at most, subjectively classifying the severity of the disease, radiologists will utilize computational image analysis tools to provide accurate disease quantification that reflects, and highly correlates with, physiologic metrics. Quantitative imaging utilizing computer-assisted detection and quantification of disease-specific imaging patterns on CT, MRI, and PET/CT will, therefore, allow development of biomarkers that will reflect disease prognosis and response to therapies far more accurately and earlier then currently possible. Future drug trials will particularly benefit from this approach.

Finally, it is of interest to consider what role plain chest radiography will play in the future, if any. Practical and economic considerations suggest that chest radiographs will not disappear soon, given their low cost, very low radiation dose, universal availability, portability, and capacity to address basic clinical questions. As we already witnessed during the COVID-19 pandemic, the information extracted from chest radiographs will likely be enhanced by AI, thereby adding value to differential diagnosis, prognostication, and patient management.

Beyond the technologic advancements in imaging, computer hardware, and software, an ongoing trend of simplifying patients' access to their medical information and better understanding of the imaging reports, by both the patient and referring physician, will continue to be emphasized in the near future. Actionable structured radiology reports that (1) integrate relevant clinical and laboratory data, (2) compare current to prior findings and convey the findings of the examination accurately and clearly lead to the appropriate intervention and/or follow up examination in a safe and timely manner, and (3) are integrated into the electronic medical record are now recommended by both the American College of Radiology and major European societies. With better IT support and widespread access to electronic medical records, this type of reporting will likely become the standard of care.

Irrespective of the many uncertainties, challenges, and exciting prospects for the future, it is undeniable that thoracic imaging will continue to be an indispensable companion to the practicing physician caring for patients with thoracic disorders and a central component of modern pulmonary medicine.

ACKNOWLEDGMENT

The authors dedicate this chapter to the memory of the late Wallace Miller, Sr., MD, who authored a previous version. The authors also acknowledge the contributions of Warren Gefter, MD, to the previous version of this chapter.

CHAPTER 29

Thoracic Ultrasonography

Andrew Weber
Fiore Mastroianni
Paul H. Mayo

INTRODUCTION

Thoracic ultrasonography is a readily available, noninvasive imaging method that is useful for pulmonary and critical care specialists. The technique is easy to learn and has multiple applications related to lung and pleural disease. The ease of use and portability of ultrasonography allows physicians to perform point-of-care imaging and reduce dependence on other thoracic imaging techniques, such as chest computed tomography (CT) and standard radiography (CXR).

This chapter focuses on use of ultrasonography for diagnosis and management of pleural and lung diseases that are of particular interest to the pulmonary specialist. The chapter is written with the understanding that the pulmonary consultant will personally perform image acquisition, interpret the image, and apply results at the bedside; this is a paradigm that is different from standard thoracic imaging, which requires the pulmonary specialist to rely on the radiology service to acquire and interpret the imaging study. While point-of-care thoracic ultrasonography (POCUS) is advantageous regarding cost and clinical efficiency, it requires acquisition of additional technical skills and knowledge by the pulmonary specialist. An advantage of clinician-performed POCUS is that it couples imaging results with the clinician's overall knowledge of the case. Thoracic ultrasonography is not performed in isolation; rather, it is combined with other key elements of clinical evaluation, such as the history, physical examination, and laboratory analysis, and it can be performed serially with ease.

TRAINING IN THORACIC ULTRASONOGRAPHY

The goal of thoracic ultrasonography training is to establish clinical competence in performing and interpreting ultrasonographic images. The Statement on Competence in Critical Care Ultrasonography provides a well-defined description of training goals in pleural and lung ultrasonography.[1] The Statement is a good starting point for pulmonary specialists who seek training in the field, and the competencies outlined should be their initial learning objectives.

No definitive literature is available to guide the optimal duration of training or the minimal number of studies to be performed and interpreted to achieve competence in thoracic ultrasonography; several professional societies offer formal training. Compared with the training required in cardiac and abdominal ultrasonography, training in thoracic ultrasonography is more straightforward. The authors have experience in training fellows and attending physicians in thoracic ultrasonography and have found that a motivated learner will achieve skill in the basic elements of pleural and lung ultrasonography with several hours of formal teaching. Training should include practice at image acquisition, initially focused on healthy human models and then on patients at the bedside. In addition, training should include the review of a comprehensive image set of normal and abnormal studies, enabling the learner to recognize a wide range of findings when they encounter them at the bedside. The cognitive elements of the field may be learned through reading chapters or review articles.[2–4] For more advanced training, comprehensive textbooks are available.[5,6] It is useful for the learner to identify a local expert who is able to help with bedside training and image review.

EQUIPMENT NEEDS

Thoracic ultrasonography may be performed using a wide variety of ultrasonography machines. Machines that are used for cardiac or abdominal ultrasonography generally provide adequate image quality. A probe designed for cardiac ultrasonography, employing a frequency range of 3.5 to 5.0 MHz, works well. The small footprint of the probe allows for easy placement between rib interspaces, and frequency selection allows for adequate penetration to enable imaging the deeper structures of the thorax. The larger curvilinear abdominal probe provides adequate images as well. A linear vascular probe, using a frequency range of 7.5 to 10.0 MHz, is required for detailed imaging of the pleural surface. The higher frequency improves the resolution, but at the sacrifice of signal penetration.

Every machine has its own performance characteristics. The operator must adapt machine setup to optimize image quality. What works well using one machine may not work well when using another. Some machines have presets for thoracic ultrasonography, but they may not necessarily be the optimal setup for thoracic imaging. Consequently, the operator must be prepared to alter machine settings from standard cardiac, abdominal, or thoracic presets. For instance, high-end cardiac echocardiography machines give excellent cardiac image quality, but they often yield poor near-field images. Many modern portable machines have acceptable thoracic imaging capability and provide the additional advantage that they are designed specifically for point-of-care scanning. In recent years, low-cost, pocket-sized, ultraportable machines with internet connectivity have become available. The authors have observed that some these models yield serviceable thoracic ultrasonography images.

SCANNING TECHNIQUE

For the pulmonary specialist, thoracic ultrasonography may be performed with the patient in a seated position. The supine scanning position is more typical for the critically ill patient, but it has the disadvantage of concealing the posterior chest from interrogation. The standard transducer orientation is with the transducer indicator oriented in a cephalad position, defining the primary scanning plane in a longitudinal axis. With the screen indicator placed to the left of the screen, images on the left side of the screen represent cephalad structures.

Machine control is integral to good-quality image acquisition; hence total, near, and far field gains must be adjusted for optimization of the image. Depth should be set to place the structure of interest in the middle of the screen, and the focal point should be adjusted for optimal image quality of the target structure. Using adequate ultrasonography coupling gel and application of firm pressure, the transducer is applied perpendicular to the chest wall and adjusted to examine the rib interspace. Adjacent interspaces are examined by sliding the transducer to the next interspace. In this way, the examiner performs a scan line while the transducer is moved over the chest wall. In an orderly fashion, multiple adjacent scan lines are performed so that the entire chest wall can be imaged. Using this approach, the examiner obtains multiple, two-dimensional, tomographic ultrasonography planes of the thorax, in effect developing a three-dimensional model of the thorax. If a focal abnormality is identified, the examiner performs a more detailed examination of the area.

Aerated lung blocks ultrasonography, whereas the liver and spleen do not. Consequently, to visualize the peridiaphragm area, the transducer may be angled such that the scanning plane passes through the liver or spleen to obtain an adequate image window. Bone also blocks ultrasonography. So, when an abnormality lies deep to a rib, the transducer may need to be angled to look over or under the rib for proper visualization. Pleural effusions and consolidated lung each transmit ultrasonography. Their presence may yield a window for examination of the heart, mediastinum, or, in the case of pleural effusion, the lung. While the standard scanning plane is longitudinal, a transverse plane may be utilized on occasion. This may be required when examining the pleura for a "lung point" or to establish an optimal angle for needle insertion for access to a lung mass.

PLEURAL ULTRASONOGRAPHY

Ultrasonography is particularly effective for identifying pleural fluid, since fluid is either anechoic or hypoechoic relative to adjacent soft tissue. While physical examination is neither specific nor sensitive for detection of pleural effusion,[7] a pleural effusion as small as 5 cc may be identified with ultrasonography.[8] Pleural ultrasonography is superior to standard chest radiography in identifying pleural effusions and in differentiating a pleural effusion from pleural thickening or lung consolidation.[7,9] Compared with chest CT, pleural ultrasonography demonstrates 93% sensitivity and specificity for identification of pleural effusion.[10] When a patient has complete opacification of one hemithorax on CXR, ultrasonography has 95% sensitivity for identification of pleural effusion.[9]

■ Identification of Pleural Fluid

The pulmonary specialist will generally examine the patient in the seated position. Pleural fluid, unless loculated, distributes by gravitational effect to the most dependent part of the thorax. Therefore, the ultrasonography examination focuses on the lower dependent area of the posterior thorax.

The examiner seeks to identify three characteristic findings indicating the presence of a pleural effusion: (1) An anechoic or hypoechoic space that is surrounded by typical anatomic boundaries defines the pleural effusion (Video 29-1). (2) The typical anatomic boundaries, including the chest wall, lung surface, and diaphragm (Fig. 29-1). The heart may form an anatomic boundary on the left side. Recognition of the diaphragm requires definitive identification of the subdiaphragmatic organs such as the liver, spleen, and kidneys in order to distinguish pleural effusion from ascites (Video 29-2) (Fig. 29-2). (3) The dynamic changes typical of a pleural effusion, such as lung movement, diaphragm movement, and mobility on echogenic elements within the effusion (Video 29-3).

Video 29-1 Typical anatomic boundaries that surround a hypoechoic pleural effusion: chest wall, surface of lung, and diaphragm. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the seventh intercostal space in the right midaxillary line. *Video available on AccessMedicine.com.*

Video 29-2 Pleural effusion above the diaphragm, subphrenic ascites below the diaphragm superior to liver, hepatorenal space, and kidney. These structures must be positively identified before proper identification of a pleural effusion, subphrenic ascites, or both can be made. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the eighth intercostal space in the right midaxillary line. *Video available on AccessMedicine.com.*

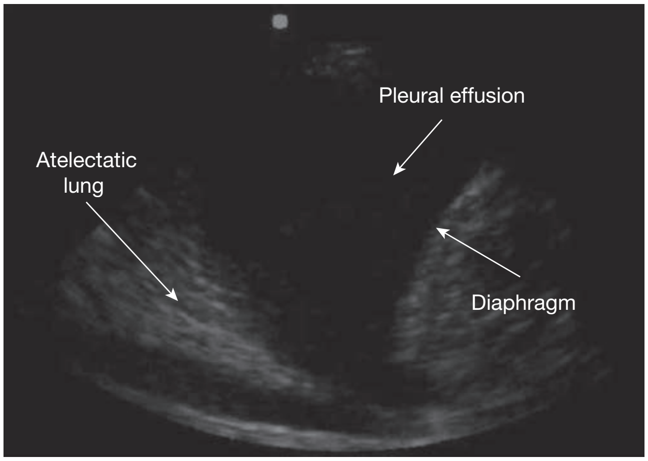

Figure 29-1 Typical anatomic boundaries that surround a hypoechoic pleural effusion. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the seventh intercostal space in the right midaxillary line.

Usually, pleural fluid is hypoechoic relative to the liver or spleen. However, complex pleural effusions may demonstrate echogenicity similar to these organs. The chest wall, as a "stationary" structure, does not show dynamic changes with respiration. Lung that is adjacent to, or surrounded by, pleural fluid is compressed by the pleural effusion and is consequently airless. The atelectatic lung, which is of tissue density and presents a pattern of alveolar consolidation on ultrasonography examination, is visualized as "floating" in the pleural fluid. It moves in both a cardio- and respirophasic fashion. This is one of the typical dynamic changes useful for identification of pleural effusion. Other typical dynamic changes include those of swirling debris or fibrin strands agitated by respiratory or cardiac motion. On occasion, a highly cellular pleural effusion may develop an echogenic layer as more and less dense components separate over time and with immobility.

Inadvertent subdiaphragmatic device insertion into the spleen or liver is a dangerous complication of thoracentesis, so identification of the diaphragm is required for localizing a pleural effusion

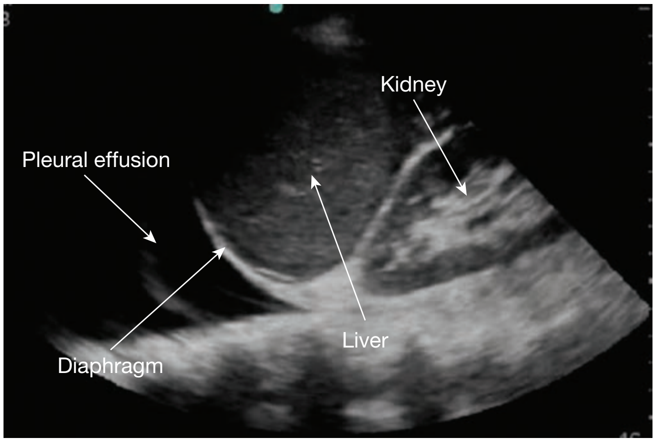

Figure 29-2 Pleural effusion above the diaphragm, liver, hepatorenal space, and kidney. These structures must be positively identified before thoracentesis to avoid inadvertent subdiaphragm device insertion. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the eighth intercostal space in the right midaxillary line.

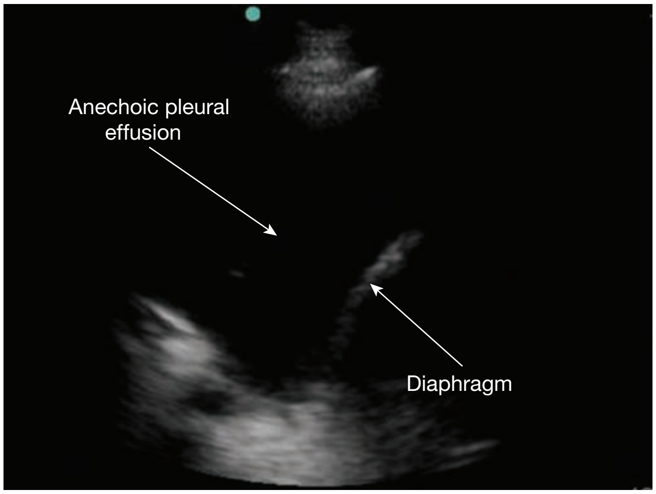

Figure 29-3 Anechoic pleural effusion, likely a transudate. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line.

and enabling safe performance of thoracentesis. The diaphragm, having respirophasic movement, is a hyperechoic curvilinear structure superior to the liver and spleen. The inexperienced operator may mistake the hepatorenal or splenorenal space for the diaphragm, as they are hyperechoic curvilinear structures. The overlying spleen or liver may then be mistaken for an echogenic pleural effusion. This may result in inadvertent subdiaphragmatic device insertion while attempting a thoracentesis, with potentially catastrophic consequence to the patient. It is helpful to identify the kidney when scanning below the diaphragm to avoid this dangerous pitfall. Identification of the chest wall allows measurement of the depth required for needle penetration when planning thoracentesis. Identification of the underlying lung allows the operator to limit the depth of needle insertion to avoid visceral pleural laceration.

■ Characterization of the Pleural Effusion

Ultrasonography may have utility in distinguishing transudative from exudative effusions; however, it is not sufficiently reliable to distinguish between the two.[11] Transudates often lack constituents that are ultrasonographic reflectors and are, therefore, anechoic (Video 29-1) (Fig. 29-3). Some pleural effusions may have a complex, non-septated pattern with slow flowing movement of ill-defined heterogeneous elements within a hypoechoic effusion, referred to as *swirling*.[12] These swirling effusions may be observed with a transudate; however, their presence suggests an exudative cellular effusion that can be associated with malignancy or infection.[13]

Video 29-3 Dynamic findings typical of a pleural effusion, including movement of homogenous echogenic elements within the effusion. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line. *Video available on AccessMedicine.com.*

Video 29-4 Multiseptated pleural effusion. This pattern is consistent with a complex parapneumonic effusion or empyema that will likely require fibrinolytic treatment or surgical drainage. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the fourth intercostal space in the left midaxillary line. *Video available on AccessMedicine.com.*

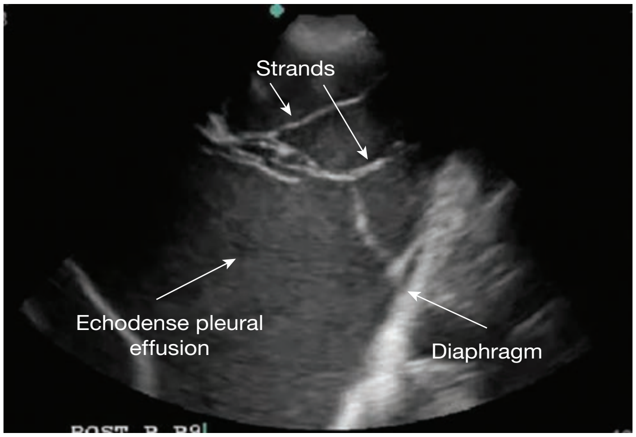

Figure 29-4 Pleural effusion with a homogeneously echogenic pattern and mobile strands suggestive of an exudate. Thoracentesis showed a hemothorax. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line.

A heterogeneously echogenic pattern, with swirling debris, septations, fronds, or strands is typically observed with exudates with a positive predictive value of 90%.[11] Highly cellular exudates, such as empyema or hemothorax, may demonstrate homogeneous echogenicity[14] (Video 29-3) (Fig. 29-4). Exudates can be echogenic, but are occasionally anechoic. The presence of strands, debris, or septations is characteristic of a parapneumonic effusion or empyema[15] (Fig. 29-5).

The presence of a septated effusion on ultrasonography suggests the need for fibrinolytic therapy or surgical intervention, prolonged chest tube drainage, and longer hospital stay when compared with effusions lacking such complexity[16] (Video 29-4). Pleural ultrasonography is superior to CT scanning in detecting pleural fluid complexity.[17]

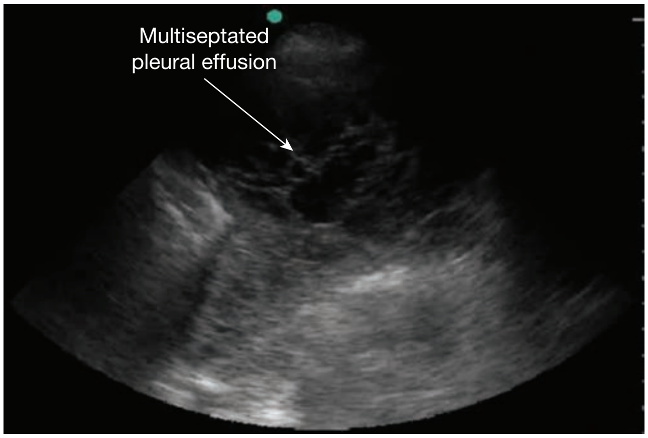

Figure 29-5 Multiseptated pleural effusion. The pattern is consistent with a complex parapneumonic effusion or empyema that will likely require fibrinolytic treatment or surgical drainage. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the fourth intercostal space in the left midaxillary line.

By making a number of defined measurements, the volume of a pleural effusion may be estimated using ultrasonography.[18] For clinical purposes, it generally suffices to characterize the effusion as small, moderate, or large. Pleural effusions may become loculated collections, which characteristically develop in nondependent positions and fail to move with changes in body position. The loculum may be thick-walled and often has internal hyperechoic complexity.

Performance of Thoracentesis

Pleural ultrasonography facilitates safe performance of thoracentesis. When compared with physical examination combined with standard chest radiography, ultrasonography is superior in identifying a safe site for needle insertion.[7] A meta-analysis supports the use of ultrasonography to guide thoracentesis to reduce the risk of pneumothorax.[19] As needle insertion is required not only for simple thoracentesis, but also for a wide variety of pleural procedures requiring use of guidewires and device placement, pleural ultrasonography is an essential component of interventional practice.

Thoracic ultrasonography allows for identification of a safe site, depth, and angle for needle insertion. Using the technique of scan lines described previously, the operator identifies the pleural effusion and establishes the best site and trajectory for needle insertion while avoiding injury to structures that surround the fluid collection. In selecting a site, the operator is aware that the lung may move in a respirophasic fashion. Safe site selection is predicated on the absence of intermittent respirophasic movement of lung into the needle path. When such movement is observed, constituting the so-called "curtain sign," needle insertion is contraindicated at that point. Examination of the planned needle insertion trajectory with the vascular probe adds an additional element of safety to the procedure by identifying aberrantly positioned intercostal vessels that can be avoided by changing the access site.[20] Once a safe site is found, it is marked by indentation of the skin. Just prior to sterile skin preparation, the operator rescans to confirm site selection, depth of needle penetration required, and the angle of insertion. The procedure is then performed using an angle of insertion of the needle and syringe assembly that duplicates the angle of the transducer employed at the time of the final scan. Patient position should not change between the final scan and needle insertion, as this may cause movement of the fluid within the thorax.

For the pulmonary specialist, thoracentesis is usually performed with the patient in the seated position. For more complex procedures requiring tunneling of a catheter or chest tube insertion, the patient may be supine or in lateral decubitus position. Using the same scan line technique as utilized for the upright patient, the operator identifies the pleural effusion based on the previously described ultrasonography criteria. The site is marked. The angle and depth for safe needle insertion are determined. Immediately before final skin preparation, the operator rescans to confirm the safety of the site for device insertion and, without patient movement, proceeds with device insertion and advancement.

While ultrasonography facilitates pleural access, pitfalls exist. Although pneumothorax is a rare occurrence with ultrasonography-assisted thoracentesis, the operator checks for pneumothorax before and after the procedure by examining the superior anterior chest for lung sliding (see "Lung Ultrasonography," below). The presence of sliding lung rules out pneumothorax. The most common cause of pneumothorax following ultrasonography-assisted thoracentesis is the presence of nonexpandable lung, rather than visceral pleural laceration.[21]

In performing ultrasonography-assisted thoracentesis, several causes may account for failure of fluid aspiration, despite good site selection. In edematous or obese patients, the operator may press the probe into the skin surface with some force, causing a compression artifact. As the measurement for depth of needle penetration is made when the skin is compressed by the probe, once the skin has rebounded, the distance of needle penetration required may be greater than that predicted during initial measurement.

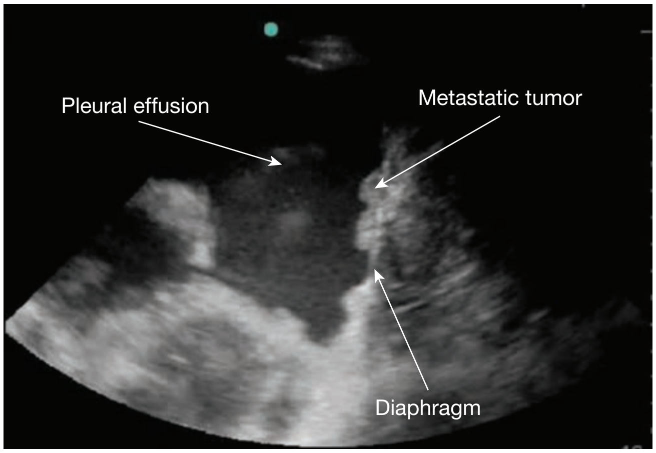

Figure 29-6 Pleural effusion with pleural masses on the diaphragm caused by metastatic breast cancer in the pleural space. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the fifth intercostal space in the left midaxillary line.

In performing the procedure in patients with loose skin, the operator may place tension on the skin at the time of mark placement, displacing the skin from the underlying soft tissue. When the tension is released, the mark may displace to a new position on the chest wall that is not appropriate for needle insertion. This underlies the importance of a final scan, post position marking, and prior to needle insertion.

While it is not necessary to use real-time needle guidance in performing ultrasonography-assisted thoracentesis, failure of needle insertion to yield fluid may warrant rescanning to confirm appropriate site selection. Occasionally, a "dry" tap results from tissue impaction in the needle during insertion or because of septations occluding the needle.

Pleural Pathology

In addition to identification of pleural fluid, ultrasonography allows visualization of a variety of pleural pathologies. A number of pleural diseases cause echogenic abnormalities within the pleural space. Some of these solid pleural abnormalities may coexist with pleural effusions. For example, metastatic pleural disease often occurs with a coexisting pleural effusion, such that the pleural effusion acts as an acoustic window that allows easy observation of the metastatic disease (Fig. 29-6). Metastatic tumors are usually hyperechoic and are often multiple (Video 29-5). They may demonstrate a variety of different sizes and shapes, such as nodular, hemispheric, or circular. The tumors may be broad-based or have frond-like protrusions. Chest wall or diaphragm invasion may cause disruption of normal tissue interfaces and direct extension of tumor into adjacent structures, each of which is visible with ultrasonography.

Video 29-5 Pleural effusion with pleural masses on the diaphragm. The patient had metastatic breast cancer in the pleural space. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the left midaxillary line. *Video available on AccessMedicine.com.*

Video 29-6 Complex multiloculated pleural effusion with thick septations caused by an empyema. The transducer was in longitudinal orientation and placed perpendicular to the chest wall. The examiner moved the transducer over several intercostal spaces to show the extent of the fluid collection. The scan line is in right midaxillary line. *Video available on AccessMedicine.com.*

Ultrasonography is superior to chest CT for the diagnosis of transpleural chest wall invasion.[22]

Benign pleural tumors, such as benign mesothelioma, chondroma, lipoma, or thoracic sclerosis, are uncommonly found during pleural ultrasonography. They are usually hyperechoic, have a distinct capsule, and do not demonstrate invasion through adjacent tissue planes. Ultrasonographic morphology is not sufficiently diagnostic, but the technique may be used to guide biopsy. Primary pleural malignancy, such as malignant mesothelioma, has ultrasonographic features that include pleural thickening with unclear and irregular borders, nodularity, and evidence of chest wall or diaphragm invasion.

Inflammatory diseases that involve the pleural space are usually caused by infection. Both parietal and visceral pleura are thickened and hyperechoic, while the underlying lung may demonstrate an alveolar consolidation pattern. Within the pleural fluid collection, linear mobile echogenic elements float freely. Over time, the elements may thicken and divide the effusion into multiple fluid-filled cavities that have variable echogenicity. Eventually, the infected space becomes a multiseptated conglomerate of thick-walled cavities (Video 29-6). A homogeneously echogenic empyema may be so dense that no dynamic findings are discernible within the pleural collection (Fig. 29-7). This makes differentiation from the underlying liver or spleen difficult and may even complicate delineation of the diaphragm, which is a key element in identifying a safe site for device insertion. Occasionally, a chest CT may be required to fully characterize a complex pleural space infection.

Pleural fibrosis shows variable echogenicity, so it may be difficult to differentiate fibrosis from an adjacent pleural effusion. Color-flow Doppler is helpful in distinguishing between the two.[23] Color-flow Doppler signals are generally absent from areas of fibrosis but are present in pleural effusions due to small ultrasonography reflectors moving within the fluid.

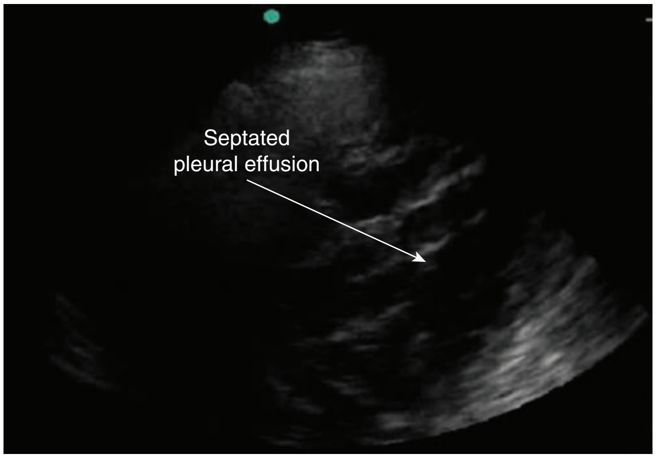

Figure 29-7 Complex, multiloculated pleural effusion with thick septations caused by an empyema. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line.

DIAPHRAGM ULTRASONOGRAPHY

Diaphragm ultrasonography is noninvasive and without ionizing radiation. It is feasible, reproducible, repeatable, and affordable when compared with other techniques to assess diaphragm dysfunction (DD). DD can be either partial (weakness) or complete (paralysis) and is often clinically underdiagnosed due to nonspecific presentations.[24] When the pulmonologist has suspicion for DD, the diaphragm can be imaged utilizing ultrasonography to acquire qualitative and quantitative measurements to guide further management. Diaphragm excursion is determined using the cardiac or abdominal probe using the liver or spleen as acoustic windows, as described above (Fig. 29-8). Best visualization is from an anterior midclavicular subcostal view or lower lateral mid-axillary view.[25]

■ Diaphragm Thickening

Diaphragm thickening is determined using the high-frequency linear vascular probe from the lateral lower midaxillary view of the zone of apposition. The examiner observes a three-layer structure consisting of two outer hyperechoic membranes with a singular

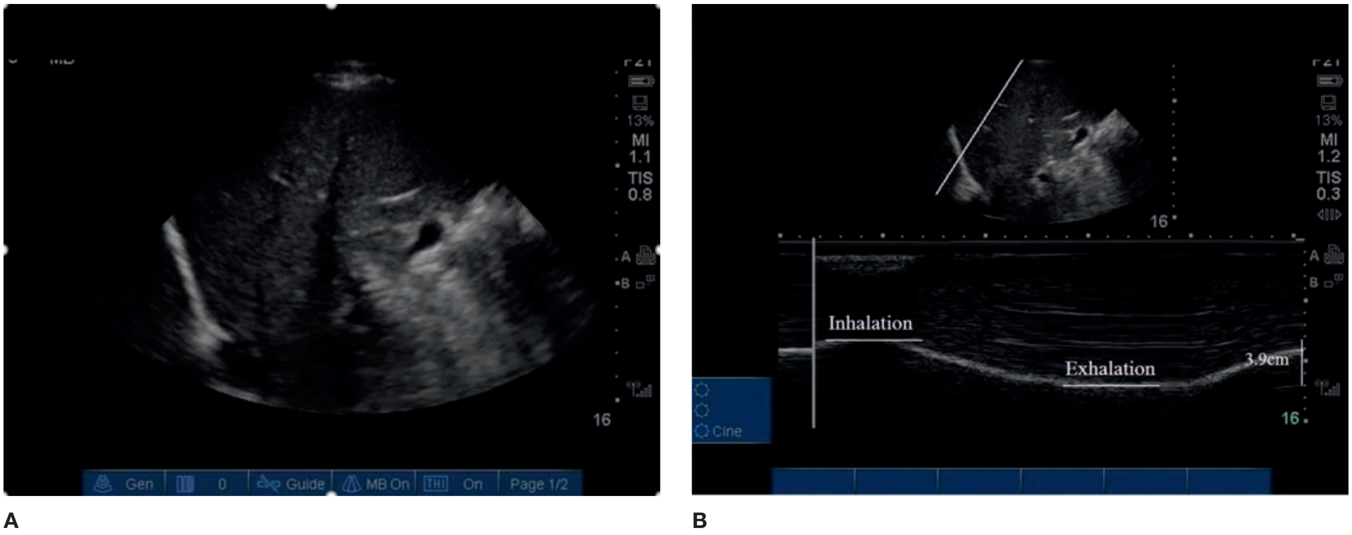

Figure 29-8 **A.** Hepatic hemidiaphragm visualized from the lateral position. **B.** Diaphragm excursion measured using M-mode. The image was obtained using a 3.5-MHz transducer. The transducer is in longitudinal orientation and placed perpendicular to the chest wall to scan through the 6th intercostal space at the mid axillary line.

Video 29-7 This video demonstrates the three-layer structure consisting of two outer hyperechoic membranes (pleura and peritoneum) with a singular hypoechoic inner muscle (diaphragm) during a respiratory cycle. The image was obtained using a 7.5-MHz vascular transducer. The transducer is in longitudinal orientation and placed perpendicular to the chest wall to scan through the 8th intercostal space in the midaxillary line. *Video available on AccessMedicine.com.*

Video 29-8 Demonstration of diaphragm excursion using B-mode. M-mode can then be applied as perpendicular to the diaphragm as possible and activated to obtain a quantitative value. The image was obtained using a 3.5-MHz transducer. The transducer is in longitudinal orientation and placed perpendicular to the chest wall to scan through the 6th intercostal space at the mid axillary line. *Video available on AccessMedicine.com.*

hypoechoic inner muscle (Video 29-7), the visualization of which allows measurement of the thickening of the diaphragm during inspiration and expiration. Thickening quantification is obtained by measuring the distance between the two hyperechoic structures during end inspiration and expiration (Fig. 29-9).[26,27]

Diaphragm Excursion

Diaphragm excursion (DE) is measured through the anterior or lateral views or with M-mode during quiet breathing during deep breathing, and during voluntary sniffing[28] (Video 29-8). Diaphragm paralysis can be diagnosed by identifying the absence of mobility during quiet and deep breathing together with paradoxical motion during voluntary sniffing.[29] Diaphragm weakness can be diagnosed by identifying reduced DE with or without paradoxical motion during voluntary sniffing.[30]

Diaphragm Thickness and Thickening Fraction

Thickness of the diaphragm (Tdi) and the thickening fraction (TF) are used to evaluate diaphragm atrophy and contraction, respectively. These measurements are obtained using the high-frequency linear probe visualizing the diaphragm at the zone of apposition. This acoustic window is found by placing the transducer between the eighth and ninth intercostal spaces in the midaxillary line using a longitudinal scanning plane. The diaphragm is identified as the hypoechoic inner muscular layer encased by two hyperechoic membranes as previously described (pleura and peritoneum).[26] Tdi is measured from the center of the pleural line to the center of the peritoneum during both end-inspiration (Tdi-insp) and end-expiration (Tdi-exp). The TF is calculated as follows:

$$[(\text{Tdi-insp} - \text{Tdi-exp})/\text{Tdi-exp}] \times 100.$$[31]

Chronic diaphragm paralysis is characterized by a thin, atrophic structure that does not demonstrate inspiratory thickening.[32] Acute or subacute diaphragm paralysis may have a normal Tdi; however, the TF is diminished.[30]

LUNG ULTRASONOGRAPHY

Lung ultrasonography is performed using the same equipment and scanning techniques as used for pleural ultrasonography. As the pulmonary specialist performs the imaging at point of care, results are immediately available for integration into the standard tools of patient evaluation, including the history, physical examination, and laboratory analysis. Lung ultrasonography is designed to be used in a goal-directed fashion at the point of care.

Basic Findings of Lung Ultrasonography

Several important, useful findings in lung ultrasonography include lung sliding, A lines, B lines, and evidence of lung consolidation, which are described below.

Lung Sliding

When the transducer is placed perpendicular to the chest wall and orientated to enable imaging through rib interspaces, the pleural

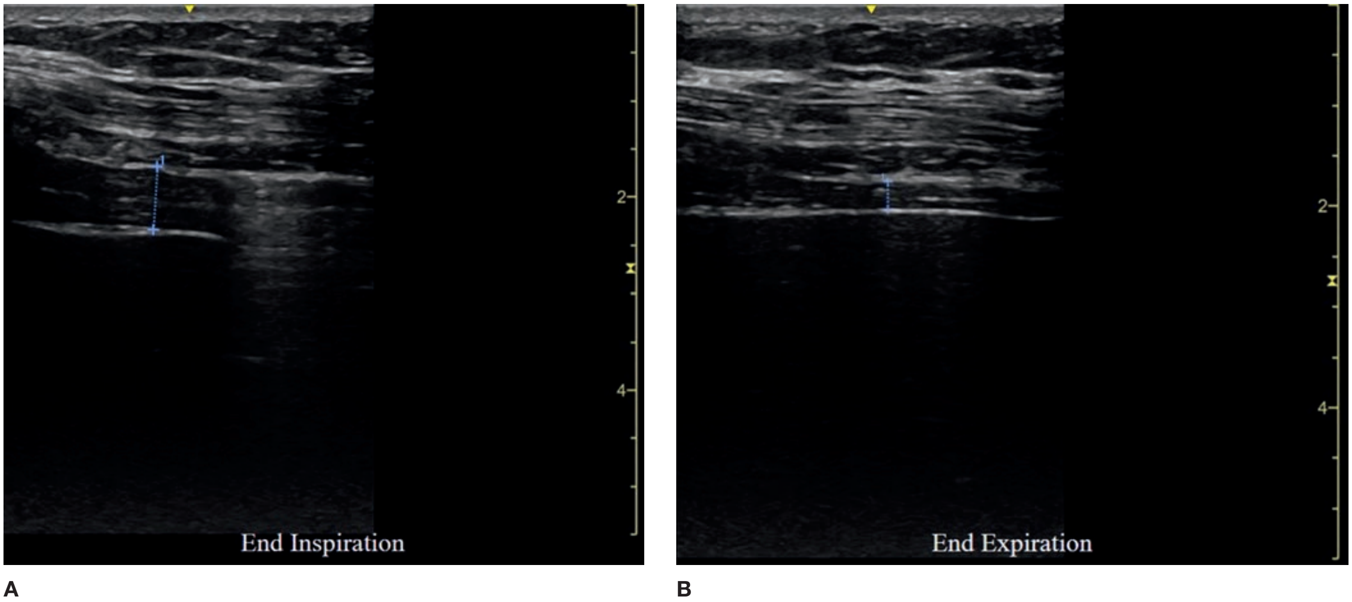

Figure 29-9 The three-layer structure consisting of two outer hyperechoic membranes (pleura and peritoneum) with a singular hypoechoic inner muscle (diaphragm) during a respiratory cycle. **A.** Measurement of diaphragm thickness during end inspiration. **B.** Measurement of diaphragm thickness during end expiration. The image was obtained using a 7.5-MHz vascular transducer. The transducer is in longitudinal orientation and placed perpendicular to the chest wall to scan through the 8th intercostal space in the midaxillary line.

Video 29-9 This video demonstrates the presence of lung sliding. The image is obtained using a 7.5-MHz vascular transducer. The transducer is in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line. The resolution of the 7.5-MHz transducer is superior to that of the 3.5-MHz transducer at the expense of reduced penetration (see also Chapter 79). *Video available on AccessMedicine.com.*

line is visualized approximately 5 mm deep to the rib periosteum. The normal pleural line demonstrates a shimmering respirophasic to-and-fro movement called *lung sliding*, which is caused by movement of the visceral pleura against the parietal pleura during breathing (Video 29-9).

The presence of lung sliding indicates that, at that point of examination, no pneumothorax is present, as the lung is apposed to the chest wall.[33] Lung sliding can be detected rapidly over the anterior upper chest by moving the probe over multiple interspaces. Since a loculated pneumothorax is uncommon, in the supine or upright patient, examination of several anterior interspaces suffices to rule out pneumothorax; free air in the pleural space rises to the nondependent part of the thorax, unlike fluid, which is dependent. Lung sliding is generally more prominent at the base of the lung because of the effect of diaphragm movement on lung inflation, so lung sliding may be more difficult to detect at the lung apex. To optimize visualization of lung sliding, the ultrasonography machine gain is decreased, and depth adjusted to place the pleural line in center of the screen.

A finding related to lung sliding is *lung pulse*. If a normal subject suspends respiration, lung sliding is temporarily absent; however, cardiophasic movement of the pleural line continues due to the lung movement that derives from transmission of cardiac contraction. The finding of lung pulse has the same implication as lung sliding; when noted, there is no pneumothorax at the site of the examination (Video 29-10).

While lung sliding and lung pulse, when present, rule out pneumothorax, their absence is less helpful (Video 29-11). The absence of lung sliding indicates the possibility of pneumothorax. Other causes for absence of lung sliding include pleurodesis, apnea, mainstem bronchial obstruction, giant lung bullae, and severe parenchymal lung disease. The absence of lung sliding should be correlated with the clinical context. For example, if a patient demonstrates lung sliding before an ipsilateral thoracentesis or central-line insertion, the absence of lung sliding following the procedure suggests an extremely high probability of a procedure-related pneumothorax. On the other hand, the patient who has had prior pleurodesis will lack lung sliding.

Video 29-10 This video demonstrates the presence of lung pulse in a tachycardic patient. Note the absence of lung sliding with perception of cardiac activity near the meeting of the parietal and visceral pleural line. The image was obtained using a 7.5-MHz vascular transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line. The resolution of the 7.5-MHz transducer is superior to that of the 3.5-MHz transducer, although depth of penetration is reduced (see also Chapter 79). *Video available on AccessMedicine.com.*

Video 29-11 Absence of lung sliding and lung pulse. The image was obtained using a 7.5-MHz vascular transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line. The resolution of the 7.5-MHz transducer is superior to that of the 3.5-MHz transducer, although depth of penetration is reduced (see also Chapter 79). *Video available on AccessMedicine.com.*

Video 29-12 Lung point. A pneumothorax has caused partial deflation of the lung. Respirophasic movement of the partially deflated lung's visceral pleura into the pneumothorax space is seen. The image was obtained using a 7.5-MHz vascular transducer. The transducer was in transverse orientation and placed perpendicular to the chest wall to scan through the fifth intercostal space in the right anterior axillary line (see also Chapter 79). *Video available on AccessMedicine.com.*

While the absence of lung sliding is only indicative of the possibility of pneumothorax, it is possible to positively diagnose a pneumothorax using lung ultrasonography based on identification of a *lung point*.[34] Most pneumothoraxes result in only partial collapse of the affected lung; hence, the partially deflated lung is, at some point, still apposed to the chest wall. Under these circumstances, when the transducer is placed into an anterior interspace, no lung sliding will be noted—as the lung is not inflated against the inside of the chest wall. More laterally, lung sliding may become apparent if there is partial collapse of the lung. At the interface between the aerated lung and the pneumothorax space, the lung will be seen to enter the scanning plane in a respirophasic manner (Video 29-12). This interface is called the lung point. Identification of a lung point is diagnostic of pneumothorax and allows for an estimate of pneumothorax size. While a lung point is 100% specific for pneumothorax, its sensitivity depends on the skill of the examiner; furthermore, a large pneumothorax will not have a lung point. High-frequency vascular probes are useful in examining for lung point.

A Lines

Once the pleural line has been examined, the depth setting on the machine is increased to examine deeper structures within the thorax. The normal lung reveals *A lines,* which are one or more horizontally oriented lines visible deep to the pleural line (Video 29-13). When multiple, they are equidistant; their separation distance corresponds to the distance between the chest wall and pleural line (Fig. 29-10). A lines are reverberations of the pleural line caused by echoes reflecting off the air just deep to the pleural line, which then reflect off of the probe face. When this reflection returns to the probe, it appears on the screen as an ultrasonographic interface similar to the pleural line, but twice as far away. A lines may be single or multiple, but they are always separated by the same distance. In the presence of sliding lung, A lines indicate normally aerated lung at the site of probe application to the chest. When present without lung sliding, they suggest the possibility of a pneumothorax. A lines correlate with a normal aeration pattern seen on a CT scan.[35]

B Lines

Using standard scanning technique and a depth set to visualize deeper structures, *B lines* may be observed instead of A lines (Fig. 29-11). B lines have several distinct characteristics: (1) They are hyperechoic;

Video 29-13 A lines. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line (see also Chapter 79). *Video available on AccessMedicine.com.*

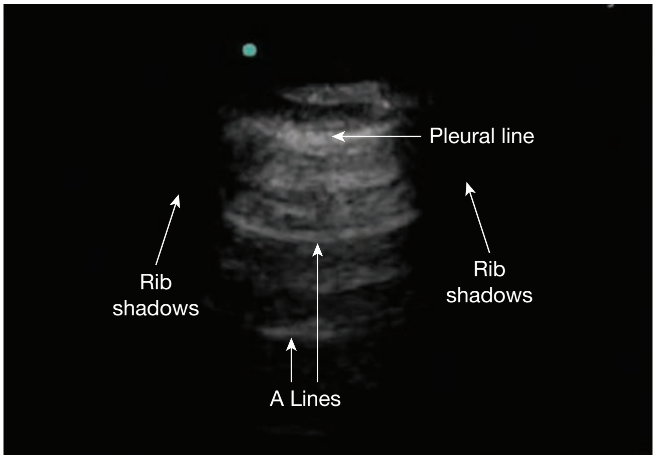

Figure 29-10 Pleural line, A lines, and adjacent rib shadows. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line.

(2) the originate at the pleural interface; (3) they extend to the bottom of the device screen in vertical orientation; (4) they fan out; (5) they move with the pleural interface (if it is mobile); and (6) they efface A lines where A lines and B lines intersect (Video 29-14). The presence of B lines correlates with alveolar or interstitial abnormalities encountered on CT scanning (reticular pattern or ground-glass abnormality).[36]

B lines result from of any interstitial infiltrative process, such as inflammation, neoplasm, fibrosis, hemorrhage, or edema.[37–41] B lines may be focal, scattered, or profuse in distribution, based on the underlying disease process.

As with any radiographic abnormality, clinical correlation is required to determine the cause of B lines. For example, healthy individuals often have one or two B lines on examination of the lateral lower rib interspaces, which are not pathologic. More than two B lines in a single field is considered abnormal. Pneumonia may manifest with focal B lines detected over the involved lobe or segment. Pulmonary fibrosis results in scattered B lines, whereas cardiogenic pulmonary edema yields profuse bilateral B lines. Pleural morphology may be useful in distinguishing B lines related to elevation of left atrial pressure from those caused by an inflammatory process. Typically, the B lines noted in cardiogenic pulmonary edema are associated with a smooth pleural surface, while those seen in primary lung injury manifest an irregular pleural surface.[41] As B lines originate from the area of the visceral pleura, their presence rules out pneumothorax.

Video 29-14 B lines. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line (see also Chapter 79). *Video available on AccessMedicine.com.*

Consolidation

Consolidated lung manifests as tissue density on ultrasonography.[42] Its echogenicity is similar to that of the liver (sonographic hepatization of lung). Consolidation may be localized to a specific lobe or segment of the lung and may also be observed in the lung periphery as a small consolidation pattern. Within the consolidated lung, punctate, hyperechoic foci are often visible (Fig. 29-12). These foci represent air retained within the bronchi. If they move in a respirophasic manner, the finding indicates patency of the bronchus supplying that portion of the lung[43] (Videos 29-15 and 29-16). Demonstration of consolidation on lung ultrasonography correlates strongly with results of chest CT scanning.[35]

As with chest radiography and CT scanning, the finding of alveolar consolidation on lung ultrasonography does not give the clinician a specific diagnosis. While pneumonia may result in alveolar consolidation, so will atelectasis (compressive, resorptive, or cicatricial). Severe pulmonary edema, with complete filling of the alveolar compartment, and infiltrative processes, such as tumor, may result in the ultrasonographic finding of lung consolidation. While lung ultrasonography identifies consolidation, the pulmonary specialist determines its cause.

LIMITATIONS OF THORACIC ULTRASONOGRAPHY

A specific limitation of lung ultrasonography relates to the physics of the technique. Due to the mismatch of acoustic impedance

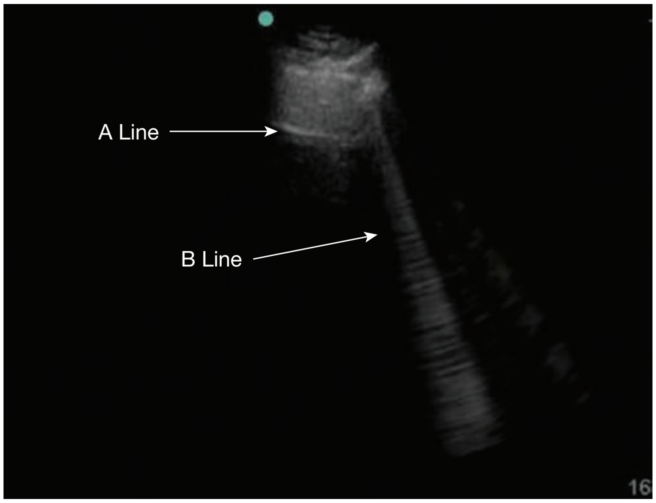

Figure 29-11 B lines. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line.

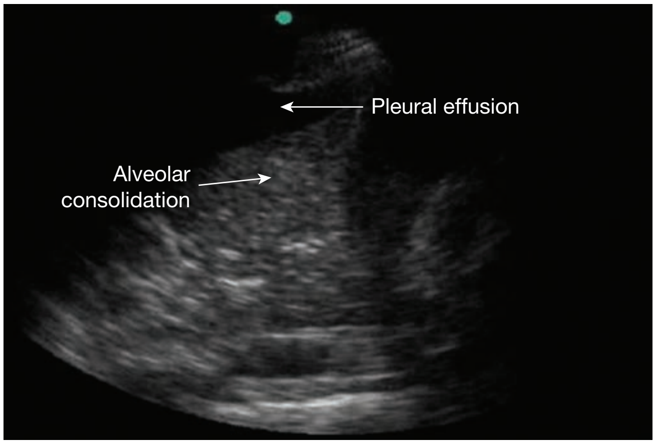

Figure 29-12 Alveolar consolidation of the left lower lobe and pleural effusion. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the left posterior axillary line.

Video 29-15 Mobile air bronchograms in an area of alveolar consolidation. The gain was turned down to bring out the punctate hyperechoic mobile foci that have respirophasic movement. The foci represent air within the bronchi surrounded by alveolar consolidation. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line. *Video available on AccessMedicine.com.*

Video 29-16 Alveolar consolidation of the right lower lobe without dynamic air bronchograms. Punctate hyperechoic foci can be seen; however, the appearance of movement demonstrated derives from translational artifact and is not from respirophasic movement. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the left posterior axillary line. *Video available on AccessMedicine.com.*

between the soft tissue of the chest wall and underlying aerated lung, there is complete reflection of ultrasonography at the interface of the two, so aerated lung is not visible as a discrete structure. Any disease process resulting in focal abnormality that is surrounded by aerated lung will not be visible with ultrasonography examination. For example, a lung mass that is surrounded by aerated lung will not be visible using ultrasonography. Similarly, mediastinal structures are not visible using surface ultrasonography unless there is a convenient acoustic window related to lung consolidation or pleural effusion.

A major limitation of thoracic ultrasonography in the critical care unit relates to the difficulty in scanning the posterior thoracic area in the unstable patient who is in supine position and encumbered by life support devices. The pulmonary specialist is advantaged as he or she will be able perform the scan with the stable patient in the sitting position, thereby allowing imaging of the posterior thorax. However, obesity, heavy musculature, subcutaneous emphysema, or surgical dressings may degrade image quality in some patients (Video 29-17). In the case of ambiguous results obtained with thoracic ultrasonography, the pulmonary specialist may revert to CXR or chest CT.

Documentation of the results of lung ultrasonography is challenging compared with CXR and chest CT scanning, for which results can be stored indefinitely in a durable format, and for which serial studies can be compared. The need for documenting the results of thoracic ultrasonography requires that the clinician have a reliable and convenient means of storing the results in a durable digital format—requirements for both clinical and billing purposes.[44]

By definition, thoracic ultrasonography is performed at the point of care by the pulmonary specialist. This requires the clinician to commit time to training to become competent, to have immediate access to a capable portable machine, and to have an easy method of saving the results of the study. These factors are barriers and, therefore, constitute limitations to use of thoracic ultrasonography in clinical practice. The clinician who decides to adopt thoracic ultrasonography as a primary imaging modality is prepared to meet these challenges, with the intent of improving patient care and reducing reliance on CXR and chest CT.

Video 29-17 Hypoechoic pleural effusion without definite septations and an adjacent translobar consolidation in a morbidly obese patient. Due to heavy musculature, connective tissue, rib shadowing artifact, and skin folding, identification of ultrasound findings can be obscured, rendered challenging, or be uninterpretable. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right posterior axillary line. *Video available on AccessMedicine.com.*

ADVANCED LUNG ULTRASONOGRAPHY

A wide variety of additional lung ultrasonography findings have been described. Mastery of the basic findings is the first step of training for the pulmonary specialist. The reader is referred to standard texts for a complete review of the subject.[5]

CONCLUSION

Thoracic ultrasonography is a useful imaging modality for the pulmonary specialist. Thoracic ultrasonography is easy to learn and has multiple applications as a point-of-care tool. The technique provides the pulmonary specialist information of immediate clinical relevance at the point of care.

CHAPTER 30

Physiologic and Metabolic Assessment of Pulmonary Disorders Using Conventional Imaging Techniques and Positron Emission Tomography

Ghassan El-Haddad
Søren Hess
Abass Alavi

INTRODUCTION

Since the mid-1950s, use of radiopharmaceuticals has made it possible to assess a variety of pulmonary disorders. In 1955, ^{133}Xe was introduced for the study of regional pulmonary ventilation.[1] Shortly thereafter, it became possible to evaluate regional pulmonary blood flow using inhaled carbon dioxide containing radioactive ^{15}O^{2} or intravenous injection of ^{133}Xe dissolved in saline solution.[3] In 1964, intravenous injection of ^{131}I-macroaggregated albumin made it feasible to obtain perfusion scans of the lungs.[4] Although these techniques rapidly gained wide acceptance as tests of regional abnormalities in ventilation and pulmonary blood flow, the main practical application was as a ventilation–perfusion lung scan ($\dot{V}/\dot{Q}$ scan) in the diagnostic evaluation of patients with suspected pulmonary embolism. Over the years, the role of nuclear medicine in respiratory medicine expanded to include such indications as preoperative assessment of lung function, mucociliary clearance, alveolar-capillary membrane permeability, inflammatory lung disease, and lung cancer. The last two indications were facilitated by the more widespread availability of positron emission tomography (PET) and integrated PET/CT (computed tomography) that has provided powerful tools to aid in the diagnosis, staging, and management of patients.

RADIOPHARMACEUTICALS AND TECHNIQUES IN VENTILATION–PERFUSION LUNG SCANNING

Perfusion lung scans are routinely utilized to examine patients with suspected pulmonary embolism. The overall principle is simple: radiolabeled microembolic particles are injected intravenously and transported to the pulmonary vasculature where they lodge uniformly and reversibly in the smallest blood vessels proportional to the perfusion. If a part of the vasculature is blocked by an embolus, a corresponding, often wedge-shaped, downstream area of the lung devoid of perfusion and injected radiolabeled microemboli appears photopenic on subsequent gamma camera examination.

Perfusion imaging is sensitive but, unfortunately, not specific for diagnosing pulmonary embolism. Virtually all lung diseases (including tumors, infections, asthma, and chronic obstructive pulmonary disease) may cause decreased pulmonary arterial blood flow in the affected lung zones. Therefore, combined use of perfusion and ventilation studies improves the diagnostic specificity of lung scanning for pulmonary embolism (Fig. 30-1). Pulmonary embolism almost always causes abnormal perfusion, while ventilation is preserved *(mismatched defects)* (Fig. 30-2). In contrast, in parenchymal pulmonary disorders, decreased ventilation and perfusion are noted in the same lung region, as perfusion is reduced secondary to ventilation disturbances due to regional hypoxic pulmonary vasoconstriction *(matched defects)*.[5] Sometimes ventilation abnormalities appear even larger than the perfusion abnormality *(reverse mismatch)*, for example, due to airway obstruction, mucus plug, atelectasis, or pneumonia.[6]

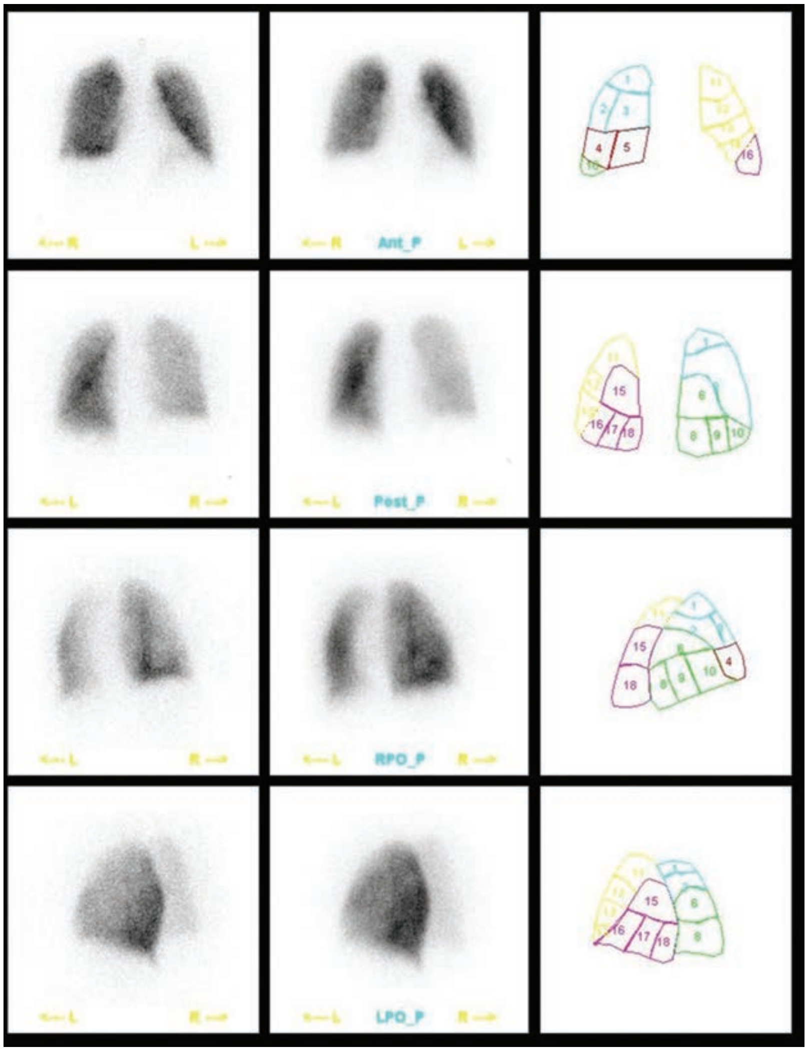

Figure 30-1 Normal ventilation–perfusion lung scanning. Ventilation scan using ^{99m}Tc Technegas aerosol (left column): Uniform distribution of the aerosol throughout both lungs. Perfusion scan using ^{99m}Tc MAA (middle column): Uniform distribution of particles throughout both lungs.

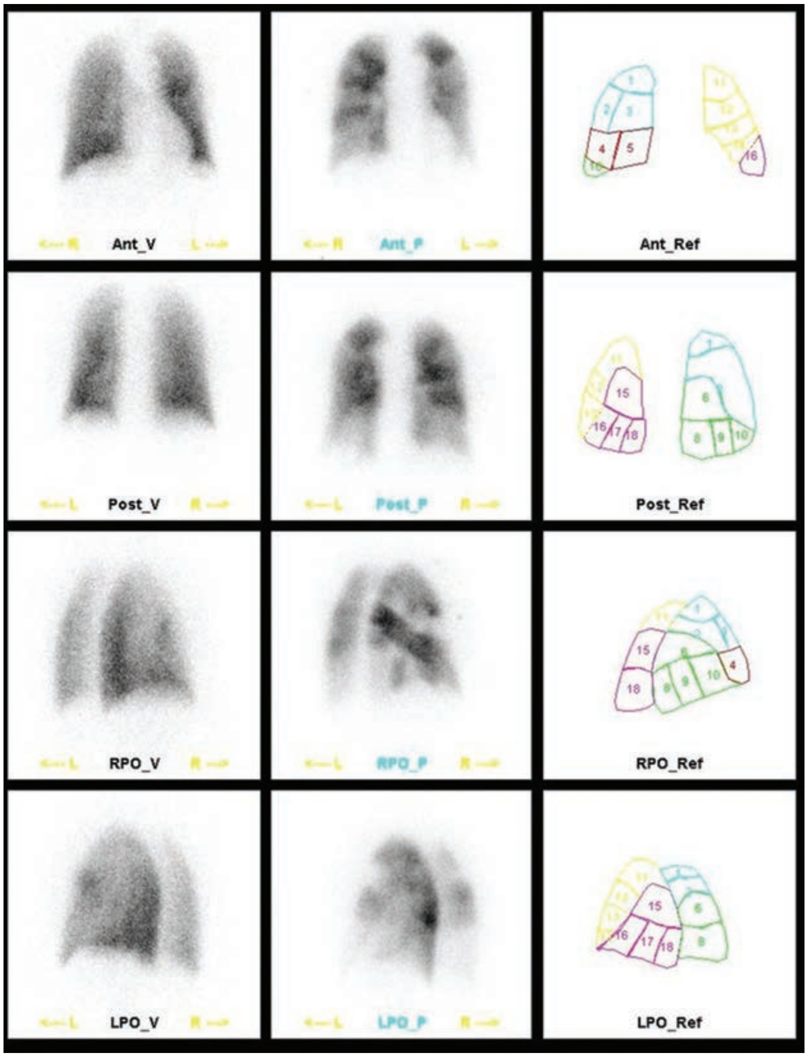

Figure 30-2 High-probability scan for pulmonary embolism. Ventilation scan using ^{99m}Tc Technegas aerosol (left column) is within normal limits. Perfusion scan using ^{99m}Tc MAA (middle column) shows large segmental defects in both lungs. This combination of findings *(mismatch)* is consistent with pulmonary embolism.

■ Perfusion Agents and Techniques

Clinical application of perfusion lung scanning was first described in 1964, when iodine 131–labeled macroaggregates of albumin were utilized in the evaluation of pulmonary perfusion.[4] Currently, the agent of choice in clinical practice is technetium 99m–labeled macroaggregated albumin (^{99m}Tc MAA) because of its availability, short residence time in the lungs, and relatively low cost.[7,8] The distribution of radiolabeled particles in the lungs is proportional to regional pulmonary blood flow at the time of injection. These particles should be injected intravenously while the patient is supine to limit the effect of gravity on regional pulmonary arterial blood.[9]

Following the administration of ^{99m}Tc MAA, particles mix uniformly with venous blood flowing to the heart; MAA particles range in size from 10 to 100 μm and lodge in precapillary arterioles and pulmonary capillaries of the lungs (usual caliber <15 μm), obstructing <0.1% of their total number. The usual administered dose of radioactivity is 40–150 MBq (1 to 4 mCi) in adults, typically 200,000 to 700,000 particles.

The blockage of pulmonary precapillary arterioles by ^{99m}Tc MAA is transient; the biologic half-life in the lung ranges between 2 and 8 h. The physical half-life of ^{99m}Tc is 6 h. The MAA particles are cleared by enzymatic hydrolysis forming smaller particles, which are phagocytized by reticuloendothelial cells. The usual administered activity and number of particles should be reduced in pediatric patients, pregnancy, (suspected) pulmonary hypertension, poor respiratory function, prior pneumonectomy or single lung transplant (to reduce blockage), and (suspected) right-to-left shunt (to avoid systemic emboli).[5,7,8,10,11]

■ Ventilation Agents and Techniques

Historically, ^{133}Xe was the agent used to determine regional ventilation.[1,12] ^{133}Xe has a physical half-life of 5.24 days and a low gamma energy emission of 81 keV compared with 140 keV of ^{99m}Tc; furthermore, the three-phase examination is somewhat laborious. Thus, other tracers, such as ^{81m}Kr and the ^{99m}Tc–labeled aerosols, have been gradually replacing it.[7,8,10]

^{81m}Kr is a noble gas that has a very short physical half-life (13 s), which allows generation of images of the lungs in multiple projections to match the perfusion images. ^{81m}Kr is produced from a rubidium 81 generator. The parent radionuclide has a physical half-life of 4.7 h, which limits the useful lifetime of the generator to only 1 day, so daily delivery is necessary at a relatively high cost. On the other hand, imaging with ^{81m}Kr may be performed simultaneously with the perfusion scan due to higher energy than ^{99m}Tc; due to a very low radiation exposure, it is particularly suitable for children.

A radioaerosol is produced by nebulizing radiopharmaceuticals into a fine mist, which is subsequently inhaled. Two ^{99m}Tc-labeled aerosols are widely available: ^{99m}Tc DTPA (diethylene triamine penta-acetic acid) and ^{99m}Tc Technegas. The advantages of ^{99m}Tc aerosols are that they are readily available, are inexpensive, and have a 140-keV energy photopeak, which is ideal for gamma camera imaging. ^{99m}Tc-labeled radioaerosols have particles between 0.5 and 2 μm in size and are produced by utilizing commercially available nebulizers.[13] The patient generally breathes from the nebulizer (with oxygen at 8 to 10 L/min) for 3 to 5 min or until 37 MBq (1 mCi) of radioactivity is deposited in the lungs. Only 2% to 10% of administered radioactivity goes to the lungs. The regional distribution of radioactivity in the lungs is proportional to local ventilation.

^{99m}Tc-labeled radioaerosol studies are generally performed before perfusion imaging. Although less desirable, the ventilation study can be performed following the perfusion scan, but the dose placed in the nebulizer should be increased to at least 1665 MBq (45 mCi) instead of the usual 1110 MBq (30 mCi) in order to overwhelm the activity present in the lungs from ^{99m}Tc MAA. Ventilation studies using ^{99m}Tc-labeled radioaerosols require some patient cooperation but can be performed at the bedside and on patients who are on ventilators. Disadvantages of ^{99m}Tc-labeled radioaerosols include the central deposition of radioactivity in patients with chronic obstructive pulmonary disease (COPD) or airway obstruction; use of ^{99m}Tc Technegas has significantly improved this deficiency.[7,8,10]

One limitation of ^{99m}Tc DTPA is its relatively rapid absorption across the pulmonary capillaries into the blood in the presence of inflammation, including that caused by smoking. (The typical ^{99m}Tc DTPA aerosol biologic half-life is about 80 min compared with ~20 to 30 min in smokers.) However, since ^{99m}Tc DTPA aerosol is cleared from the alveoli by transepithelial diffusion, the clearance rate may be used as an index of alveolar epithelial membrane integrity.[7]

LUNG SCANNING IN THE DIAGNOSIS OF ACUTE PULMONARY EMBOLISM

Pulmonary embolism (PE) is a common and potentially fatal disorder for which treatment is highly effective in decreasing mortality and morbidity if initiated soon after the event. The accurate and expeditious diagnosis of acute PE can be difficult because of the nonspecificity of clinical, laboratory, and radiographic findings.[14] Despite diagnostic advances, delays in diagnosis of PE are still common and represent an important clinical issue.[15]

Venous thromboembolism and PE are no longer considered a one-time only event, as they have a high recurrence and mortality rate.[16] Although the incidence of PE has increased over the past two decades, the overall mortality rate from PE has decreased substantially, which has been attributed to more effective therapy and better adherence to guidelines. However, trends toward overdiagnosis also have been reported, which may contribute to falsely lowering the case fatality rate by inflating the population with alleged PE.[17] Although prompt anticoagulation therapy has remained the cornerstone of PE treatment, as it is effective and reduces mortality, it is not without risks, specifically hemorrhagic complications. Therefore, accurate diagnosis of PE is essential, not only to prevent death from recurrent embolism, but also to avoid complications related to unnecessary anticoagulant therapy.

During the past half century various imaging modalities have come and gone, and the modality of choice remains controversial; however, the choice in contemporary clinical practice has been narrowed to radioisotope-based $\dot{V}/\dot{Q}$ scan and pulmonary CT-based angiography (CTA).[5,17]

The first major study that utilized perfusion lung scanning as a screening test for the diagnosis of PE was the Urokinase Pulmonary Embolism Trial (UPET).[18] Despite suboptimal radiopharmaceutical and imaging equipment, this study established the potential of perfusion lung scanning in screening for PE and assessing restoration of pulmonary blood flow. Approximately 75% to 80% of perfusion defects resolved by 3 months; the remainder persisted to some extent after 1 year, indicating that most patients either completely lyse the thrombi or partly recanalize the pulmonary artery clots. This finding is corroborated by clinical experience and may prompt follow-up scans after 6 to 12 months to obtain a new baseline in patients with persisting risk factors for PE recurrence.[5]

■ Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) Study

Subsequent studies acknowledged the need for supplemental ventilation images and the added value of combined $\dot{V}/\dot{Q}$ scans, and much work was invested in establishing the best possible interpretation criteria. To date, the most comprehensive prospective investigation addressing the role of ventilation–perfusion scanning in the diagnosis of PE remains the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study. This multi-institutional study was designed to evaluate the efficacy of various conventional methods for diagnosing acute PE. In particular, PIOPED focused on the sensitivity and specificity of planar $\dot{V}/\dot{Q}$ scans in the diagnosis of acute PE.

Although the clinical diagnosis of PE is not definitive, results from PIOPED emphasize the importance of incorporating clinical assessment in evaluating patients suspected of having acute PE. As expected, combining clinical assessment with lung scan interpretation improves diagnostic accuracy of the imaging technique. Of patients with PE in PIOPED, 92% had at least one of the following risk factors: immobilization and recent surgery (two most common risks), underlying malignancy, history of DVT or PE, estrogen use, and pre-existing cardiac disease. Of patients diagnosed with PE, more than 90% had dyspnea, tachycardia, or pleuritic chest pain. Similarly, although chest radiographic findings alone are not sensitive or specific for PE, they are essential for diagnosing conditions that can mimic PE clinically. The most common radiographic finding in patients with PE was atelectasis and/or parenchymal opacity. Furthermore, chest radiographic findings heavily influence the criteria utilized for estimating the probability of PE based on lung scan patterns. For example, in patients with COPD, the sensitivity of a high-probability $\dot{V}/\dot{Q}$ scan is significantly lower than in patients with no cardiopulmonary disease. The worse the underlying cardiopulmonary disease, the higher the likelihood of the $\dot{V}/\dot{Q}$ scan to be of intermediate probability. Intermediate probability occurred in 60% of patients with COPD in PIOPED, compared with only 13% of patients with normal chest x-ray.[19] The sensitivity, specificity, and positive predictive value from PIOPED of ventilation–perfusion lung scans in detecting acute PE are presented in Table 30-1.

TABLE 30-1 Sensitivity, Specificity, and Positive Predictive Value of Lung Scans in Detecting Pulmonary Embolism in Patients Enrolled in PIOPED

Lung Scan Interpretation (Probability)	Sensitivity	Specificity	Positive Predictive Value
High	40%	98%	87%
High, intermediate	82%	64%	49%
High, intermediate, low	98%	12%	32%

All patients enrolled in PIOPED were to undergo $\dot{V}/\dot{Q}$ scan and pulmonary arteriogram. However, a large number of patients with low probability or normal $\dot{V}/\dot{Q}$ scan did not undergo pulmonary arteriogram to avoid additional risks. Therefore, there was a selection bias toward patients with intermediate or high probability for PE, leading to an overestimation of the sensitivity, but underestimation of the specificity, of $\dot{V}/\dot{Q}$ scan. In an analysis of the angiography results in PIOPED, PE occurred more frequently on the right than on the left, and more commonly in the lower lung zones.

One of the limitations of $\dot{V}/\dot{Q}$ scan in PIOPED was the interobserver variability in scan interpretation. As expected, agreement among readers was excellent for normal, high-probability, and very low-probability $\dot{V}/\dot{Q}$ scan (92%–95%), but it was not as good for intermediate and low probability.[19] Use of anatomic lung segment reference charts has been shown to reduce interobserver disagreement when interpreting scans. Other interpretative pitfalls include false-negative and false-positive readings. False-negative interpretations (i.e., low-probability read with PE present) do occur, and patients who have a recent history of immobilization (bed rest for 3 days), recent surgery, trauma to the lower extremities, or central venous instrumentation are particularly at risk. In patients with low- or very low-probability scans who have none of the aforementioned risk factors, the prevalence of PE was only 4.5%. Conversely, in patients with low- or very low-probability scans and one or more of the risk factors, the prevalence of PE was 12% and 21%, respectively (Table 30-2). Patients with false-negative lung scans tend to have nonocclusive subsegmental thrombi and a low pulmonary clot burden. The prognostic value of a low-probability scan is excellent, particularly in patients with a low clinical pretest likelihood of disease or negative lower leg ultrasound.[20]

The most common cause of $\dot{V}/\dot{Q}$ mismatch in patients who do not have acute PE is chronic or unresolved PE. Other causes include compression of the pulmonary vasculature (e.g., from mass lesions, lymphadenopathy, or mediastinal fibrosis), vessel wall abnormalities (e.g., pulmonary artery tumors or vasculitis), nonthromboembolic

TABLE 30-2 Risk Factors and Prevalence of Pulmonary Embolism in Patients with Low-Probability and Very Low-Probability Lung Scans Enrolled in PIOPED

	Patients with 0 Risk Factors (%)[a]	Patients with 1 Risk Factor (%)[a]	Patients with ≥2 Risk Factors (%)[a]	Total
PE positive	14 (2.2%)	19 (2.9%)	37 (5.7%)	70
PE negative	301 (46.4%)	136 (21.0%)	142 (21.9%)	579
Prevalence of PE	4.5%	12.2%	20.7%	10.8%

[a] *Risk factors include immobilization, trauma to lower extremities, surgery, and central venous instrumentation within 3 months of enrollment.*

intraluminal obstruction (e.g., tumor emboli or foreign body emboli), and congenital vascular abnormalities (e.g., pulmonary artery agenesis or hypoplasia). In patients who have unilateral V̇/Q̇ mismatch (hypoperfusion or absent perfusion) within an entire lung or in multiple contiguous segments and normal perfusion in the contralateral lung, extrinsic compression of the pulmonary vasculature, congenital abnormalities, or proximal PE should be considered. Patients with a suspected false-positive scan or unilateral V̇/Q̇ mismatch often require further imaging using CTA, even though emboli are frequently multiple (in 90%) and bilateral (in 85% of cases), and unilateral decreased/absent perfusion to one lung is uncommonly the result of pulmonary embolism.

Shortly after the PIOPED study, helical CTA was introduced.[21] This led to PIOPED II, which is the largest multicenter, prospective, outcome-based study to date that was designed to assess the accuracy of CTA in the evaluation of acute PE in comparison with composite reference standard.[22] In PIOPED II, for the detection of acute PE, CTA had a sensitivity, specificity, PPV, and NPV of 83%, 96%, 86%, and 95%, respectively.[22] The results of PIOPED II suggested that the predictive value of CTA is highly concordant with the pretest clinical probability of PE using Wells' criteria, but highly dependent of vascular segment involved.[23]

The PPV of PE with a positive CTA was 97% for main or lobar artery, 68% for segmental vessel, and 25% for subsegmental branch. The probability of false-negative chest CTA is minimal in large PE, but false-negative findings may occur in the small group of patients with PE limited to subsegmental arteries. PPV of PE in patients with positive CTA and high, intermediate, or low clinical probability was 96%, 92%, and 58%, respectively. NPV of PE in patients with negative CTA and low, intermediate, or high clinical probability was 96%, 89%, 60%, respectively. The limitations of this study included use of 4- to 16-slice multidetector CT devices (mostly 4), and application of a noninvasive diagnostic test as the reference standard.

In contrast to original PIOPED population, which included 68% of inpatients, PIOPED II included only 11% inpatients. Inpatients are more likely to have abnormalities on chest radiographs, which would potentially interfere with optimal V̇/Q̇ scan reading.[24] The accuracy of CTA would also be lower if patients with inconclusive interpretations of CT (51 patients or 6%) were included, giving an overall sensitivity and specificity of 78% and 90%, respectively. The overall PPV of 86% and NPV of 95% are values comparable to V̇/Q̇ results. The combination of CT venography with CTA increased the sensitivity to detect PE to 90% from 83% when using CTA alone. CT venography, however, showed similar results in diagnosing or excluding DVT as compression ultrasound.[25]

Finally, PIOPED III, a multicenter collaborative investigative trial, was designed to determine the diagnostic accuracy of gadolinium-enhanced magnetic resonance angiography (Gd-MRA) of the pulmonary arteries in combination with magnetic resonance venography (MRV) of the veins of the thighs in patients with clinically suspected acute PE. In PIOPED III, most centers had difficulty in obtaining adequate-quality MR pulmonary angiograms, which were inadequate in 25% of patients.[26] This varied from 11% to 52% between centers. Adequate-quality images were obtained in 91% in main or lobar pulmonary arteries, 87% in segmental pulmonary arteries, and 73% in subsegmental branches. Technically adequate MRA had a sensitivity of 78% and specificity of 99%. This led the PIOPED III investigators to conclude that MRA should be considered only at centers that routinely perform it well, and for patients who have contraindications to other standard tests.

V̇/Q̇ Scan Interpretation and Modifications to Original PIOPED Criteria

Several diagnostic schemes have been suggested for interpretation of V̇/Q̇ scans. The original PIOPED criteria were developed to interpret the scans generated from the study based upon experience gathered over the preceding decade.

A PE is characterized by V̇/Q̇ mismatch, which is an area of normal ventilation corresponding to a segmental wedge-shaped area of decreased or absent perfusion extending to the pleural surface. The segmental defect should correspond to vascular anatomy. The probabilistic, categoric interpretation scheme resulted in either high sensitivity or high specificity, but never both in a dichotomous setting; if only high-probability scans were considered positive for PE (and all other categories were considered negative), sensitivity was only 41%, but specificity 96%; conversely, if only normal scans were considered negative for PE (and all other considered positive), sensitivity reached 97%, but with specificity of only 10%.

Due to the high number (44%) of intermediate-probability V̇/Q̇ scans in PIOPED[27] and interobserver disagreements, several revisions and modifications have been made to the original criteria. Some of the V̇/Q̇ scan interpretation nuances include the "Gestalt interpretation," which is based on an experienced nuclear medicine physician's subjective estimate of the likelihood of PE (without using specific interpretation criteria). This interpretation takes into account various published lung image interpretation algorithms, clinical data, ancillary findings, and pathophysiologic features of PE, which are integrated with the individual case presentation. The Gestalt interpretation has been shown to correlate well with the fraction of patients with angiographic evidence of PE in the PIOPED study, with good to excellent intra- and interobserver variability.[28,29] Thus, experienced readers (such as the PIOPED investigators) can provide an accurate estimate of the probability of PE based on clinical, radiographic, and scintigraphic findings.

Other nuances include the so-called "triple match," that is, matching perfusion, ventilation, and chest x-ray abnormalities. Based on the PIOPED data, the prevalence of PE in the presence of a triple match varies depending on the location, that is, 11% to 12% in the upper or middle lung (low probability for PE), but 33% in the lower lung zones and, therefore, intermediate probability.[30] Another nuance to the intermediate category is single defects; for example, a single moderate-sized V̇/Q̇ mismatch was found to harbor PE in 36% of cases,[31] whereas a single matched V̇/Q̇ defect of any size corresponded with PE in 26% of cases. Thus, both should be classified as intermediate probability.[31]

The limitations of the original PIOPED criteria led the investigators to revise the original interpretation criteria for easier application and better integration of clinical pretest probability of PE. Modifications to original PIOPED interpretation criteria were used in the PIOPED II trial[32] (Table 30-3), which decreased the number of intermediate scan readings (73.5% of patients had V̇/Q̇ scans with

TABLE 30-3 Revised PIOPED Criteria for Interpretation of Lung Scans[a]

High probability (≥80%)	
	≥2 Large segmental perfusion defects (>75% of a segment) without corresponding ventilation or radiographic abnormalities
	1 Large segmental perfusion defect and ≥2 moderate segmental perfusion defects (25%–75% of a segment) without corresponding ventilation or radiographic abnormalities
	≥4 Moderate segmental perfusion defects without corresponding ventilation or radiographic abnormalities
Intermediate probability (20%–79%)	
	1 Moderate to <2 large segmental perfusion defects without corresponding ventilation or radiographic abnormalities
	Corresponding ventilation-perfusion defects and radiographic parenchymal opacity in lower lung zone
	Single, moderate, matched ventilation-perfusion defects with normal radiographic findings
	Corresponding ventilation-perfusion defects and small pleural effusion
	Difficult to categorize as normal, low, or high probability
Low probability (<19%)	
	Multiple matched ventilation-perfusion defects, regardless of size, with normal radiographic findings
	Corresponding ventilation-perfusion defects and radiographic parenchymal opacity in upper or middle lung zone
	Corresponding ventilation-perfusion defects and large pleural effusion
	Any perfusion defects with substantially larger radiographic abnormality
	Defects surrounded by normally perfused lung (stripe sign)
	>3 Small segmental perfusion defects (<25% of a segment) with a normal radiograph
	Nonsegmental perfusion defects (cardiomegaly, aortic impression, enlarged hila)
Very low probability	
	≥3 Small segmental perfusion defects (<25% of a segment) with a normal radiograph
Normal probability	
	No perfusion defects; perfusion outlines the shape of the lung seen on the radiograph

[a] *Criteria generated after completion of prospective study.*

definitive interpretation) and provided a more accurate assessment of angiographically proven PE than the original criteria (increased sensitivity of 83% compared with the original criteria, with virtually unchanged specificity of 96%).

In another attempt to avoid the clinically problematic intermediate probability category, which in some series accounted for half of the results and contributed to the reputation of planar $\dot{V}/\dot{Q}$ scan as an equivocal examination, the Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis (PISA-PED)[33] introduced criteria (Table 30-4) for interpretation of perfusion-only lung scan. Instead of size, number, and match or mismatch, criteria were based on shape and anatomy. Thus, PE was considered present when there was one or more wedge-shaped perfusion defects and absent when there was normal perfusion, nonsegmental perfusion defects smaller than radiographic lesions, or non-wedge-shaped defects. All other findings were called nondiagnostic. When the PISA-PED study[33] utilized perfusion scanning alone in conjunction with the chest radiograph, the sensitivity and specificity of scintigraphy were 92% and 87%, respectively. The prevalence of PE was high (39%). When considered in conjunction with clinical assessment of the likelihood of PE (very likely, possible, or unlikely), the positive predictive value (PPV) of a perfusion scan was 99%; the combination of a near-normal or abnormal perfusion scan without segmental defects and low clinical likelihood of PE had a negative predictive value (NPV) of 97%. Using standardized clinical assessment and perfusion lung scanning, the authors were able to accurately diagnose or exclude PE (PPV, 96%; NPV, 98%). CT angiography was required in only a minority of cases having discordant clinical and scintigraphic findings. Thus, although results from the PISA-PED study have never been reproduced and relied heavily on skilled interpretations of chest x-ray, they at least suggest that perfusion-only images may be a viable option in patients incapable of completing ventilation images.[5]

Along the same lines, modified PIOPED II criteria (Table 30-4) were established in 2008, diagnosing PE when the equivalent of ≥2 large segmental perfusion scan-chest radiograph mismatches were observed. (Findings could include 1 large and 2 moderate segmental mismatches or 4 moderate segmental mismatches.)[34] PE was considered absent when there was normal or near-normal perfusion, and the perfusion defect was nonsegmental and non-wedge-shaped.[34] All other scans were called nondiagnostic.

When perfusion scans obtained in PIOPED II were reinterpreted using composite reference standard (all PIOPED II patients were eligible for this study if they had a CTA or digital subtraction angiography [DSA] diagnosis, an interpretable perfusion scan and chest radiographs, and a Wells' score), investigators found only 21% of patients with nondiagnostic results using revised PIOPED II criteria.[34] Only 11% patients had nondiagnostic perfusion scans among the 72% of patients with normal or near normal chest radiograph. The prevalence of PE in the sample was 19%. Using the modified PIOPED II criteria, and after excluding the nondiagnostic perfusion scans, the sensitivity of "PE present" reached 85%, and the specificity of "PE absent" was 93%. When using PISA-PED criteria, none had nondiagnostic perfusion scans; the sensitivity of a "PE present" scan was 80%, and the specificity of "PE absent" scan was 97%. Based on these findings, it was postulated that perfusion scintigraphy combined with chest radiography can provide diagnostic accuracy similar to CT angiography at a lower cost and, more importantly, at a lower radiation dose.[34]

Older data from prospective and large studies have reported outcome-based results of $\dot{V}/\dot{Q}$ scans combined with clinical assessment and noninvasive leg testing.[23,35] In patients with suspected PE with nonhigh probability or nondiagnostic $\dot{V}/\dot{Q}$ scan, normal cardiorespiratory reserve, and negative serial noninvasive leg tests for proximal venous thrombosis (as determined by serial impedance plethysmography), PE at 3-month follow-up occurred in only 0.6% of cases while the patients were not on anticoagulation.[35] Among patients with suspected PE but a low-probability clinical assessment and negative serial noninvasive leg tests, as well as a nondiagnostic $\dot{V}/\dot{Q}$ scan, PE at 3-month follow-up occurred in 0.5% of patients.[23] When the probability for clinical assessment was intermediate, PE occurred in only 0.4% of patients.[23] These studies determined that anticoagulation could be safely withheld in patients with adequate cardiorespiratory reserve who did not have high-probability ventilation–perfusion scans or proximal venous thrombosis, since the incidence of recurrent PE is very low. Unfortunately, the criteria used in these studies to categorize the probability of PE (normal, nondiagnostic, or high) were different than those used in the PIOPED study, and direct comparison is not possible.

■ Imaging Protocols for the Evaluation of Pulmonary Embolism

All of the aforementioned interpretation criteria are based on planar images, that is, static, two-dimensional images in various projections. A routine planar perfusion scan should include at least six

TABLE 30-4 Modified PIOPED II and PISA-PED Criteria for Interpretation of Perfusion Scans

	Modified PIOPED II	PISA-PED
PE present	• High probability (≥2 segments of perfusion scan—chest radiograph mismatch. May be ≥2 large segmental mismatches, or 1 large and 2 moderate mismatches, or 4 moderate segmental mismatches)	• ≥1 Wedge-shaped perfusion defects
PE absent	• Normal perfusion • Near normal • Contour defect (caused by enlarged heart, mediastinum, or diaphragm) • Perfusion defect, not wedge-shaped	• Normal perfusion • Very low probability • Nonsegmental lesion (e.g., prominent hilum, cardiomegaly, elevated diaphragm, linear atelectasis, costophrenic angle effusion with no other perfusion defect in either lung) • Perfusion defect smaller than radiographic lesion • 1–3 Small segmental defects • Solitary CXR-Q matched defect in the mid or upper lung zone confined to a single segment • Stripe sign present around the perfusion defect (best tangential view) • Pleural effusion ≥1/3 the pleural cavity with no other perfusion defect in either lung
Not diagnostic	• Cannot classify as PE-positive or PE-negative	• All other findings

Modified with permission from Sostman HD, Miniati M, Gottschalk A, Matta F, Stein PD, Pistolesi M. Sensitivity and specificity of perfusion scintigraphy combined with chest radiography for acute pulmonary embolism in PIOPED II. J Nucl Med. 2008;49(11):1741–1748.

views of the lungs: anterior, posterior, right and left lateral, and right and left posterior oblique views, using a large-field-of-view high-resolution gamma camera. Right and left anterior oblique views may be helpful in selected cases. Ventilation images are obtained in multiple projections, which correspond to those obtained during the perfusion study. However, despite imaging in multiple projections, two-dimensional images of three-dimensional organs may underestimate abnormalities. For instance, a solitary segmental perfusion defect within the medial basal segment of the right lower lobe is completely surrounded by normal lung. Consequently, a perfusion defect in this segment will not be detected on planar perfusion imaging. Also, interpretation may be equivocal, as some anatomic structures may appear suspicious on planar images due to overlapping activity or artefact (e.g., interlobar fissures).

Thus, in recent years the use of single-photon emission computed tomography (SPECT) imaging has increased generally.[36] Technologic advances have also been made with SPECT in PE-imaging, including use of new radiopharmaceuticals like ^{99m}Tc Technegas,[37] which is currently not available in the United States (Figs. 30-3 and 30-4). Total acquisition time for the SPECT $\dot{V}/\dot{Q}$ exam is 20 to 30 min for a dual-headed camera; it generally increases specificity and reduces the number of equivocal results.[7,10,38]

SPECT has several advantages over planar imaging, including higher contrast resolution and avoidance of overlapping small perfusion defects by normal tissue, resulting in better sensitivity and/or specificity with SPECT compared to planar images. In a pivotal proof-of-concept animal study using artificial emboli, the sensitivity of planar $\dot{V}/\dot{Q}$ lung scan was 67% compared with 93% for SPECT.[39] Later clinical studies found similar results, that is, more and better delineated mismatched defects, better quantification, and less interobserver variation.[40] One study found 53% more mismatched regions with SPECT, and another noted an increase in specificity from 78% to 96% at similar sensitivities. Finally, one study found increases in sensitivity (76% to 97%) and specificity (85% to 91%) with SPECT compared to planar images.[7]

A recent meta-analysis summarized the current literature on SPECT $\dot{V}/\dot{Q}$ scan, including the results from a few other

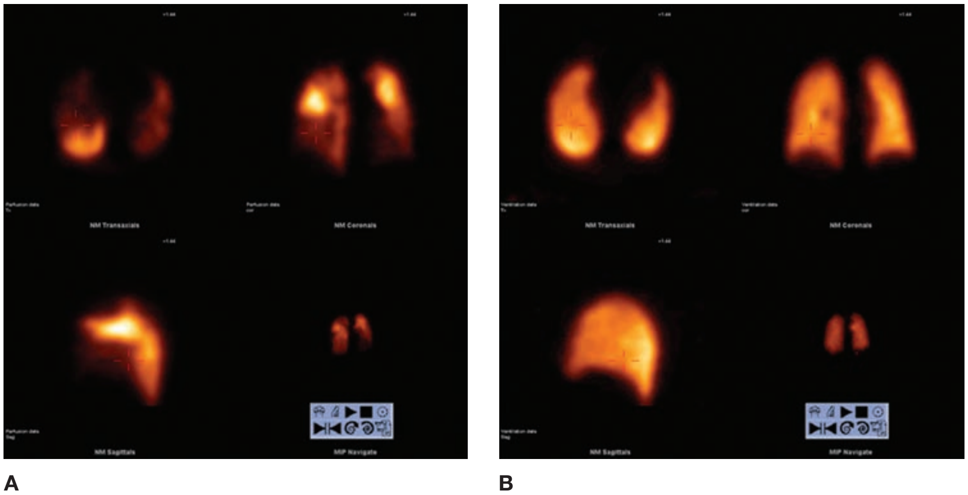

Figure 30-3 High-probability $\dot{V}/\dot{Q}$ SPECT scan for pulmonary embolism. Ventilation scan using ^{99m}Tc Technegas aerosol in transaxial, sagittal, and coronal views (**B**) is within normal limits. Perfusion scan using ^{99m}Tc MAA in transaxial, sagittal, and coronal views (**A**) shows large segmental defects in both lungs. This combination of findings *(mismatch)* is consistent with pulmonary embolism.

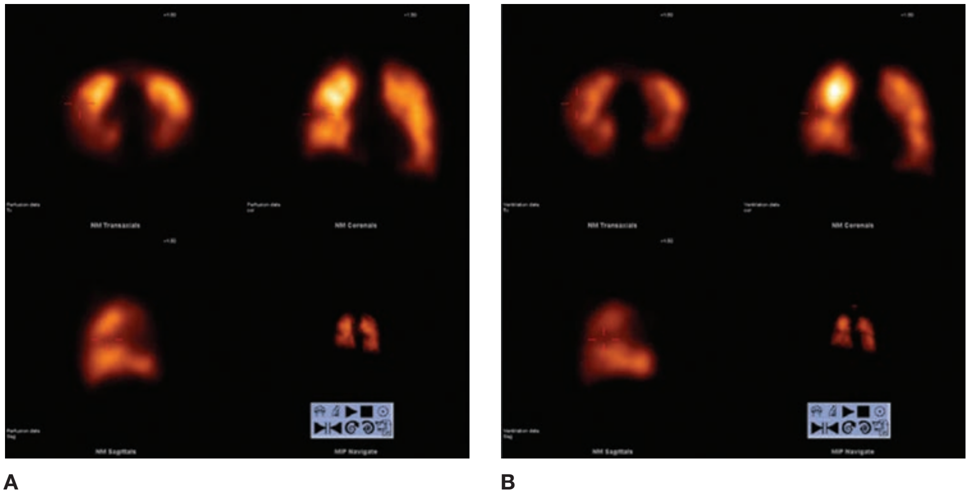
FIGURE 30-4 V̇/Q̇ SPECT scan for pulmonary embolism. Ventilation scan using ^{99m}Tc Technegas aerosol in transaxial, sagittal, and coronal views (**B**) and perfusion scan using ^{99m}Tc MAA in transaxial, sagittal, and coronal views (**A**) show *matched* defects.



meta-analyses. Although the data were relatively sparse, the sensitivity of V̇/Q̇ SPECT was generally better than CTA with comparable specificity (Table 30-5).[38] Some investigators have also suggested the use of combined SPECT V̇/Q̇ scan and low-dose CT scan to further improve accuracy in diagnosing PE and to help provide a differential diagnosis in those patients with V̇/Q̇ scan results negative for PE.[41] The interpretation criteria, however, for SPECT V̇/Q̇ scan are not yet clearly defined or universal. It seems that the classic PIOPED or PISA-PED criteria cannot simply be transposed from planar to SPECT V̇/Q̇ scanning.[38] Instead, much simpler criteria (Table 30-6) have been proposed and propagated in the latest guidelines. Perhaps the most important advantage of SPECT V̇/Q̇ scans is a significant reduction in equivocal scans; that is, most investigators report a ≤3% nondiagnostic rate.[10,38,42] Despite the many advantages of SPECT, the substitution of planar V̇/Q̇ by SPECT V̇/Q̇ scan has been considered controversial.[24,43,44] However, according to the latest guidelines on V̇/Q̇ scans from the European Association of Nuclear Medicine, SPECT or SPECT/CT is now considered the method of choice.[10]

Interest has arisen in “positive” imaging based on antibody fragments and radiolabeled peptides directed against components of thromboemboli and glycoprotein IIb/IIIa receptors on the surface of activated platelets.[45] ^{99m}Tc-labeled apcitide is a synthetic peptide that binds with a high affinity and specificity to the glycoprotein IIb/IIIa receptor on the membrane of activated platelets.[46] The main advantage of the agent is its ability to distinguish between acute and chronic DVT.

Several ^{99m}Tc-labeled peptides directed against activated platelets are currently under investigation in the evaluation of patients with suspected pulmonary embolism. Radiolabeled peptide imaging has the potential to serve as a single, comprehensive modality in the evaluation of patients with venous thromboembolism.

TABLE 30-5 Comparative Diagnostic Values of CT Angiography and V̇/Q̇ SPECT

Modality	Sensitivity	Specificity	PPV	NPV
CT angiography	82%–88%	95%	94%	85%
V̇/Q̇ SPECT	93%–96%	93%	88%	96%

Data from Hess S, Frary EC, Gerke O, et al. State-of-the-Art Imaging in Pulmonary Embolism: Ventilation/Perfusion Single-Photon Emission Computed Tomography versus Computed Tomography Angiography—Controversies, Results, and Recommendations from a Systematic Review. Semin Thromb Hemost. 2016;42(8):833–845.

Another agent is the ^{99m}Tc-labeled anti–D-dimer (DI-80B3) monoclonal antibody Fab′ fragment that binds specifically to thromboemboli. In a small, prospective, multicenter study to investigate the sensitivity and specificity of ^{99m}Tc DI-80B3/SPECT in patients with suspected acute PE, ^{99m}Tc-DI-80B3/SPECT had a sensitivity of 76.2% and a specificity of 90.5%.[47] Several preclinical studies are underway to investigate the role of fibrin and platelet imaging for thrombus detection.[48] At the current time, most results are limited to the preclinical setting, and translation to clinical results is not warranted.

■ Recommendations for the Use of V̇/Q̇ Scan and CT Angiography in Suspected Pulmonary Embolism

Over the past decade, there have been significant technical improvements in both CTA and V̇/Q̇ scanning. However, usage of chest CTA in patients with suspected PE has increased significantly and markedly surpassed the usage of V̇/Q̇ scan.[49] Studies show equivalent outcomes-based results, and a recent meta-analysis actually found V̇/Q̇ SPECT superior to CTA.[38] However, the ready availability of CTA, particularly after regular work hours, and the bias towards anatomic, rather than functional, imaging has made CTA the favored diagnostic test for PE.[17]

In a large, prospective, randomized study with high pretest probability and/or positive D-dimer levels, the false-negative rates for V̇/Q̇ scan and CTA were very close at 1% and 0.4%, respectively.[50]

TABLE 30-6 New V̇/Q̇ SPECT Diagnostic Criteria for Pulmonary Embolism (PE)

PE	• Wedge-shaped V̇/Q̇ mismatch (≥1 segment or 2 subsegments)
No PE	• Normal perfusion pattern in keeping with the anatomic boundaries of the lungs • Only matched or reversed-mismatched V̇/Q̇ defects of any size, shape, or number • Mismatch that does not follow a lobar, segmental, or subsegmental pattern
Nondiagnostic	• Widespread V/P abnormalities not typical of specific diseases

Adapted with permission from Bajc M, Schumichen C, Gruning T, et al. EANM guideline for ventilation/perfusion single-photon emission computed tomography (SPECT) for diagnosis of pulmonary embolism and beyond. Eur J Nucl Med Mol Imaging. 2019;46(12):2429–2451.

Despite the fact that CTA in some studies detects more emboli than $\dot{V}/\dot{Q}$ scanning,[50] the risk of recurrent PE and death have not decreased during the CTA era.[51] In fact, the ability of sophisticated multidetector CT scans to detect emboli in subsegmental branches of the pulmonary arteries created a healthcare problem by encouraging clinicians to treat patients who have incidental, asymptomatic pulmonary emboli whose natural history and optimal management are currently unknown (except in cancer patients in whom these emboli carry a poor prognosis).[52,53] The scans are usually ordered in the emergency department with no particular pretest diagnosis; this may represent a double-edged sword.

Recent reports of overutilization of imaging for suspected PE is probably due to a combination of increased awareness of PE and widespread availability of advanced imaging. However, the result is a significant drop in confirmed PE diagnoses in patients undergoing a workup for suspected PE; that is, the incidence of a positive diagnosis has dropped from 50% in the 1980s to 5% at present.[54] The same may be true with SPECT $\dot{V}/\dot{Q}$ scanning, as it is not yet clear whether treating a small peripheral PE confers an outcome benefit unless patients have significant clot burden and limited cardiovascular reserve.[27]

In patients with a normal chest radiograph, the ventilation–perfusion lung scan is an effective, noninvasive initial study. However, in patients with significant chest radiographic abnormalities, CT angiography is more likely to provide a definitive diagnosis of PE or an alternative diagnosis, as well as risk assessment of PE based on the evaluation of right ventricular size and function.[55,56] Furthermore, the combination of CT angiography and CT venography has the potential to provide a single, comprehensive evaluation of patients with suspected venous thromboembolism (VTE), albeit with increased radiation exposure.

$\dot{V}/\dot{Q}$ scanning remains an important alternative to CTA in patients with contrast allergy or renal failure. On the other hand, $\dot{V}/\dot{Q}$ scanning may be the modality of choice to evaluate patients with chronic thromboembolic disease, and for follow-up of PE after therapy.[24] Additionally, concern exists regarding the high radiation exposure, particularly to the female breast, that is associated with chest CTA.[57,58] Despite dose-reduction schemes, CTA may deliver significant radiation doses of 20 mGy (2.0 rad) to the breasts of an average-sized woman;[59] in contrast, breast irradiation with $\dot{V}/\dot{Q}$ scan is approximately 0.28 to 0.9 mGy.[60]

In general, there is great concern that the increasing use of CTA may result in an increased incidence of radiation-related cancer in the future.[57] However, the potential latent carcinogenic effects of such radiation exposure at this time remain unknown. As part of the Choosing Wisely campaign initiated in 2013 by the American Board of Internal Medicine, which focused on questioning medical tests and procedures that may be unnecessary, and in some instances can cause harm, the Society of Nuclear Medicine and Molecular Imaging (SNMMI) has recommended to avoid using a CTA to diagnose PE in young women with a normal chest radiograph and to consider a $\dot{V}/\dot{Q}$ study instead.[61]

Finally, there is considerable debate about the radiation doses received by the fetus from pulmonary CTA compared with $\dot{V}/\dot{Q}$ scanning.[62] During pregnancy, when only a perfusion scan with 50 MBq of ^{99m}Tc MAA is used, the fetal absorbed dose is 0.1 to 0.2 mGy. It is estimated that a 16-slice MDCT scan gives an absorbed fetal dose of 0.24 to 0.66 mGy during the first trimester.[63] The advantages and disadvantages of CTA and $\dot{V}/\dot{Q}$ scan in the evaluation of PE are summarized in Table 30-7.

TABLE 30-7 Comparison of CTA and $\dot{V}/\dot{Q}$ Scan in the Evaluation of PE

	Advantages	Disadvantages
CTA	• Accuracy • Interobserver agreement • Provides alternative diagnosis, and risk assessment based on the evaluation of right ventricular size and function • After-hours availability • High speed in image acquisition • Suitable for unstable patients • Binary reports ("PE" or "no PE")	• Radiation exposure • Contrast allergy • Nephrotoxicity • Relative cost • Potential overdiagnosis of non–clinically relevant peripheral PE
$\dot{V}/\dot{Q}$ scan	• High NPV in low pretest probability • High PPV in high pretest probability • Low radiation • Relative cost • Serial follow-up	• Low overall specificity • Low interobserver agreement • After-hours availability • Slower speed in image acquisition • Unsuitable for unstable patients • Limited in providing alternative diagnosis • Unpopular probabilistic reports

Data from Reid JH, Coche EE, Inoue T, et al. Is the lung scan alive and well? Facts and controversies in defining the role of lung scintigraphy for the diagnosis of pulmonary embolism in the era of MDCT. Eur J Nucl Med Mol Imaging. 2009;36(3):505–521.

■ Use of $\dot{V}/\dot{Q}$ Scan in the Era of COVID-19

On February 11, 2020, the World Health Organization (WHO) gave the official name of COVID-19 for a 2019 novel coronavirus (SARS-CoV-2) that caused a global pandemic.[64] COVID-19 is caused by a highly transmittable and pathogenic viral infection that is believed to be transmitted via respiratory droplets and fomites.[64] Most people who contracted COVID-19 had mild symptoms, but the disease also caused severe illnesses and even death, especially in older people and patients with underlying medical conditions.[65]

Patients who contract COVID-19 have a high risk of PE and DVT.[66] A recent systemic review and meta-analysis found the pooled incidence rate of PE and DVT to be 16.5% and 14.8%, respectively, with more than half of PE patients lacking a DVT.[67] Due to the risk of transmission of COVID-19 to patients and staff alike, the SNMMI and European Association of Nuclear Medicine (EANM) issued warnings in March 2020 about use of lung ventilation studies with aerosolized agents.[68,69] In view of the unknown risk of transmission of COVID-19 and ability to disinfect the ventilation systems, early during the pandemic most institutions used perfusion-only studies when other imaging modalities, such as CTA, could not be obtained. Ventilation images were acquired rarely, and only if necessary, to make the diagnosis of acute PE after patients tested negative for COVID-19 using xenon (^{133}Xe) gas in the United States or krypton (^{81m}Kr) gas or ^{99m}Tc Technegas where available. Since Technegas does not release aerosolized particles, it has the potential to allow institutions to resume full $\dot{V}/\dot{Q}$ scans. Technegas is still under review by the U.S. Food and Drug Administration (FDA) as a ventilation agent.

Although there is a paucity of data supporting lung perfusions studies only,[70] it is likely that data on use of PISA-PED criteria in the era of COVID-19 will grow in the foreseeable future. This is particularly important since COVID-19 can also cause renal injuries,[71] thereby limiting use of intravenous contrast agents. Since this is a new disease, many questions remain unanswered about the best imaging modality for patients with COVID-19 suspected to have a PE.

Summary of Conclusions Regarding V̇/Q̇ Scanning

In summary, based on results from prospective and outcome-based studies, the following conclusions can be drawn regarding use of V̇/Q̇ scan and CTA in evaluating patients with suspected PE:

- Proper pretest clinical probability scoring is important, irrespective of the imaging modality used. When imaging results for either V̇/Q̇ scan or CTA are discordant with the pretest probability, the alternative test should be recommended.
- Whenever possible, SPECT or SPECT/CT V̇/Q̇ scanning should be performed instead of planar V̇/Q̇ scanning.
- Whenever possible, V̇/Q̇ scans should be interpreted as either "positive for PE," "nondiagnostic study," or "no evidence of PE."
- A normal V̇/Q̇ scan excludes the diagnosis of clinically significant PE.
- Patients with very low- or low-probability scans and a low clinical likelihood of PE have a low (<5%) prevalence of PE and generally do not require CTA or anticoagulation.
- Patients with very low- or low-probability scans, intermediate or high clinical likelihood of PE, and negative serial noninvasive venous studies of the lower extremities generally do not require anticoagulation. In selected cases, CTA is helpful in excluding PE and providing an alternative diagnosis.
- Clinically stable patients with an intermediate-probability scan require noninvasive venous studies of the legs; if negative, CTA is required for definite diagnosis of PE.
- A clinically stable patient with a high-probability scan and high clinical likelihood of PE requires treatment; no further diagnostic tests are required to confirm the diagnosis.
- Clinically stable patients with a high-probability scan and a low clinical likelihood of PE require noninvasive venous studies of the legs; if negative, CTA may be required for definitive diagnosis.
- V̇/Q̇ scanning has a high negative predictive value and should be used particularly when a low radiation dose is desirable, for example, in young females with normal chest radiograph, outpatients with low clinical probability plus normal chest radiograph, patients with high clinical probability plus normal chest radiograph, patients with prior contrast allergy, or patients with renal failure.
- To minimize radiation to the fetus in a pregnant patient, a 1- to 2-day protocol is suggested. Perfusion-only scans should be performed on day 1, using a reduced dose of ^{99m}Tc MAA. If normal, ventilation images are not required.
- V̇/Q̇ scanning is preferred over pulmonary CTA for follow-up of PE and investigating the etiology of pulmonary hypertension.
- If after-hours imaging is not available, and a clinically stable patient has a high clinical suspicion of PE, a reasonable approach includes administering a single dose of low-molecular-weight heparin and imaging the patient the next morning. This strategy may be particularly advisable for performing V̇/Q̇ scanning in young women in order to avoid the excessive breast radiation exposure associated with CTA.
- If there is a contraindication to V̇/Q̇ scanning or CTA, MRA of the pulmonary artery may be performed in centers that perform it well. Caution is advised if contraindications are present related to poor renal function, as nephrogenic systemic fibrosis/nephrogenic fibrosing dermopathy occurs rarely after gadolinium-containing contrast material.[72,73]
- In regions where COVID-19 numbers are high or increasing, or if there is inadequate testing, it may be appropriate to perform perfusion-only studies. If a ventilation study is still necessary to help diagnose airway and vascular diseases, it should be performed following local and institutional protective protocols for aerosol-generating procedures. A perfusion-only study is unlikely to benefit patients with COVID-19 infection who have an abnormal chest x-ray, as ^{99m}Tc MAA distribution will probably be abnormal. The use of pretest probability for PE assessment and D-dimer level measurement are paramount in these scenarios.

EVALUATION OF CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Chronic thromboembolic pulmonary hypertension (CTEPH) is defined as the persistence of pulmonary hypertension (defined as a mean pulmonary artery pressure >25 mm Hg) after a single or recurrent PE. CTEPH is a serious underdiagnosed disease and the only cause of pulmonary hypertension that can be potentially cured by pulmonary endarterectomy (PEA). Estimates are that between 0.5% and 3.8% of patients eventually develop CTEPH after an acute PE; CTEPH occurs in up to 10% of those with a history of recurrent PE.[74,75]

It is not entirely clear why some patients with a history of acute PE go on to develop CTEPH. The risk of developing CTEPH increases in patients with a history of prior PE, presentation at a younger age, larger perfusion defects, and idiopathic pulmonary embolism at presentation.[74] Diagnosis is the key to survival in CTEPH, as without appropriate treatment, long-term prognosis is poor. There is a positive correlation between increased mean pulmonary artery pressure and mortality.[76] Unfortunately, the clinical features, laboratory studies, chest radiograph, electrocardiogram, and echocardiogram are often unreliable in distinguishing CTEPH from primary and nonthromboembolic secondary pulmonary hypertension. In most centers, conventional pulmonary angiography remains the gold standard imaging study to confirm the diagnosis of CTEPH and to determine whether surgical intervention is indicated; chest CTA and MRA provide complementary information if needed.

V̇/Q̇ scanning is a safe, noninvasive technique that facilitates selection of patients with pulmonary hypertension for pulmonary angiography to confirm the diagnosis of chronic PE. V̇/Q̇ scanning remains one of the most important diagnostic tests to help distinguish CTEPH from other forms of pulmonary hypertension. In a retrospective analysis, V̇/Q̇ scanning had a sensitivity of 97.4% for the detection of chronic thromboembolic disease, while CT angiography was only 51% sensitive.[77]

Patients with CTEPH usually have at least one, and often several, segmental or larger, mismatched perfusion defects.[78] In order to prevent potential adverse hemodynamic effects when performing V̇/Q̇ scans in patients with pulmonary hypertension, the number of ^{99m}Tc MAA particles administered should be reduced. V̇/Q̇ scanning may underestimate the magnitude of central vascular occlusion by chronic emboli, as determined at conventional pulmonary angiography and/or thromboendarterectomy.[79]

Most patients with primary or secondary nonthromboembolic pulmonary hypertension have low-probability scans. The distribution of ^{99m}Tc MAA particles within the lungs is diffuse and nonhomogeneous. Patients with CTEPH rarely, if ever, have normal or very low-probability scans. Thus, a low-probability ventilation-perfusion scan effectively excludes chronic thromboembolism as the cause of pulmonary hypertension.

Even though SPECT is more sensitive than planar perfusion lung scanning for identifying obstructed segments in CTEPH, it still underrepresents the true extent of the vascular occlusions in CTEPH.[80] Although CTA and MRA may provide complementary information, they often miss the eccentric lesions of CTEPH. Any patient with unexplained pulmonary hypertension should be evaluated for the presence of CTEPH, and a V̇/Q̇ scan remains the recommended screening method of choice.[81]

QUANTITATIVE VENTILATION–PERFUSION LUNG SCANNING

In patients undergoing pulmonary resection, bronchoscopic lung volume reduction surgery, or lung transplantation, quantitative ventilation–perfusion lung scanning is a useful method for determining regional lung function and predicting postoperative pulmonary function.[82–85] Currently, the presurgical assessment to predict response to lung volume reduction surgery (LVRS) in patients with emphysema is mainly performed using chest CT scan, which provides an anatomic diagnosis of emphysema, delineates its extent and distribution, and detects any other incidental findings that may represent a contraindication to the procedure.[86,87]

$\dot{V}/\dot{Q}$ scanning can provide additional and important information concerning the heterogeneity and distribution of the functional disruption caused by emphysema; patients with advanced upper lobe–predominant emphysema derive the most benefit from LVRS.[83,87,88] Rectangular regions of interest over the anterior and posterior scintigraphic images of each lung are divided into upper, middle, and lower zones of equal craniocaudal height, and the geometric mean for a given zone is obtained and presented as the percent perfusion to that zone.[89]

In patients being considered for lung cancer surgical resection, $\dot{V}/\dot{Q}$ scan can predict postoperative pulmonary function and assess the risk of surgery for patients with borderline pulmonary function.[90] The predicted postoperative forced expiratory volume in 1 s (ppo FEV_1) is calculated by multiplying the preoperative value by the ratio of the counts in the remaining lung to total lung activity[91,92] (Fig. 30-5).

Lung perfusion scintigraphy can quantify the degree of right-to-left shunting due to patent foramen ovale, atrial septal defect, elevated right heart pressures, or hepatopulmonary syndrome (HPS). HPS is defined as the triad of liver disease, pulmonary gas exchange abnormalities leading to hypoxemia, and intrapulmonary vascular dilatations leading to right-to-left intrapulmonary shunting.[93,94] The number of injected ^{99m}Tc MAA particles should be reduced in patients with suspected right-to-left shunt. Normally, there is $<5\%$ of ^{99m}Tc MAA uptake in the brain, but in HPS, fewer MAA particles are entrapped in pulmonary vasculature and are able to enter the systemic circulation and lodge in different organs (thyroid, spleen, liver, kidneys, and brain), leading to $>6\%$ uptake in the brain (Fig. 30-6). The major disadvantage of perfusion scintigraphy is that it cannot distinguish intracardiac from intrapulmonary right-to-left shunt. Estimation of the right-to-left shunt fraction is calculated using the equation: $100 \times (\text{TBC} - \text{TLC})/(\text{TBC})$ where TBC is total body count and TLC is total lung count. A less precise alternative method of right-to-left shunt quantification derives an estimate of total body counts from the measurement of renal and/or cerebral activity.

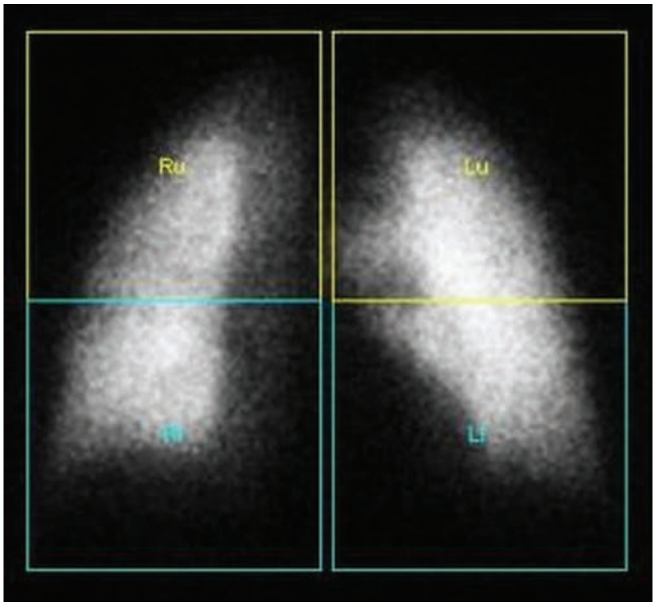


Figure 30-5 Quantitative perfusion lung scan. Regional perfusion can be quantified by outlining regular or irregular regions of interest and generating ratios that correspond to percentage of total pulmonary function. Images shown were analyzed by dividing each lung into two equal rectangles.

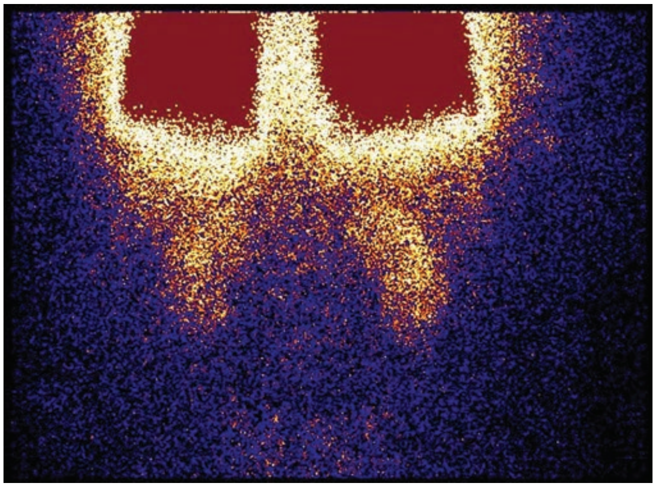

Figure 30-6 Right-to-left shunt in a patient with hepatopulmonary syndrome. Perfusion scan using ^{99m}Tc MAA is showing particles in the systemic circulation lodged in the kidneys.

ASSESSMENT OF ALVEOLAR-CAPILLARY MEMBRANE PERMEABILITY AND MUCOCILIARY CLEARANCE

The clearance rate of inhaled ^{99m}Tc DTPA aerosol from the lungs can be measured using a gamma camera and used as an index of lung epithelial permeability.[95] Aerosols of relatively small aerodynamic diameter (e.g., ^{99m}Tc DTPA) are deposited largely within the small airways and alveoli; the normal half-time of ^{99m}Tc DTPA washout from the lungs is about 80 min.[96] In the presence of epithelial alveolar damage, the clearance of ^{99m}Tc DTPA is accelerated.[95] Such injuries are noted in amiodarone toxicity, inhalation damage in fire victims, pneumoconiosis, idiopathic pulmonary fibrosis, collagen vascular diseases, sarcoidosis, acute respiratory distress syndrome, and pneumocystis pneumonia.[95,97] Cigarette smoking or physiologic factors, such as posture and exercise, also influence epithelial lung clearance.[95,98] Since increased alveolar-capillary membrane permeability is relatively nonspecific, ^{99m}Tc DTPA aerosol clearance studies have been utilized only to assess the effects of therapy in patients with known pulmonary diseases.

Mucociliary clearance is the primary physiologic defense mechanism that protects the lungs from damage caused by inhaled particles and microorganisms. Determination of mucociliary clearance may be obtained after inhalation of relatively large, aerosolized particles, followed by measurement of the rate of clearance with a gamma camera. The rate of mucociliary clearance depends on several factors, including ciliary activity and mucus production.[99,100]

Inhaled particles, such as ^{99m}Tc MAA or ^{99m}Tc sulfur colloid, tend to be deposited within the proximal airways.[101] The normal mucociliary clearance half-time is approximately 24 h. Delayed mucociliary clearance is seen in patients with airway inflammation (e.g., cystic fibrosis, COPD, asthma, or viral respiratory tract infections), following bronchial surgery, or after irradiation. Scintigraphic assessment of alveolar-capillary membrane integrity and mucociliary clearance has not gained wide clinical use, and only a few centers worldwide use it routinely in a clinical context.[97,99] It has been employed in the development of orally inhaled drugs administered by inhalation by assessing their deposition patterns and the extent of delivery and the depth of penetration in the lungs.[102] Also, quantification of the impact of new drugs on the rate of mucociliary clearance is a key biomarker for products in development for the treatment of respiratory diseases.[103]

POSITRON EMISSION TOMOGRAPHY: BASIC PRINCIPLES

Positron emission tomography (PET) is a nuclear medicine imaging modality that provides a 3D image of molecular processes in the body. A PET scan detects gamma rays emitted by positron-emitting tracers. The most commonly used radiopharmaceutical in clinical PET today is 2-[^{18}F] fluorodeoxy-D-glucose (FDG), a fluorine-labeled glucose analogue with a favorable, 110-min half-life. FDG competes with glucose for transport into the cell and for enzymatic phosphorylation by hexokinase. Unlike glucose, once phosphorylated to FDG-6-phosphate, it does not undergo further metabolism and is trapped inside the cell—a net accumulation that allows for detection by PET.[104] FDG uptake is proportional to the metabolic activity of the cells that have undergone malignant transformation, and as such, have increased glucose transport and metabolism and increased hexokinase activity. FDG accumulation also depends on various factors, including cell mitotic rates, level of hypoxia (hypoxia-inducible factor 1-α upregulates glucose transport receptors), and the degree of cell differentiation (well-differentiated tumors have low FDG uptake).[105] In addition, inflammatory cells share many of the same features as malignant cells; therefore, FDG-PET imaging can be employed to assess infectious and inflammatory processes and diseases. FDG-PET imaging is performed in the fasting state to minimize competitive inhibition of FDG uptake by the circulating glucose in the plasma. (Hyperglycemia can result in decreased FDG accumulation in either malignant or inflammatory cells.)

A key feature of PET compared to conventional imaging techniques is the possibility of accurate quantification of the ongoing metabolic activities in normal or diseased states. The most common means used for this purpose is measurement of the *standardized uptake value* (SUV), a semiquantitative expression of the intensity of FDG accumulation in a region of interest (ROI) assigned on the PET scan. SUV normalizes the amount of FDG accumulation in a ROI to the total injected dose and the patient's body weight. It is calculated by dividing the mean activity within a selected region (or volume) of interest (in mCi/mL) by the injected dose (in mCi/kg). SUV_{max} is derived from the single voxel showing the highest uptake within a defined ROI, which typically represents the most metabolically active part of a tumor or inflammatory process.[106,107] However, it is important to note that several factors can impact SUV, including extravasation of the compound administered, hyperglycemia, exercise, nonfasting state, respiratory motion, time from injection, and size of ROI.[108]

During the past decade, efforts have been made for accurate quantification of focal, as well as diffuse, pulmonary diseases and disorders in the lung.[109] PET/CT imaging allows for precise assessment of disease activity compared to what is achievable by CT or other structural imaging techniques.[110] Significant efforts have been made for accurate quantification of focal lesions due to disorders, such as malignancies, as well as inflammatory processes in the lung (Fig. 30-7).[111] Over the years, these techniques have become readily available and can be adopted in the community for routine daily application. Partial volume correction for accurate quantification of focal lesions is a necessary step for assessing the true degree of aggressiveness of either benign or malignant disorders.[112] Furthermore, employing PET imaging for global disease assessment has become a necessity for determining and quantifying overall disease activity during the course of benign or malignant processes.[113–116]

Today, a mainstay of PET imaging is integrated PET/CT scanners, which allow combining metabolic and structural imaging modalities and have been shown to be superior to images generated from

	Volume	SUV_{max}	SUV_{mean}	$\text{cSUV}_{\text{mean}}$	MVP	cMVP
2009	216.08	11.98	6.17	13.34	1333.73	2882.24
2010	131.40	10.59	5.30	12.29	690.75	1615.87

Figure 30-7 **A.** Comparison of MIP FDG-PET images of a patient with sarcoidosis performed in 2009 (*left*) and 2010 (*right*) reveals no significant difference in the extent and degree of FDG uptake in the thoracic structure. In fact, SUV of a comparable lesion in the mid-mediastinum was 5.83 and 5.75, respectively, which is almost identical. **B.** The same images with segmentation using an iterative thresholding algorithm (region of interest visualization, evaluation and registration [ROVER]; ABX, Radeberg, Germany) permits generating significant data with regard to the size of the lesions and their metabolic activities. These include the volume, SUV_{max}, SUV_{mean}, partial volume corrected SUV_{mean} ($\text{cSUV}_{\text{mean}}$), metabolic volume product (MVP), and corrected MVP as recorded above. These values clearly demonstrate a substantial reduction in the overall metabolic burden of the disease, which was not apparent from standard approach. MIP, maximum intensity projection; SUV, standardized uptake value. *(Reproduced with permission from Basu S, Saboury B, Werner T, et al. Clinical utility of FDG-PET and PET/CT in non-malignant thoracic disorders. Mol Imaging Biol. 2011;13(6):1051–1160.)*

separate PET and CT scans.[117] Current PET/CT scanners contain a state-of-the-art multidetector CT machine and time-of-flight PET technologies that reconstruct high-quality images with low FDG doses and short scan times, especially in large patients.[118]

PET/CT has some limitations related to attenuation artifacts leading to false-positive results on corrected images; motion and misregistration between PET and CT images can also result in major artifacts in regions adjacent to the heart and diaphragm.[119]

The newest technologic advances in PET include larger fields of view, including a total-body scanner[120] that can cover the entire human body. This allows very short single data acquisition without any movement,[121] better signal-to-noise ratio, smaller amounts of radioactivity injected, and the ability to perform kinetic analysis.[122] These instruments have significantly reduced the time required to image the body and improved the overall quality of the images.[123,124] Furthermore, these new PET scanners allow for delayed imaging over several hours in patients with lung cancer and other malignancies. Based on experience gained over the years, it has been established that delayed imaging allows for accurate determination of the extent of various malignancies, particularly lung cancer (Fig. 30-8). Therefore, it is conceivable that delayed imaging by these new PET scanners will eliminate unnecessary surgeries in patients with lung cancer.[125] Also, combined early and delayed imaging allows determination of tumor biology and, therefore, degree of aggressiveness of the cancer,[126] which may radically change management of patients with this common and potentially fatal disease.

Figure 30-8 Multiple-time-point FDG-PET of a patient with left upper lobe malignancy. Sagittal, axial, and coronal PET scans of the patient at the first, second, and third hours are shown in the top three rows. The left upper lobe tumor (asterisks) is segmented using a commercial tool, and PET parameters including MTV, TLG, SUV$_{max}$, SUV$_{mean}$, pvcSUV$_{mean}$, and pvcTLG are quantified in the bottom chart. There is an increasing trend of FDG uptake in various parameters over time. MTV, metabolic tumor volume; pvcSUV, partial volume corrected standardized uptake value; pvcTLG, partial volume corrected total lung glycolysis; SUV, standardized uptake value; TLG, total lesion glycolysis. *(Reproduced with permission from Houshmand S, Salavati A, Segtnan EA, et al. Dual-time-point Imaging and Delayed-time-point Fluorodeoxyglucose-PET/Computed Tomography Imaging in Various Clinical Settings. PET Clin. 2016;11(1):65–84.)*

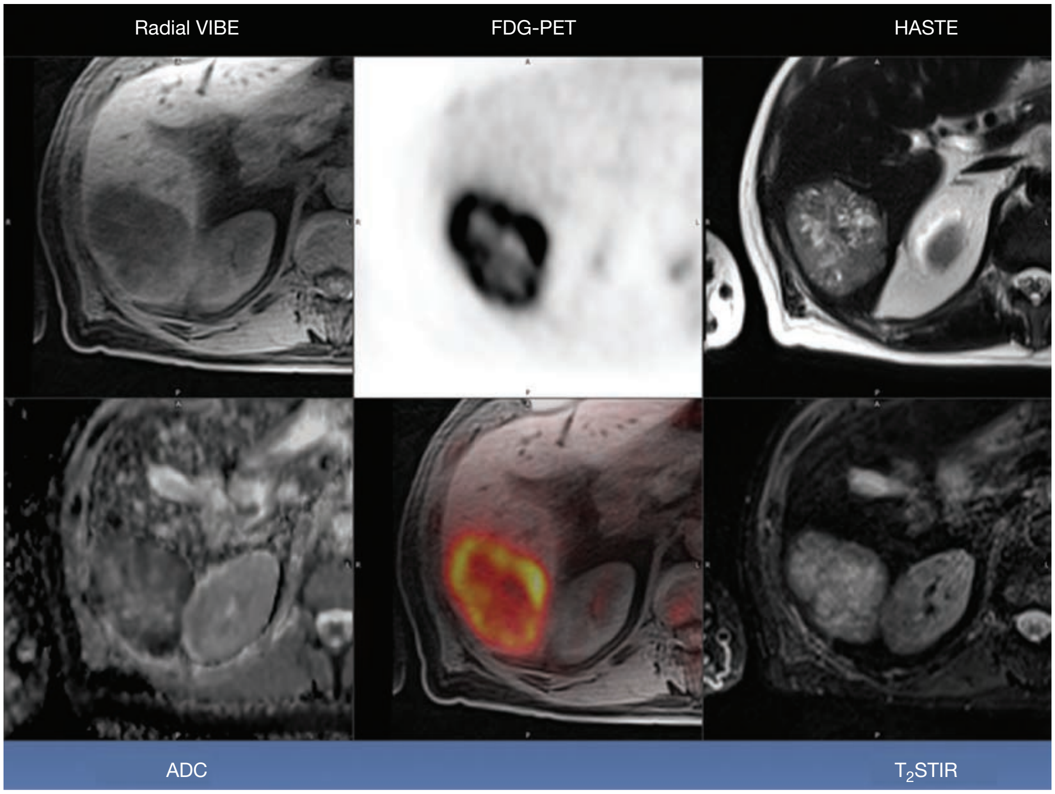

Figure 30-9 72-year-old male with lung cancer and liver metastases. Multisequence PET/MR of the liver demonstrates excellent co-registration of PET and multiple MRI sequences. Simultaneous acquisition maximizes accuracy of image registration and facilitates voxel-to-voxel correlations to support quantitative imaging. *(Reproduced with permission from Dr. Kent Friedman, Department of Radiology, Nuclear Medicine Section, New York University School of Medicine, New York, NY, USA.)*

Combined PET/MRI systems are now commercially available, but their added potential clinical benefit is still not fully validated,[127] particularly in thoracic disorders. There are early data on the value of diffusion-weighted MRI in assessing early response to chemotherapy in patients with lung cancer.[128] Tumor cellularity and proliferation can be evaluated using the "apparent diffusion coefficient" (ADC), and changes can be detected before tumor size reduction.[129] One of the main advantages of combined PET/MRI systems is the large amount of data obtained, allowing for quantitative studies (Fig. 30-9). Some limitations of MRI include issues related to the presence of implanted devices, claustrophobia, large body habitus, and cost. However, continued technologic advances aim to reduce those barriers.

ROLE OF POSITRON EMISSION TOMOGRAPHY IN THROMBOEMBOLISM, PULMONARY INFLAMMATION, AND INFECTION

PET can be used in evaluating patients with a variety on nonmalignant conditions, including suspected venous thromboembolism, suspected lung infection in the immunocompromised host, and noninfectious inflammatory lung diseases.

■ Potential Role for FDG-PET in Evaluating Suspected Venous Thromboembolism

In recent years, FDG-PET/CT has been explored in many inflammatory conditions, given the increased FDG uptake by activated inflammatory cells resulting from increased cell surface glucose transporters after cellular stimulation by various cytokines.[130] This is also the case with venous thromboembolism (VTE). Based on our own experience and the literature,[131] PET may be of value in assessing VTE for several reasons. Current imaging techniques, which are based on structural detection of thrombi, are limited in detecting thrombi throughout the body; deep venous thrombosis (DVT) and pulmonary embolism (PE) are only two manifestations of VTE, which may occur in parts of the venous vasculature not easily accessible by conventional methods (e.g., the pelvis). This also applies to the detection of any occult disease (i.e., cancer), which is often a key factor in developing VTE (Fig. 30-10). Additionally, structural imaging techniques cannot differentiate among different phases of thrombus formation, which may hold therapeutic implications.

Many of these shortcomings may be overcome by using FDG-PET/CT. Several case reports have addressed the incidental detection of VTE using FDG-PET in patients with cancer and bacteremia.[132,133] Inflammatory processes also play a key role in nonmalignant, noninfectious VTE in the setting of local vessel wall inflammation and inflammatory components, like activated leukocytes, in the thrombus itself.

In a small, prospective proof-of-concept series,[134] both DVT and PE were visible on FDG-PET/CT. All patients with proven acute lower-extremity DVT had marked FDG uptake along the venous wall at the site of thrombus. Diagnosis was established by positive compression ultrasound in patients with symptoms less than a week in duration; no history of cancer, infection, or prior DVT; and a high clinical probability according to Wells' DVT score. Conversely, none of the control patients with suspected, but disproven, DVT had FDG uptake in any part of the venous vasculature (patients with negative compression ultrasound; symptoms less than a week in duration; no history of cancer, infection, or prior DVT; and a low clinical probability according to Wells' DVT score. Results were more equivocal in PE, with some patients with high-probability $\dot{V}/\dot{Q}$ scans showing no FDG uptake in the pulmonary arteries. However, this may be attributed to significantly longer symptom duration (i.e., months) in some patients. It may, in fact, be that FDG-PET/CT was truly negative for active thrombi, since recent data suggest a significant decrease in FDG avidity over time.

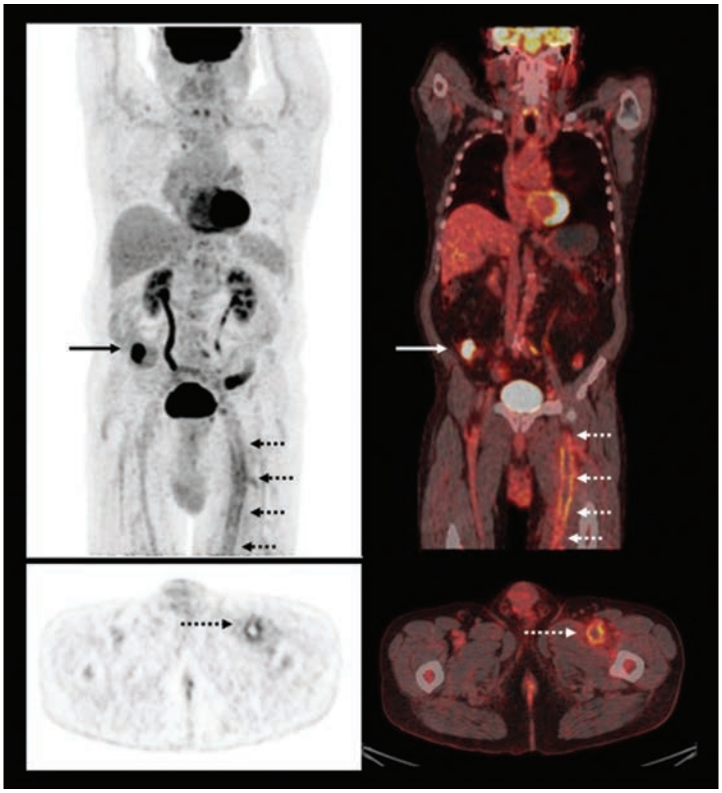

Figure 30-10 Incidental left femoral venous thrombosis on FDG-PET/CT scan. Coronal PET scan (***top left***), transaxial PET scan (***bottom left***), fused coronal PET/CT scan (***top right***), and fused transaxial PET/CT scan (***bottom right***) in a patient who underwent an FDG-PET/CT for malignancy of unknown etiology. Increased FDG uptake is seen along the acutely thrombosed vein *(interrupted arrows)*, and focally increased FDG uptake is seen in the cecum *(solid arrows)* corresponding to a biopsy-proven colon cancer.

In a pivotal study of 12 patients with confirmed proximal thrombosis in the lower extremity, the authors found a specificity of 87.5% to 100% and sensitivity of 87.5% to 100%, depending on SUV_{max} threshold used. In addition, they noted a steady decrease in SUV_{max} and possible complete normalization within 3 months.[135] This is in accordance with VTE pathophysiology. The thrombus may be classified as acute when inflammatory cells and mediators are abundant, subacute with subsiding inflammation and increasing fibrosis, and chronic with recanalization and loss of inflammation. These distinctions have significant clinical implications, since active thrombi require therapy, while unresolved old clots require no treatment. However, a substantial fraction of VTE patients experience symptoms of recurrence, and in as many as half, the morphologic features suggestive of the diagnosis remain for years after the first event.[131] FDG-PET/CT likely will differentiate new, active clots from old, inactive ones and facilitate an individualized therapeutic approach.

Although the literature is sparse, the role of FDG-PET/CT imaging appears to be promising in select patients suspected of VTE. The technique may contribute to detection of clots at any location throughout the body, establishment of an early diagnosis of underlying malignancy, and differentiation of acute from chronic thrombi.

Imaging of the Thorax in the Immunocompromised Host

^{67}Ga-citrate and white blood cells labeled with ^{111}In or ^{99m}Tc were once considered appropriate agents for imaging pulmonary infection and inflammation. However, due to poor image quality, laborious labeling techniques, and the requirement for imaging several days after injection, imaging with either ^{67}Ga-citrate or radiolabeled white blood cells is now considered obsolete in these settings. In recent years, these methods have been largely replaced by FDG-PET/CT in the evaluation of suspected infection or inflammation in many anatomic locations. This is certainly true in the lungs, where FDG-PET/CT is employed for suspected pulmonary infections, fever of unknown origin in the immunocompromised host (Fig. 30-11), and assessment of opportunistic infections in patients with HIV (Fig. 30-12) and a multitude of inflammatory disorders.[136]

FDG-PET/CT is also emerging as a potential diagnostic tool in tuberculosis and for establishing disease extent, especially extrapulmonary tuberculosis. A meta-analysis suggested that FDG-PET might be helpful in determining treatment response in patients with tuberculosis.[137] The high sensitivity of FDG-PET allows for the detection of response within weeks after initiating treatment, contrary to structural imaging using CT, which is of limited value for this purpose.[138] This approach will be particularly important in detecting drug resistance in this population. Similar to its role in the management of patients with tuberculosis, FDG-PET has become an important tool in assessing patients with other mycobacterial infections (Fig. 30-13).

Noninfectious Inflammatory Lung Diseases

^{67}Ga citrate lung imaging has been used to quantify the degree of alveolitis in various interstitial lung diseases, particularly sarcoidosis and idiopathic pulmonary fibrosis. However, pulmonary accumulation of ^{67}Ga in idiopathic pulmonary fibrosis proved not to be reliable in predicting response to treatment with corticosteroids or prognosis.[139] FDG-PET/CT appears to be substantially superior to ^{67}Ga.

Additionally, even with sparse reports in the literature, the evidence points toward a correlation between the

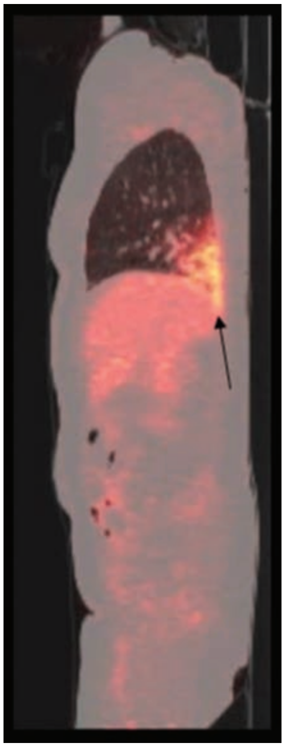

Figure 30-11 Fever of unknown origin in an immunocompromised patient with a kidney transplant. Conventional chest x-ray was non specific. Fused sagittal FDG-PET/CT image shows characteristically increased FDG uptake in the right lower lung *(arrow)* consistent with lobar pneumonia.

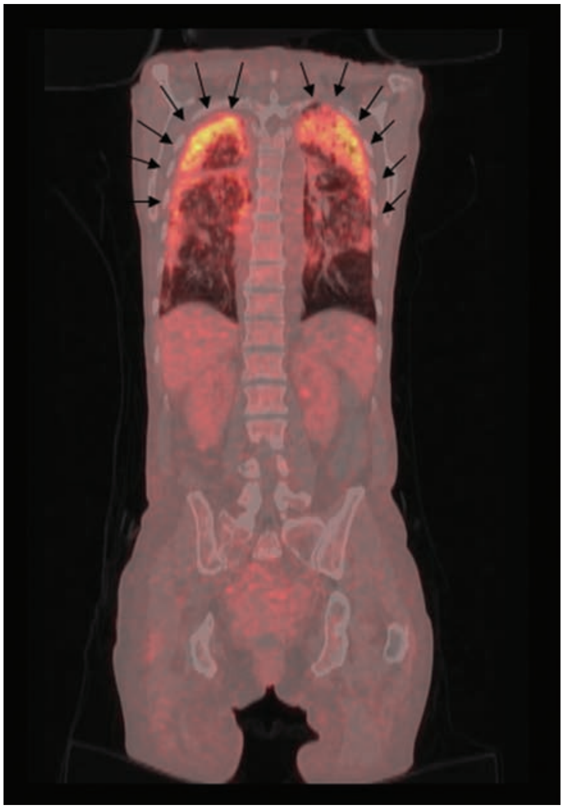

Figure 30-12 *Pneumocystis jirovecii* pneumonia. Diffuse, markedly increased FDG lung uptake bilaterally *(arrows)* in a patient with human immunodeficiency virus.

distribution and severity of emphysema and the degree of FDG uptake.[140]

Over the past two decades, FDG-PET has been proven to be very effective for the detection of inflammation, and as such, it has been adopted for assessing many infectious and inflammatory disorders.[141,142] The technique has proved to be of great value, due to both its sensitivity and accurate quantification of various inflammatory processes.

Sarcoidosis is a multisystem inflammatory granulomatous disease that involves the lungs in 90% of patients; however, it can affect almost any organ. Historically, scintigraphy using ^{67}Ga citrate was used for assessment of disease activity in pulmonary sarcoidosis, but its use has been overshadowed by FDG-PET.

FDG-PET has several advantages to ^{67}Ga citrate scintigraphy, including lower radiation exposure, shorter time interval between injection and imaging, higher image quality, better interobserver agreement, and better detection of intra- and extrathoracic lesions.[143–146] Hilar and mediastinal lymph nodes (as well as any other soft tissues) harboring active granulomas due to sarcoidosis accumulate FDG (Fig. 30-14). Although FDG-PET cannot distinguish

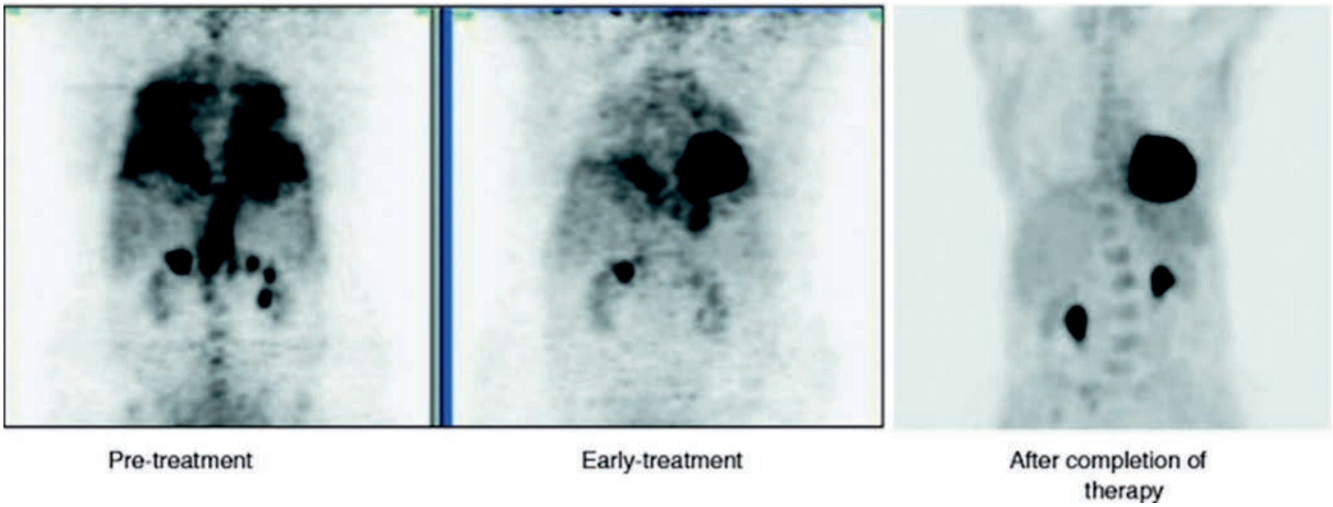

Figure 30-13 FDG-PET maximum-intensity projection images (antero-posterior view) demonstrating the FDG uptake during the treatment course in a patient with *Mycobacterium avium–intercellulare* (MAI) infection. *(Reproduced with permission from Basu S, Saboury B, Werner T, et al. Clinical utility of FDG-PET and PET/CT in non-malignant thoracic disorders. Mol Imaging Biol. 2011;13(6):1051–1160.)*

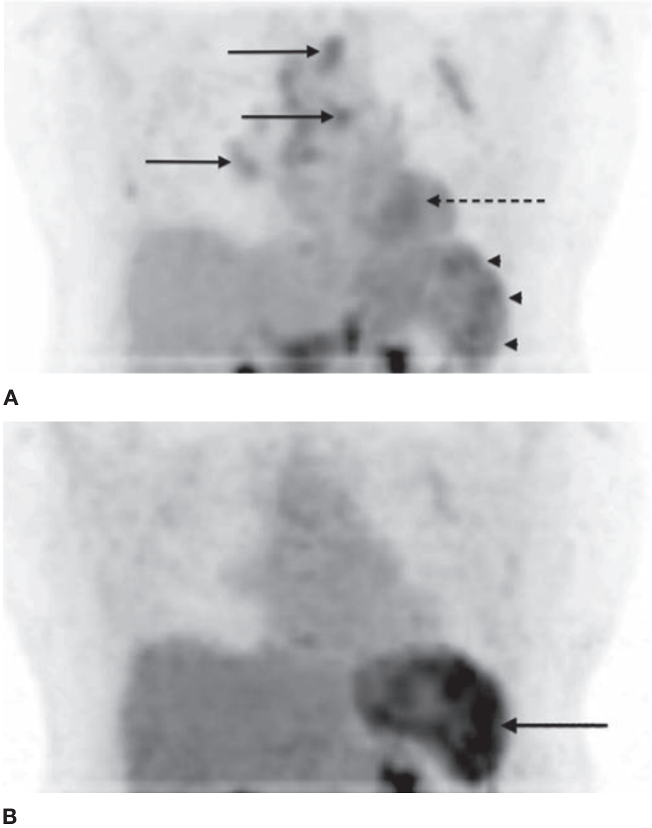

Figure 30-15 **A.** FDG-PET/CT images of the thorax and upper abdomen reveal increased metabolic activity in hilar lymph nodes *(solid arrow)*, myocardium *(interrupted arrow)*, and spleen *(arrow heads)* secondary to involvement with sarcoidosis. **B.** Following successful treatment, there is substantial response in the affected sites within the myocardium and lymph nodes. However, there is significantly increased FDG uptake in the splenic lesions *(solid arrow)*, which demonstrates the complexity of the biologic behavior of sarcoidosis in various organs during the course of the disease.

sarcoidosis from other diseases, such as Hodgkin's or non-Hodgkin's lymphomas, it is quite effective in guiding an appropriate site for biopsy and staging after an initial diagnosis is made. Increasingly, this technology is employed for determining the extent of sarcoidosis in the lung, as well as its presence and extent in other organs, particularly in the heart.[147,148] More importantly, FDG-PET provides a means for assessing response to treatment (Fig. 30-15).[138,149] High FDG uptake in the involved lung parenchyma correlates with disease severity[150] as revealed by bronchoalveolar lavage (BAL).[151] In a study on 90 patients with chronic sarcoidosis and persistent symptoms, FDG-PET/CT proved helpful in detecting active inflammatory sites, especially in patients with normal angiotensin-converting enzyme (ACE) levels, thereby influencing adjustment of therapy.[152] On the other hand, total-lesion glycolysis (TLG) by FDG-PET as an index of lung inflammation in 87 patients with positive uptake failed to correlate with clinical symptoms, functional impairment, or need for therapy.[153]

Finally, FDG-PET may be useful in evaluating pneumoconiosis. Pneumoconioses may be progressive, even after dust exposure has ceased. The inhaled particles activate pulmonary macrophages that secrete cytokines that mediate an inflammatory reaction, inducing fibroblast proliferation and collagen deposition. FDG is taken up by both fibroblasts and alveolar inflammatory cells. The intensity of pulmonary FDG uptake in pneumoconioses depends on whether active inflammation (increased uptake) or end-stage fibrosis (reduced uptake) predominates at the time of the scan.[154] In addition, progressive massive fibrosis has been shown to be associated with increased FDG accumulation.[155]

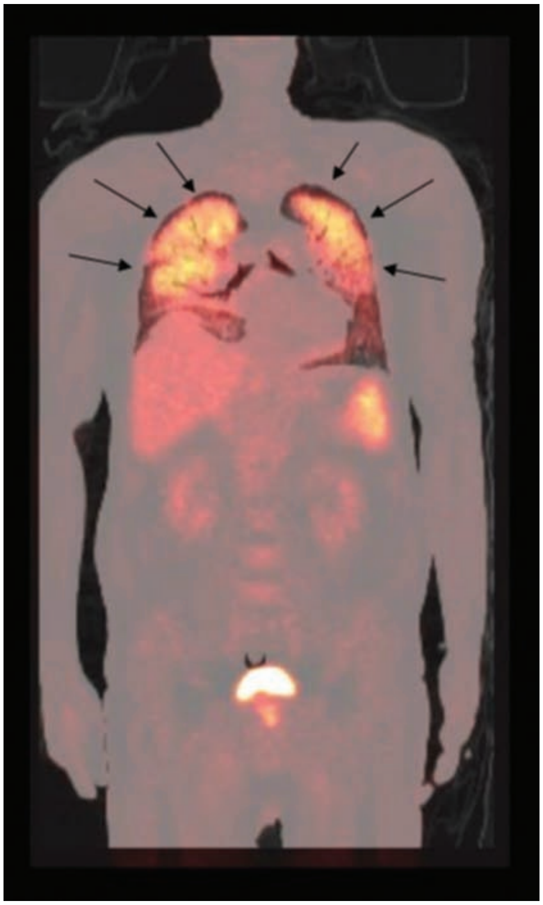

Figure 30-16 Interstitial lung disease. The patient presented with dyspnea and intermittent fever and the PET/CT showed diffusely increased FDG uptake in both lungs *(arrows)*.

The findings from FDG-PET have direct clinical implications, as therapeutic interventions are ineffective in end-stage fibrosis. Interstitial lung disease may also be FDG-avid, but there are limited data on the use of FDG-PET in this setting (Fig. 30-16). In a small prospective study of 21 patients, FDG-PET did not allow differentiation of idiopathic from nonidiopathic pulmonary fibrosis.[156] However, dual-timepoint FDG-PET with early and delayed imaging might help in the differential diagnosis and predict disease progression in idiopathic interstitial pneumonia.[157] Early preclinical and human studies are underway to investigate the role of new PET tracers to determine disease activity in IPF and response to therapy. One such radiotracer is ^{64}Cu-DOTA-ECL1i, which tracks the C-C motif CCR2 (chemokine receptor 2) expressing monocytes and interstitial macrophages, which are active in IPF and play a central role in fibrosis.[158]

ROLE OF POSITRON EMISSION TOMOGRAPHY IN THE ASSESSMENT OF THE SOLITARY PULMONARY NODULE AND LUNG CANCER

Current clinical indications for FDG-PET imaging in malignant lung disease include evaluation of a solitary pulmonary nodule, staging of lung cancer (non–small-cell, small-cell, mesothelioma), and planning and monitoring response to therapy.

Evaluation of a Solitary Pulmonary Nodule

A solitary pulmonary nodule (SPN) is defined as a round or oval radiographic opacity in the lung parenchyma that measures up to 3 cm in size and is not accompanied by mediastinal adenopathy or atelectasis.[159] SPNs are among the most common incidental thoracic imaging findings on chest radiographs or CT scans.[160] In the United States, about 1 million new SPNs are detected each year, and approximately 40% to 50% of such lesions are malignant. Of the malignant SPNs, adenocarcinoma is the most common (47%), followed by squamous cell carcinoma (22%) and small-cell lung cancer (4%).[161] An early and accurate diagnosis is essential for timely intervention, as lung cancer remains, by far, the leading cause of cancer death among both men and women in the world, and survival depends on the stage of the cancer when diagnosed (Fig. 30-17).[162]

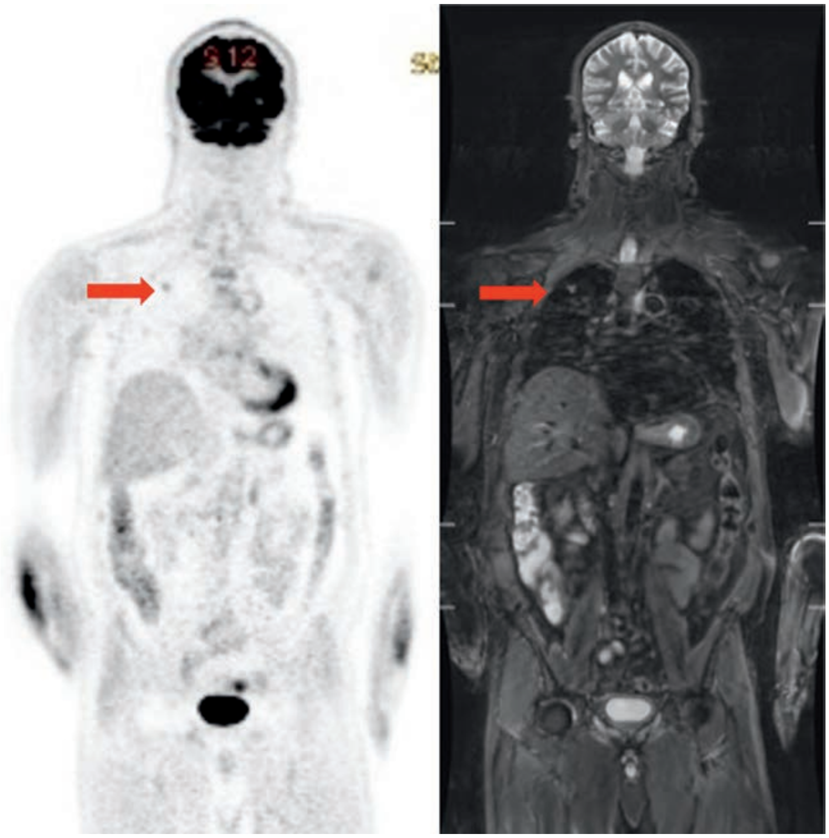

Figure 30-17 Coronal FDG-PET/MRI demonstrating a hypermetabolic right upper lobe solitary pulmonary nodule with no evidence of metastatic disease. *(Reproduced with permission from Dr. Andrei Iagaru, Department of Radiology, Nuclear Medicine Division, Stanford University, Stanford, CA.)*

Of SPNs that are benign, about 80% are caused by infectious granulomas.[159] While a number of benign etiologies for SPNs may have a characteristic appearance on CT, many cannot be characterized accurately using CT and often require further invasive assessment for accurate diagnosis. Certain factors, including the history of smoking, characteristics of the nodule (e.g., size, edge irregularity and spiculation, appearance as a pure ground glass opacity, absence of calcification) and patient age when detected are features that determine the probability of malignancy. However, there is considerable overlap in the appearance of benign and malignant lesions[163] in spite of radiographic and other clinical criteria employed for this purpose. CXR and CT scan are not accurate in differentiating benign from malignant, noncalcified pulmonary nodules that range 1 to 3 cm in diameter; benign patterns of calcification and morphologic stability over 2 years are the most reliable signs of benignity.[163]

FDG-PET provides a highly accurate, noninvasive diagnostic assessment of solid SPNs >8 mm, without the morbidity and costs associated with invasive tissue sampling.[164,165] In a prospective multicenter trial designed to determine the ability of FDG-PET to discriminate between benign and malignant pulmonary nodules, the sensitivity and specificity of FDG-PET ranged from 80% to 100% and 60% to 95%, respectively.[164] False-positive studies are seen with active granulomas due to aspergillosis, tuberculosis, or sarcoidosis.[130] False-negative results are noted with hyperglycemia, malignancies that have a low metabolic activity (e.g., bronchoalveolar carcinoma or carcinoid tumors[166]), and nodules <8 mm in diameter.[167]

In an early meta-analysis of 40 studies that included 1474 pulmonary lesions studied with FDG-PET, the technique had an average sensitivity of 97% and specificity of 78%.[168] Optimal visual criteria for malignancy were greater than mediastinal uptake for nodules >1 cm and any FDG uptake for smaller nodules. A meta-analysis done 7 years later reported a similar sensitivity of 95%, specificity of 82%, PPV of 91%, and NPV of 90%.[169]

A more recent systematic review and meta-analysis of 12 studies including a total of 1297 patients and 1301 pulmonary nodules found significant heterogeneity among the studies included, but reported a pooled sensitivity and specificity of FDG-PET/CT of 82% (95% confidence interval [CI], 0.76–0.87) and 81% (95% CI, 0.66–0.90), respectively.[170] As expected, the lowest heterogeneity and the best results for sensitivity (0.90; 95% CI, 0.68–0.86) and accuracy (0.93; 95% CI, 0.90–0.95) were seen in prospective studies.[170] These results were in line with a large meta-analysis that included 70 studies reporting a total of 8511 nodules, 60% (5105) of which were malignant; however, the accuracy of FDG-PET for diagnosing lung nodules was extremely heterogeneous.[165]

Pretest probability and Bayesian analysis can be used to stratify risk (based on clinical information and imaging characteristics) and guide management of SPN.[171,172] In areas with a high incidence of infectious diseases and a low incidence of lung cancer, the specificity of FDG-PET/CT is low.[165] However, even in that scenario, FDG-PET/CT can safely guide tissue diagnosis to confirm or exclude malignancy. In a prospective study that evaluated 341 patients comparing the diagnostic accuracy of FDG-PET/CT–guided lung biopsy (216 patients) to CT-guided biopsies (125 patients), no difference was noted in complication rates; however, there were fewer inconclusive results leading to a second biopsy in the PET group (5 of 216 [2.3%]) than in the CT group (13 of 125 [10.4%]).[173]

The optimal SUV cut-off point to distinguish benign from malignant lesions is yet to be determined. An SUV_{max} >2.5 has been shown to be very sensitive and specific for differentiating malignant from benign lesions.[167,174] However, several studies have shown that no significant differences between use of a semiquantitative analysis of FDG uptake with SUV and a qualitative visual assessment.[168,175,176] With this approach, FDG uptake in the lesion that is greater than that in the liver or mediastinum (typically, an SUV of about 2.0) is considered indicative of malignancy.[164] Visual analysis may be more sensitive for nodules that are smaller than 1.5 cm in diameter, but the approach results in a lower specificity.[164] In a prospective study of 344 patients for whom a definitive diagnosis was known (prevalence of malignancy, 53%; average size of nodule, 16 mm), FDG-PET had a sensitivity of 92% compared with 96% for CT; however, the specificity of PET was markedly better than that of CT (82% vs. 41%).[177]

The low accuracy of FDG-PET in assessing nodules having a "ground-glass" or "mixed" appearance on CT scanning is likely related to the cell types that predominate in these lesions, including pure bronchioalveolar cell cancer or adenocarcinomas with bronchioalveolar features.[178] In "ground-glass" SPNs, FDG-PET/CT demonstrates a sensitivity and specificity of only 10% and 20% for detecting malignancy, respectively.[176] Therefore, nonsolid SPNs are better assessed using thin-section CT.[179,180]

The sensitivity of FDG-PET is affected by lesion size and the degree of respiratory motion. The threshold of 8 mm for SPN is based on the limited spatial resolution of PET. In one study addressing this issue, the technique's sensitivity in detecting malignancy was 69% for nodules ranging from 5 to 10 mm in diameter and 95% for nodules >10 mm in diameter.[181] Therefore, PET is not recommended for SPN <8 mm.[167] One method aimed at compensating for this limitation is based on using lesion size measured on CT imaging to correct the underestimated SUV with conventional measurements.[112] Data in the literature are based on assigning standard ROIs to the lesions visualized by FDG-PET. Unfortunately, because of the limited spatial resolution of PET imaging, along with respiratory motion of pulmonary lesions, this approach results in substantially underestimated values for SUV, which are proportional to the size of the lesion and the degree of respiratory motion.

The physical factors described are known as partial volume effect and, as such, introduce substantial errors to the quantitative data from PET studies, particularly those related to pulmonary nodules.[112] Therefore, methodologies that can correct for partial volume effect should be employed for accurate measurement of metabolic activity of the lesions assessed. By adopting this approach, significant changes will be noted in the SUV in most clinical settings. Therefore, total reliance on what has been described in the literature will result in significant mismanagement of patients with solitary pulmonary nodules.[182] In particular, we wish to point out that adopting the SUV of 2.5 as a threshold for separating malignant and benign lesions is fraught with error and should be abandoned altogether in the future. Many lesions that are smaller than 3 or 4 cm in size will be prone to such errors.

Errors in the interpretation of PET/CT can occur from misregistration of PET and CT images, since CT images are obtained in a single breath-hold, while FDG is obtained during quiet breathing. This occurs more frequently for SPNs close to the diaphragm and heart. Different respiratory gating techniques have been employed to synchronize PET and breathing with encouraging results;[183] however, the results come at the cost of a longer scan time, thereby increasing the likelihood of patient movement.

The data acquired by simultaneous performance of PET and CT has significantly improved the diagnostic accuracy of PET or CT alone. In a small retrospective study of 42 patients with known pathology of an SPN, PET/CT outperformed (sensitivity and specificity of 97% and 85%, respectively) CT alone (sensitivity and specificity 93% and 31%, respectively) and PET alone (sensitivity of 69% and 85%, respectively).[184] With whole-body FDG-PET/CT, areas beyond the lungs are evaluated, which can facilitate the diagnosis of SPN. Neither intravenous nor oral contrast is necessary for the evaluation of SPN by FDG-PET/CT. The average effective radiation doses are 8.19 ± 0.83 mSv and 13.44 ± 5.14 mSv for PET and CT, respectively.[185]

While most infectious or inflammatory pulmonary disorders generally have a lower FDG uptake than malignancies, overlap exists, and false positives can occur, especially in cases of pneumonia, mycobacterial disease, sarcoidosis, or rheumatoid nodules. Based on the observation in animal and human studies that FDG uptake by malignant tumors increases over time, while that of inflammatory tissue decreases, dual-timepoint FDG-PET scanning has been proposed as a potentially useful means of improving discrimination between benign and malignant diseases.

Using dual-timepoint FDG-PET scanning, images are obtained at 1 h and at a later time following administration of FDG. In one study in which an SUV cut-off value of 2.5 and a 10% increase in SUV were used to indicate malignancy, the sensitivity and specificity of FDG-PET were 80% and 94%, respectively, for the single-timepoint method, and 100% and 89%, respectively, for the dual-timepoint technique.[111] There are no standard protocols or strict guidelines for dual time imaging, specifically with regard to the optimal time between scans.

A meta-analysis comparing diagnostic performance in evaluating SPN showed that dual-timepoint FDG-PET/CT is more specific than single-timepoint FDG-PET/CT.[186] Dual-timepoint imaging is not required in lesions with a baseline SUV of <1.0, since these lesions have a very high likelihood of being benign; dual-timepoint imaging may result in false-positive examinations.[111] Even for nodules with an SUV_{max} <2.5, dual-timepoint imaging may not discriminate accurately between benign and malignant lesions, particularly in areas with a high incidence of granulomatous disease, as false-positive exams have been reported in association with granulomatous inflammation.[187] In two meta-analyses conducted in 2012 and 2013, the overall diagnostic accuracy of dual-timepoint imaging was similar to single-timepoint PET scanning.[186,188]

In a study comparing the accuracy of FDG-PET/CT scanning to dynamic CT scanning for pulmonary nodule characterization, FDG-PET/CT scanning was found to be more sensitive and accurate than dynamic CT scanning. The sensitivity, specificity, and accuracy for malignancy with dynamic CT scanning were 81%, 93%, and 85%, respectively, whereas the values for PET/CT scanning were 96%, 88%, and 93%, respectively.[189]

Guidelines form the American College of Chest Physicians (ACCP) recommend use of FDG-PET/CT in patients where the probability of cancer is intermediate (5%–60%) and an indeterminate nodule measures at least 8 mm.[167] Current National Comprehensive Cancer Network (NCCN) guidelines for lung cancer screening recommend considering FDG-PET/CT for the diagnosis of a solid SPN >8 mm on initial screening with low-dose CT.[190] PET/CT scan is not recommended as a screening tool for healthy individuals, as the likelihood of finding cancer is extremely low, and an increased risk of detecting harmless findings may lead to more tests or invasive procedures.[61,190]

■ Use of Positron Emission Tomography in Lung Cancer

PET has been used extensively in the evaluation and staging of lung cancer, including non–small-cell lung cancer, small-cell lung cancer, and mesothelioma.

Non–Small-Cell Lung Carcinoma

Principal types of lung cancer include the most common variety, non–small-cell lung cancer (adenocarcinoma, squamous cell carcinoma, and large cell carcinoma), which accounts for about 84% of lung cancers.[162] About 13% of lung cancers are small-cell carcinoma, which tends to spread quickly, and 1% to 2% of lung cancers are neuroendocrine (carcinoid) tumors, which tend to grow slowly and rarely spread.[162] FDG-PET scanning has assumed a central role in the staging of non–small-cell lung cancer (NSCLC).[191]

Correct lung cancer staging is important because the treatment options and prognosis vary significantly by stage. FDG-PET imaging can have a significant impact on patient management by identifying unsuspected sites of disease (Fig. 30-18) and by guiding selection of a biopsy site (Fig. 30-19). Similarly,

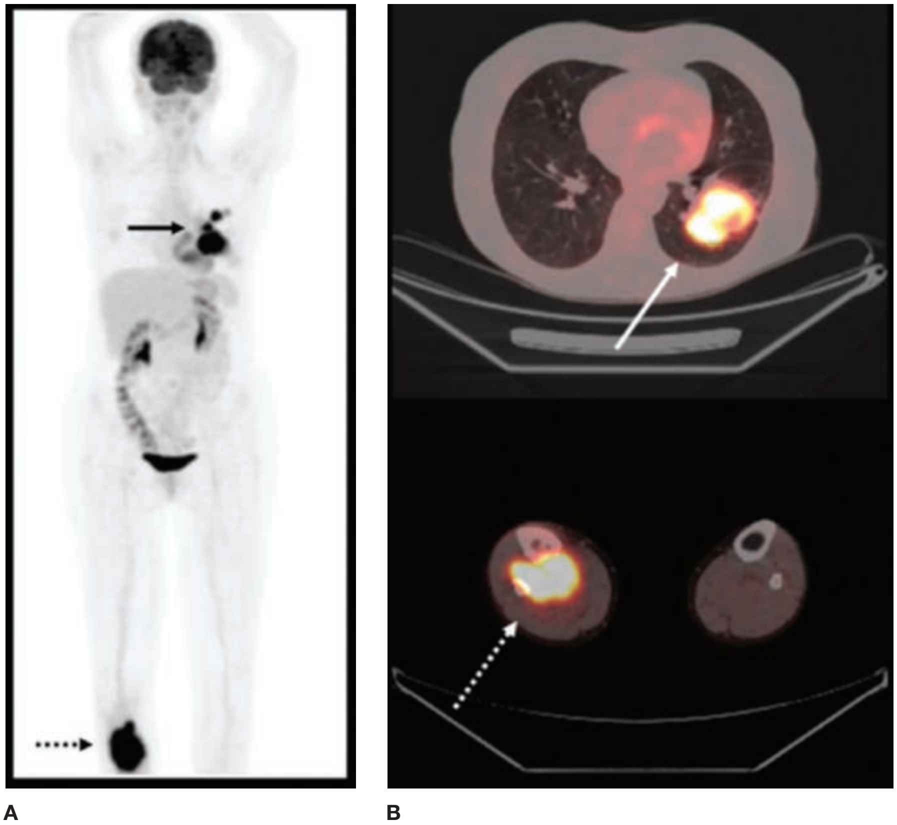

Figure 30-18 Lung cancer. Preoperative evaluation of a patient with a lung cancer in the left lower lobe intended for curative surgery. Whole-body coronal PET (**A**) and fused transaxial PET/CT *(***B** *top and bottom right)* show increased FDG uptake in the lung tumor *(solid arrows)*, and unexpected focal FDG uptake in a soft tissue mass in the left proximal tibia *(interrupted arrows)*. Biopsy showed metastasis from the lung cancer, obviating surgery.

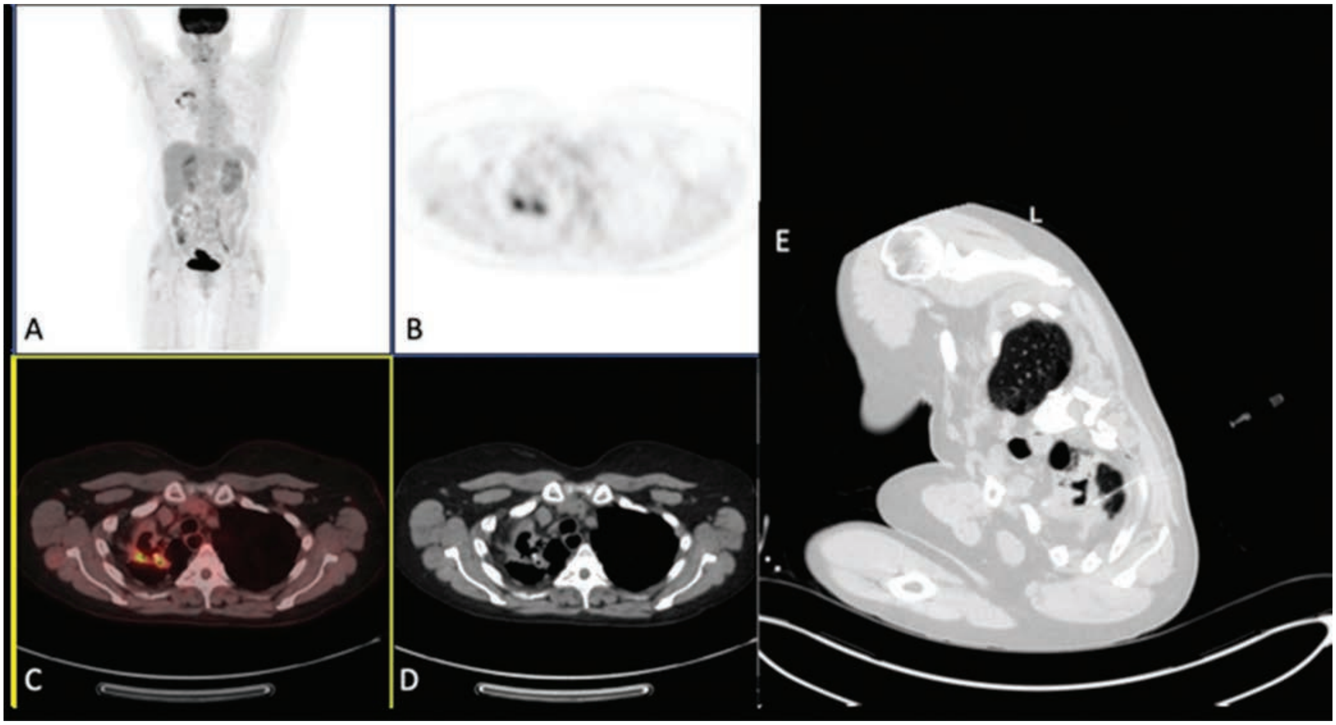

Figure 30-19 FDG-PET/CT guiding a percutaneous biopsy. Maximal-intensity projection PET (**A**), axial PET (**B**), fused axial PET/CT (**C**), and axial CT (**D**) of patient with a cavitary right upper lobe lung lesion. Using the data from PET, a percutaneous CT-guided biopsy targeted the most metabolically active part of lesion yielding non–small-cell lung carcinoma. Without the information from FDG-PET, it would be impossible for the interventional radiologist to determine which part of the lesion will have the best diagnostic yield.

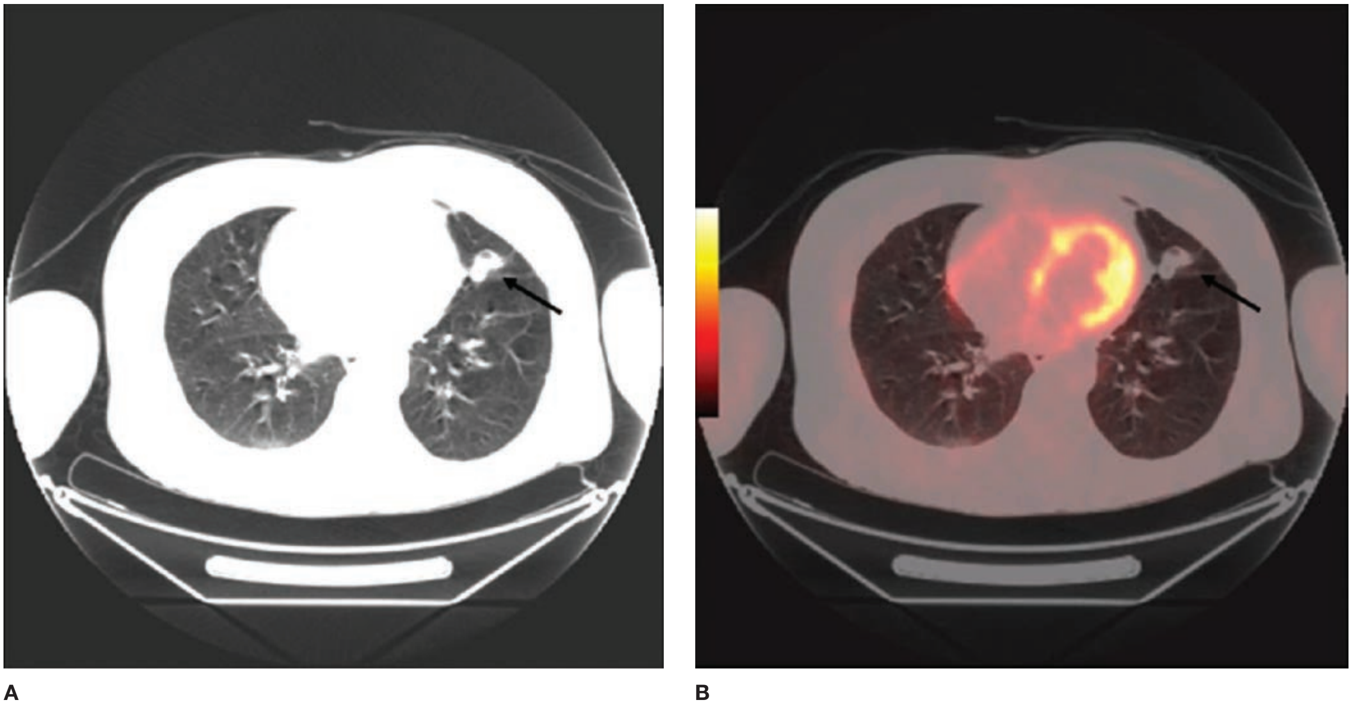

Figure 30-20 Suspected lung cancer. CT scan (**A**) shows a consolidation/mass in the lingula suspected of malignancy *(arrow)*. Transaxial fused PET/CT (**B**) shows no abnormal FDG uptake in the lesion *(arrow)*, consistent with a benign etiology.

a negative FDG-PET scan indicates a low likelihood for malignancy[177] and supports the use of conservative management and follow-up (Fig. 30-20). When used in staging, FDG-PET/CT scanning has to be done within a month from the surgical evaluation.[191] Patients with stage I or II NSCLC are typically referred for surgical resection, while those with stage III or IV disease are almost never surgical candidates; they may benefit from chemotherapy, radiation therapy, or both. The basis for staging NSCLC is the TNM system.[192]

Tumor Staging

For T (tumor) staging, CT and MRI remain the best imaging modalities to demonstrate the local extension of the tumor and its relationship to adjacent organs and vessels. FDG-PET/CT is limited for T staging due to its inability to accurately define tumor limits. However, FDG-PET/CT has demonstrated a clear advantage in T staging of certain cases, especially in areas of post-obstructive atelectasis[193] or low CT density variation; in the future it may replace CT and MRI alone for this purpose.[194,195]

In a prospective study of 50 patients with NSCLC, integrated PET/CT provided additional diagnostic information in 41% of patients and was significantly more accurate in TNM disease staging than either PET or CT alone.[196] Integrated PET/CT provides important clinical information by virtue of accurate localization of known disease and identification of lesions that do not consistently accumulate FDG, such as carcinoid tumors and bronchioloalveolar carcinoma.[196] PET/CT without contrast-enhanced CT is unable to distinguish confined, centrally located tumors from those producing direct invasion of mediastinal structures. Therefore, clinicians may still rely on contrast-enhanced CT scans to help define mediastinal vascular invasion.

From a prognostic point of view, FDG uptake in NSCLC has been correlated with tumor growth rate, aggressiveness, and proliferation capacity, and it is has been found to be an independent prognostic factor correlated with survival in patients with NSCLC, especially in early-stage disease.[197] A meta-analysis of 13 studies showed that tumor SUV$_{max}$ pre- and post- radiotherapy is an independent prognostic indicator for NSCL; higher FDG uptake in the primary tumor is associated with less local control and shorter overall survival.[198] New volumetric parameters have been proposed to better assess the overall metabolic activity of tumors, such as total-lesion glycolysis (TLG) that is defined as the product of the metabolically active tumor volume (MATV) and the SUV$_{average}$ (average SUV of each voxel within the tumor volume). In a group of 214 patients from the multicenter prospective study of the American College of Radiology Imaging Network (ACRIN) 6668/Radiation Therapy Oncology Group (RTOG) 0235 that included 250 patients with NSCLC treated with concomitant radiochemotherapy, MATV was found to be an independent factor for predicting overall survival.[199]

A meta-analysis of 13 studies with 1581 patients (that did not include the results of the previously mentioned study) aimed at assessing the prognostic value of MATV and TLG found that the likelihood of worsening and death was greater for patients with higher MATV or TLG values.[200] Nevertheless, in the absence of a reproducible generalized threshold for SUV, MATV, or TLG, accurate staging remains the only prognostic indication for FDG-PET/CT.

Nodal Staging

From a practical standpoint, mediastinal nodal staging most often determines appropriateness for surgical resection. Mediastinal staging using CT scanning is based primarily on assessment of lymph node size; nodes <1 cm in their short axis are considered benign, while those >1 cm are considered potentially malignant. Unfortunately, up to 21% of nodes smaller than 1 cm are malignant, and up to 40% of nodes larger than 1 cm are benign.[201,202]

A large meta-analysis reported the median sensitivity and specificity of CT scanning for identifying malignant mediastinal nodes as 61% and 79%, respectively.[203] These results were similar to those from an earlier meta-analysis that reported an average sensitivity and specificity of 60% and 77% for CT scanning (using an axial short axis >1.0 cm), respectively.[204] In that same meta-analysis on the diagnostic performance of FDG-PET (14 studies, 514 patients) and CT (29 studies, 2226 patients), FDG-PET had a higher sensitivity and specificity for determining nodal status in patients with non–small-cell lung cancer, with a sensitivity and a specificity of 79% and 91%, respectively.[204]

The accuracy of PET in the evaluation of mediastinal lymph nodes depends on the size of the nodes. In patients with enlarged mediastinal lymph nodes, a large meta-analysis of 39 studies reported a sensitivity and a specificity of FDG-PET of 100% and 78%, respectively.[203] These numbers changed to a sensitivity and specificity of 82% and 93%, respectively, in normal-size nodes.[203] Positive PET findings in this situation should be confirmed by directed biopsy, as inflammatory and/or infectious processes can lead to false-positive results. Absence of tissue diagnosis could result in patients with surgically resectable disease being denied curative surgery.

Exact classification as N1 or N2 disease is somewhat difficult with PET alone; anatomic information provided by CT scan as part of combined PET/CT imaging is important for this purpose. In one study, the accuracy of mediastinal lymph node staging increased from 89% with PET alone to 93% with PET/CT, compared to 63% with CT, and resulted in a change in the planned treatment in up to 15% of patients.[202] In another study, PET/CT was significantly better than CT alone for nodal staging, with improved accuracy, as sensitivity rose from 70% for CT to 85% for PET/CT, specificity rose from 69% to 84%, and accuracy rose from 69% to 84%.[205]

FDG-PET is the best modality to detect tumor in normal size lymph nodes. Using an SUV_{max} of 2.5 is a reasonable threshold between benignity and malignancy, but SUV may be falsely low in lymph nodes <1 cm due to partial volume effect, and visual assessment is generally as accurate.[206] A meta-analysis following databases up to April 2013 found a sensitivity and specificity of PET-CT for evaluating mediastinal involvement of 77.4% and 90.1%, respectively, when nodal uptake was compared with mediastinal background, and 81.3% and 79.4%, respectively, when an SUV threshold of 2.5 was used.[207]

Lymph nodes containing calcification are more likely to be benign even if they accumulate FDG.[208] Interestingly, a few studies have shown that FDG-PET/CT has a lower specificity and accuracy for nodes >1 cm compared with those <1 cm, but the technique still performs better for large lymph nodes than CT alone.[209,210] False-positive nodes are generally larger in size than true-negative nodes as staged by FDG-PET and contain more macrophages.[210]

For patients with stage II or III disease, the incidence of false-negative results is higher with PET than with mediastinoscopy (11.7% and 3%, respectively).[211] These studies illustrate an important limitation of FDG-PET. The variability in false-positive examinations suggests that FDG-PET results cannot replace histologic confirmation for suspected mediastinal nodal metastases.[212] Therefore, FDG-PET-positive lymph nodes still require pathologic confirmation.[213] This is accomplished via transbronchial, transesophageal, or transthoracic nodal needle aspiration, or a more invasive surgical approach (e.g., mediastinoscopy or video-assisted thoracic surgery [VATS]). These invasive procedures can be guided by the PET findings, as mediastinoscopy is limited to the anterior mediastinum, and approximately 15% of patients may still be found to have N2 disease at thoracotomy.[214]

The use of intraoperative FDG-sensitive gamma probes to guide lymph node sampling following the injection of FDG may be helpful.[215] While studies have demonstrated that patients with metastases detected at mediastinoscopy have a worse prognosis than patients in whom N2 disease is found only at surgery,[216,217] no prospective studies have yet been performed to determine whether patients with negative mediastinal nodes on preoperative FDG-PET have a similar prognosis to patients in whom N2 disease is found at thoracotomy following a negative mediastinoscopy. Therefore, mediastinoscopy still remains part of the standard protocol for mediastinal staging.[211] On the other hand, there is low likelihood of involvement of mediastinal nodes when they are negative by both CT and FDG-PET criteria in solid tumors <1 cm or nonsolid tumors <3 cm,[191] highlighting the importance of multimodality evaluation. In fact, a cohort study that included 43,912 patients from the Surveillance, Epidemiology, and End Results–Medicare data (1998–2005) found that multimodality (CT, PET, invasive staging) mediastinal staging has increased over the years and is associated with better survival.[218]

Following the analysis of selected meta-analyses, practice guidelines, and reviews up to June 2012, the ACCP reported a sensitivity and specificity of PET scanning for identifying mediastinal metastasis of approximately 77% and 86%, respectively, in comparison to 55% and 81%, respectively, for CT scanning.[213] Current ACCP guidelines recommend the use of FDG-PET/CT to evaluate for mediastinal evidence of disease in patients with lung cancer being treated with curative intent.[213] For patients with peripheral clinical stage IA lung tumor and negative nodal involvement by CT and PET, invasive evaluation is not required,[213] whereas in patients with intermediate suspicion of N2,3 involvement with a central tumor or enlarged N1 lymph node, invasive staging of the mediastinum is recommended.[213]

Metastatic Staging

In addition to being the most accurate noninvasive imaging modality available to evaluate the mediastinum in patients with lung cancer, whole-body FDG-PET imaging evaluates extrathoracic sites for possible metastatic disease. FDG-PET is superior to conventional imaging in detecting metastases in distant lymph nodes, pleural effusions, contralateral nodules, and viscera.

In a prospective study, FDG-PET showed a high sensitivity and specificity in the detection of distant metastases alone (92% and 83%, respectively), and 11% of patients in the study had distant metastases detected by FDG-PET that other modalities had failed to detect.[212] Detection of unsuspected extrathoracic metastases can be identified in 6% to 24% of patients (mean frequency of about 13%), and the likelihood for detecting unsuspected metastases increases with the patient's stage.[211] This is particularly important in patients with locally advanced, stage III lung cancer.[219]

In one multicenter trial, addition of PET to the conventional workup prevented unnecessary surgery in one out of five patients with suspected non–small-cell lung cancer, with a 50% decrease in futile thoracotomy in comparison to conventional workup.[220] The likelihood for occult metastatic disease at presentation can be found in up to 30% of patients with adenocarcinoma or large cell carcinoma, but is less common with squamous cell carcinoma (under 15% of patients).[211] A meta-analysis that included 9 studies (780 patients) reported an overall sensitivity and specificity for PET of 93% and 96%, respectively, irrespective of the type of lung cancer metastases.[221] Based on multiple randomized clinical trials, about 20% more patients were correctly suggested as having distant or N2,3 metastases by PET compared with conventional staging.[220,222,223] However, confirmation of PET scan findings remains essential in order to prevent incorrect upstaging (which would have occurred in 5% to 42% of patients), thereby preventing a patient from a potentially curative resection.[220,222–224]

The two most common sites for NSCLC metastases are the adrenal glands and bone marrow. Studies have shown that FDG-PET has a sensitivity of 93% to 100% for the characterization of metastatic adrenal lesions in patients with bronchogenic carcinoma (specificity 80%–100% and accuracy 92%–100%).[225–227] Necrotic or hemorrhagic adrenal metastases and small lesions can lead to false-negative FDG-PET results.[227] Despite the fact that benign adrenal adenomas generally demonstrate mild FDG uptake that is less than the liver, false-positive studies may still occur.[226] FDG-PET/CT can improve characterization of adrenal masses by improving the specificity with the combination of SUV and CT attenuation.[228] A Hounsfield Unit (HU) measurement of <10 is indicative of a benign adrenal lesion, even if the SUV measurement is >3.1.[228]

In detecting bone marrow metastases, a comparison of ^{99m}Tc methylene diphosphonate (^{99m}Tc MDP) standard bone scintigraphy to FDG-PET showed a higher accuracy with FDG-PET, 96% versus 66%.[229] FDG-PET can detect bone marrow metastases before reactive bone formation takes place or prior to development of gross anatomic abnormalities. When comparing FDG-PET/CT to ^{99m}Tc MDP and ^{18}F-fluoride PET (F-PET), FDG-PET/CT had a lower sensitivity than F-PET but was superior to ^{99m}Tc MDP.[230] However, FDG-PET/CT had a higher specificity.[230] Numerous benign skeletal conditions (including trauma, infection, and physiologic variants) can cause false-positive FDG-PET results. A meta-analysis of 17 studies addressed this issue by comparing FDG-PET/CT, FDG-PET, MRI, and ^{99m}Tc MDP. The pooled sensitivity of each modality in the detection of bone marrow metastases was 92%, 87%, 77%, and 86%, respectively; the specificity was 98%, 94%, 92%, and 88%, respectively.[231] Based on these data, obtaining bone scintigraphy is not necessary when FDG-PET is performed.

Regarding the initial evaluation for brain metastases in patients with NSCLC, FDG-PET brain imaging does not provide additional clinical information,[232] which is likely due to the high background activity in the brain and small size of most brain metastases. Instead, based on current NCCN guidelines, a brain MRI or CT (if MRI is not available) is recommended in patients with stage II, III or IV disease, even if they are asymptomatic and if aggressive combined-modality therapy is being considered.[191]

Current ACCP recommendations are to obtain PET scans in patients who are considered for a curative-intent treatment with normal clinical evaluation and no suspicious extrathoracic abnormality on chest CT.[213] This should be followed by histologic confirmation in the event of a positive PET finding.

Guiding and Monitoring Radiation Therapy

During the past two decades, by adopting PET-based methodologies, radiation therapy (RT) for lung cancer has significantly improved the outcome of affected patients.[233–238] Currently, in most advanced centers, patients with lung cancer are treated based on PET/CT assessment of disease activity. This has significantly improved the efficacy of treatment for both the primary and metastatic sites. The high sensitivity of PET allows detection of metastatic lesions in the mediastinum and elsewhere and, therefore, improves the overall efficacy of PET in managing these patients.[239]

Historically, RT planning has been based on CT imaging because the excellent delineation of structures allows for precise assignment of the radiation portals. However, PET/CT has gradually replaced CT scanning since a number of studies have demonstrated the additional benefit of PET in defining and refining radiation treatment volumes. Consequently, the reduction or increase in the radiation portal allows more directed dose delivery to target tissues, thereby reducing radiation exposure of normal tissues.[240] In a study of 54 patients with locally advanced NSCLC treated with radiation therapy, PET changed the contours of lymph node stations in 51% of cases.[240]

PET/CT is particularly helpful in planning radiation therapy for patients with lung cancer associated with atelectasis. In a prospective study of 76 patients, 34% of patients eligible for radical radiation therapy after conventional staging received palliative therapies instead because PET/CT detected advanced disease.[241] FDG-PET/CT frequently changed the planning target volume, which was associated with excellent survival.[241]

In recent years, FDG-PET has been employed to assess the inflammatory complications of RT. It is well established that photon therapy using a conventional x-ray approach results in significant inflammation in the lung ipsilateral to the cancer, as well as the contralateral side (Fig. 30-21).[233,236,237] CT scanning is of limited value in detecting and quantifying such complications. By employing novel quantitative techniques, the degree of inflammation can be assessed precisely, and its course determined during and following treatment.

It has been shown that photon therapy for treating lung cancer is associated with significant inflammation compared to that of proton therapy (Fig. 30-22).[236,237] Therefore, the latter modality has gained a major position in both research and clinical settings as the most safe and effective in lung malignancies. Furthermore, PET has allowed detection of vasculitis due to RT, which is also of great importance in minimizing morbidity and mortality.[242] This serious complication is of particular importance in the aorta, as well as the coronary arteries, which may adversely impact the management of these patients.

In patients with residual parenchymal abnormalities following RT for lung cancer, FDG-PET scanning can be used to distinguish between persistent or recurrent cancer and radiation fibrosis.[243] In a study evaluating changes in FDG uptake following definitive radiation therapy, the higher the residual SUV_{max} in the primary tumor (cutoff, 3.7) or lymph nodes (cutoff, 3.1), the worse was the prognosis.[243] FDG-PET is also useful in assessing response to percutaneous radiofrequency ablation of NSCLC.[244]

FDG-PET imaging can better evaluate the response to treatment than anatomic imaging and can also provide prognostic information that correlates strongly with survival rate following initiation of therapy[199,245] (Fig. 30-23). A meta-analysis of 36 studies (5807 patients) found that high values for SUV_{max}, metabolic tumor volume (MTV), and TLG predicted a higher risk of recurrence or death in patients with surgical NSCLC.[246] Assessment of prognosis can be improved with early FDG-PET imaging, as a 50% decrease in SUV between scans performed at 1 and 3 weeks following initiation of chemotherapy has been shown to predict a favorable response.[247]

In recent years, the introduction of immune checkpoint inhibitors has made a significant impact on patients with lung cancer. The use of FDG-PET/CT to evaluate the response to immunotherapy remains a challenge in the face of issues such as pseudoprogression, hyperprogression, and immune-related side effects.[248] Only a few studies have investigated tumor response to immunotherapy outside of melanoma. FDG-PET/CT may play a future role in predicting response to immunotherapy for NSCLC.

A limited, single-institution, retrospective study of 579 patients with primary lung cancer (441 with adenocarcinoma [ADC], 103 with squamous cell carcinoma [SCC], 4 with large-cell carcinoma [LCC], 16 with small-cell carcinoma [SCLC], and 15 with large-cell neuroendocrine carcinoma [LCNEC]) who underwent complete surgical resection found that overall SUV_{max} was significantly higher in patients with PD-L1 protein expression than in those without PD-L1 expression ($p < 0.0001$) (specifically in patients with ADC, SCC, or LCC, but not in SCLC or LCNEC).[249] The link between FDG uptake and PD-L1 protein expression remains unclear, as it may depend on many factors, including cancer cells and the tumor microenvironment (e.g., glucose metabolism, hypoxia, angiogenesis, mammalian target of rapamycin [mTOR] signaling pathway), in addition to tumor-related activated immune cells, such as tumor-infiltrating lymphocytes (TILs) and tumor-associated macrophages (TAMs).[250]

A small preliminary study of 24 patients with NSCLC found that FDG-PET/CT before and 1 month after administration of the anti–programmed death 1 (PD-1) agent nivolumab could predict early therapeutic response using SUV_{max}, MTV, and TLG parameters.[251] The predictive probability of partial response (100% vs. 29%; $p = 0.021$) and progressive disease (100% vs. 22.2%; $p = 0.002$) at 1 month after nivolumab was significantly higher with FDG-PET/CT than with CT scanning. While FDG uptake was an independent prognostic

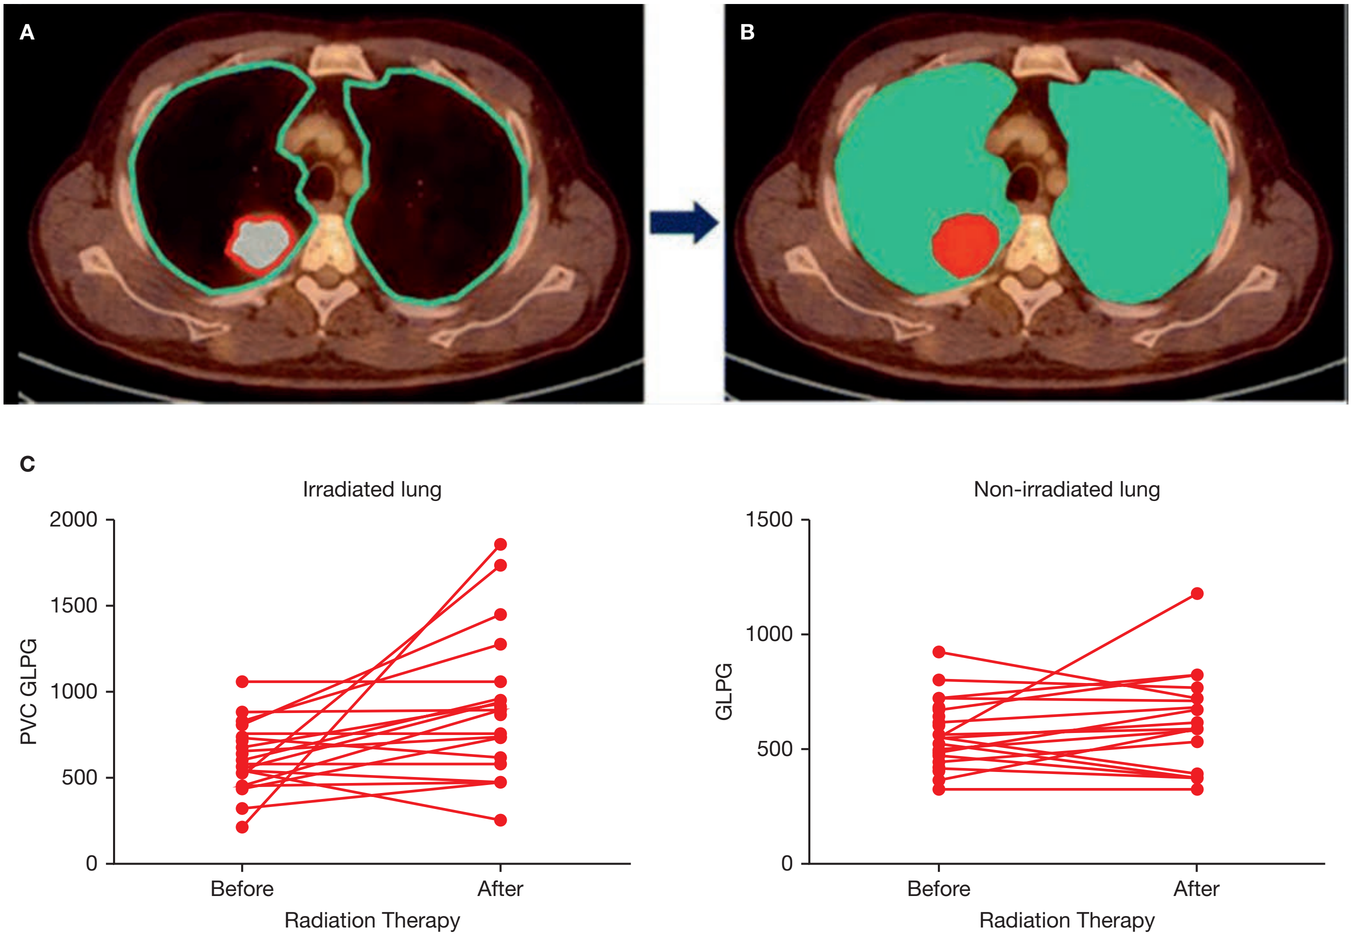

Figure 30-21 Global lung glycolysis (GLG) and global lung parenchymal glycolysis (GLPG) calculation. **A.** Manually drawn ROIs *(green)* around the irradiated right and nonirradiated left lung on a representative transverse FDG-PET/CT slice. The tumor boundary *(red)* was delineated by semiautomatic software. **B.** In the irradiated right lung, GLPG *(green area)* was calculated by subtraction of tumor total lesion glycolysis *(red area)* from the GLG. In nonirradiated left lung, GLPG *(green area)* was equal to GLG. **C.** In non-irradiated lung, GLPG is equal to GLG. In irradiated lung, PVC GLPG shows statistically significant changes between baseline and follow-up studies (PVC GLPG = GLG − PVC TLG). factor, PD-L1 expression and nivolumab plasma concentration could not precisely predict the early therapeutic efficacy of nivolumab.[251]

In a larger study, FDG-PET/CT scans were used to evaluate response to the anti–programmed death ligand 1 (anti-PD-L1) agent atezolizumab in 103 patients with NSCLC. Patients with an early FDG response at 6 weeks according to the European Organization for Research and Treatment of Cancer (EORTC) criteria (the first metabolic PET criteria for solid tumors)[252] achieved a higher objective response rate on subsequent CT than metabolic nonresponders (17 of 23 [73.9%] vs. 5 of 80 [6.3%]).[253]

Small-Cell Lung Carcinoma

Small-cell lung carcinoma (SCLC) accounts for about 13% of cases of lung cancer[254] and has a high proliferation rate that results in avid FDG uptake.[255] At presentation, patients are considered to have either limited disease (LD) (tumor confined to ipsilateral hemithorax and regional nodes able to be included in a single tolerable radiotherapy port) or extensive disease (ED) (tumor beyond the boundaries of limited disease, including spread to contralateral chest or distant metastases, malignant pericardial, or pleural effusion). At presentation, about 60% to 70% of patients present with ED, while about 30% to 40% of patients have LD. Except in rare cases of surgically operable, limited-stage SCLC, patients with LD receive chemotherapy and radiation vs. chemotherapy alone for ED.

The role of FDG-PET in staging of SCLC is not as widely studied as for NSCLC. Most reports are retrospective and include small number of patients.[256–260] The major impact that PET has on SCLC is that it can change management in up to 37% of patients for initial staging, and in up to 15% of patients for restaging.[255] Complete metabolic response on posttherapeutic FDG-PET/CT in patients with SCLC is an important prognostic factor, as overall survival is significantly longer than for patients who do not have complete response.[261] A recent systematic review and meta-analysis (9 articles until June 2019 with 721 patients) found a better diagnostic accuracy of FDG-PET/CT for staging SCLC compared with conventional staging.[262] A change of the binary SCLC staging (LD vs. ED) was found in 15% of patients.[262] Whether FDG-PET/CT improves survival in patients with SCLC remains uncertain and will require large prospective studies.

Mesothelioma

Benign fibrous mesothelioma is a rare, nonmalignant, localized tumor of the pleura that is unrelated to asbestos exposure. The tumor can be cured by excisional surgery. In contrast, malignant

pleural mesothelioma (MPM), although rare, is the most common primary pleural neoplasm. Patients affected with this disease have a median survival of 12 to 18 months. Thus, it is important to differentiate between benign pleural lesions and MPM.

The radiologic appearances of benign and malignant pleural diseases are very similar. More than 50% of patients have a pleural effusion at the time of diagnosis; however, pleural fluid cytology is positive in only approximately 25%.[263] Reverse-bevel needle biopsy and CT-guided percutaneous needle biopsy of the pleura have low diagnostic sensitivities of about 21% to 43% and 25% to 60%, respectively.[263] Distinction based on histopathologic criteria is also difficult. Currently, definitive diagnosis is based on video-assisted thoracoscopic surgery (VATS)

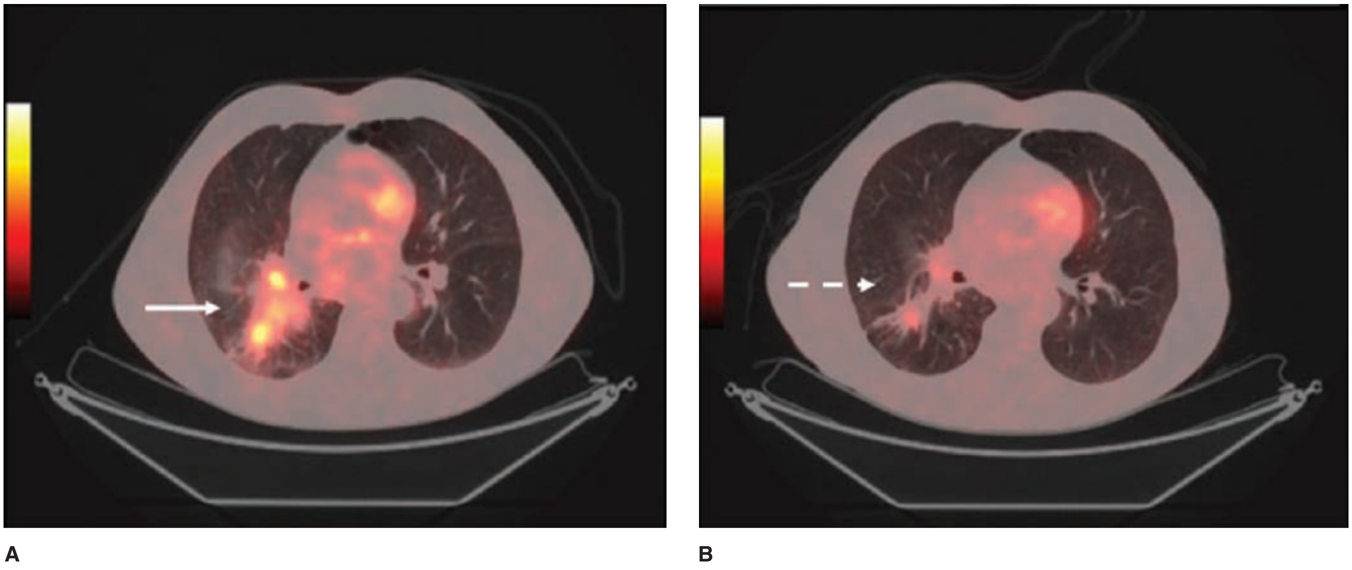

Figure 30-23 Treatment response in lung cancer. Fused transaxial PET/CT scan (**A**) at baseline shows marked FDG uptake in a tumor in the right lung hilum and mediastinal lymph nodes *(solid arrows)*. Repeat scan (**B**) after three cycles of chemotherapy reveal marked response to treatment *(interrupted arrows)*.

(sensitivity, 90%) which, for MPM, carries the risk of tumor seeding along the operative tract. Therefore, radiation therapy is performed to all entry ports following the procedure.

CT scanning and MRI cannot always differentiate between benign and malignant pleural processes and are limited in staging of MPM.[264] Findings from CT and MRI studies can be used in tandem with those from FDG-PET in managing these difficult patients (Fig. 30-24). The use of FDG-PET in mesothelioma in the mid-1990s provided a paradigm shift in the management of patients with this serious cancer.[265]

Because of the rarity of this disease, only limited studies have been performed, but FDG-PET has shown promising results in differentiating MPM from benign pleural disease. FDG uptake in MPM is significantly greater than in benign pleural disease.[266] For the first time, this approach allowed separation of a malignant etiology from that purely related to inflammatory reactions. This significantly improved the ability to determine the sites of biopsy in this population.

The degree of metabolic activity of the lesion has been shown to correlate with survival in these patients;[267] higher FDG uptake in MPM is associated with significantly shorter survival.[264] Using single SUV cutoff technique, however, may not be the optimal approach for this purpose. Dual-timepoint imaging and SUV_{max} on PET/CT in the delayed phase (120 min) have been found to be more reliable diagnostic and prognostic factors than that in the early phase (60 min).[268] By performing dual-timepoint imaging, the role of FDG-PET is further enhanced in this population.[269] This approach allows separating malignant from inflammatory lesions. While malignant lesions show increasing activity over time, inflammatory lesions show a decline. In recent years, the use of global disease assessment has become feasible with modern quantitative techniques.[270] These image segmentation methodologies permit better definition of the boundaries of malignant lesions based on PET images and provide assessments of lesional and whole-body metabolic burden.[270]

In addition to differentiating benign from malignant pleural disease and MPM prognosis, FDG-PET has shown good results in staging, planning of radiotherapy, evaluation of therapy response, and posttreatment surveillance.[270] For diagnosed cases, PET/CT currently plays an integral part in staging[271] since it has a better sensitivity than CT in the assessment of mediastinal lymph nodes.[272,273]

Several relatively small studies have shown the advantage of FDG-PET/CT over CT when determining whether a tumor is resectable. FDG-PET was found to be useful in identifying the extent of disease in the mediastinum, evaluating abnormal findings in the contralateral lung, and detecting occult extrathoracic metastases.[274–276] In a study of 29 patients, FDG-PET/CT had a major impact on increasing the accuracy of MPM TNM staging and determining appropriate therapy.[277] In one series of 42 consecutive patients with potentially resectable disease, 29% of cases (12 patients) were upstaged and made inoperable due to unexpected T4 or distant metastasis.[275]

Current consensus recommendations regarding response assessment are based on contrast-enhanced CT scanning with 1-mm sections for evaluation of local disease, or MRI with contrast and FDG-PET/CT staging. The metabolic response after neoadjuvant chemotherapy as determined by FDG-PET has been found to be an independent prognostic factor for patients with resectable MPM and may help determine which patients are good candidates for extrapleural pneumonectomy.[278]

CHAPTER 31

Pulmonary Function Testing

Michael A. Grippi
Gregory Tino

INTRODUCTION

The assessment of human pulmonary function dates back to the seventeenth century, when the earliest measurements of tidal volume were noted. In 1800, Humphry Davy employed a hydrogen dilution technique to measure his own residual volume (RV).[1] Subsequently, John Hutchinson, in his treatise, *On the Capacity of the Lungs and on Respiratory Functions*, defined the functional subdivisions of lung volume and reported the results of vital capacity measurements performed in more than 1800 subjects. He related these measurements to the subjects' height, age, and weight, thereby establishing a basis for determining normal values.[2,3]

Progress in development of techniques for pulmonary function testing progressed slowly over the next century. However, in the 1950s, pulmonary physiologists made use of the tools provided by the evolving fields of electronics and computer science. Currently, many techniques exist for assessing both the integrated performance of the cardiovascular and respiratory systems and their individual components. This chapter focuses on commonly used tests of pulmonary function.[4–6]

Detailed assessment of integrated pulmonary and cardiovascular function is described in Chapter 32. Additional tests that have not yet been validated or are not routinely available for clinical purposes[7] are not included in the discussion.

LUNG VOLUMES AND SUBDIVISIONS

Important quantitative aspects of respiratory function are the changes in lung volume with inspiration and expiration and the absolute volume of air that the lungs hold at various times during the respiratory cycle. These volumes and changes in volume are described in subsequent sections.

Definitions and Assessment

For purposes of quantification and comparison, the total volume of gas in the lungs is conventionally subdivided into compartments (volumes) and combinations of two or more volumes (capacities). For many of these subdivisions, the end-expiratory volume—the volume of gas remaining in the lungs at the end of normal expiration—is the point of reference. Lung volumes and capacities are defined in Table 31-1 and are depicted schematically in the tracing shown in Fig. 31-1, which was obtained using a device called a spirometer. The relationships between the volumes recorded directly by the spirometer and the other lung volumes and capacities—including total lung capacity (TLC), functional residual capacity (FRC), RV, and inspiratory capacity (IC)—are highlighted in the figure.

Spirometers that measure volume or change in volume versus time have been used extensively in pulmonary function laboratories. Previously, through manual calculations, or, in modern times, through application of microprocessors, the relationships among volume, flow, and time are generated to provide a measure of the respiratory system's ability to move air. Two examples of volume-type spirometers of historic note are shown in Fig. 31-2. They are discussed briefly to highlight the ingenuity behind their use in determining clinically important physiologic measurements.

In the water-sealed spirometer (Fig. 31-2A), a mouthpiece is attached to a tube through which air passes into a lightweight bell that is inverted over a water bath. Air movement through the mouthpiece into the bell during expiration causes the bell to rise; conversely, as air is withdrawn from the system during inspiration, the bell falls. The change in volume with time can be recorded on a calibrated rotating drum or digitally noted by a computer and displayed on a screen in both graphic and numeric formats.

In the dry, rolling-seal spirometer (Fig. 31-2B), a cylinder with a rolling plastic seal is substituted for the spirometer bell and its water seal. Movement of air through the mouthpiece effects a change in the position of the piston, which is attached to a variable resistor. The resistor, in turn, generates voltage signals proportional to volume changes reflected in displacement of the piston. These signals are processed by a computer to generate graphic and numeric outputs similar to those of the water-sealed spirometer.

Currently, most pulmonary function laboratories utilize flow-type spirometers using pneumotachographs or rotating turbines to determine airflow. Two types of pneumotachographs are in general use: hot wire and flow resistive. In the hot-wire type, air flowing past a heated wire cools the wire, thereby altering its resistance

TABLE 31-1 Glossary for Static Lung Volumes and Capacities

Term	Symbol	Definition
Volumes		
Residual volume	RV	Volume of air remaining in the lungs after maximal expiration
Expiratory reserve volume	ERV	Maximal volume of air expired from the resting end-expiratory level
Tidal volume	TV[a]	Volume of air inspired or expired with each breath during quiet breathing
Inspiratory reserve volume	IRV	Maximal volume of air inspired from the resting end-inspiratory level
Capacities		
Inspiratory capacity	IC	Maximal volume of air inspired from the end-expiratory level (the sum of IRV and TV)
Vital capacity	VC	Maximal volume of air expired form the maximal inspiratory level
Inspiratory vital capacity	IVC	Maximal volume of air inspired form the maximal expiratory level
Functional residual capacity	FRC	Volume of air remaining in the lungs at the end-expiratory level (the sum of RV and ERV)
Total lung capacity	TLC	Volume of air in the lungs after maximal inspiration (the sum of all volume compartments)

[a] *The symbol TV is traditionally used for tidal volume to indicate a subdivision of static lung volumes. However, the symbol* V_T *is used for tidal volume in formulas for gas exchange.*

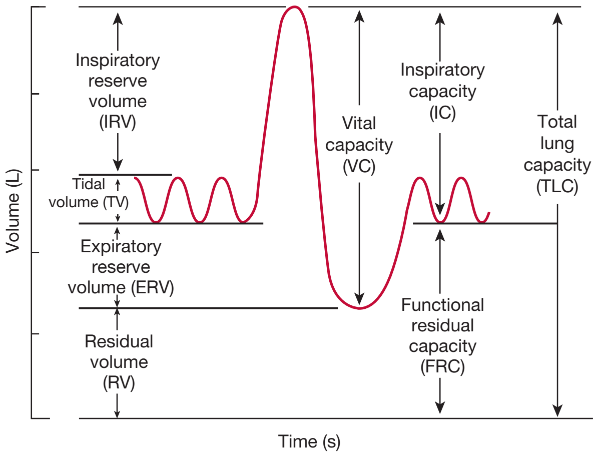

Figure 31-1 The subdivisions of lung volume as recorded by a spirometer. The record is generated on paper calibrated for volume in the vertical direction and time in the horizontal. The term *capacity* is applied to a subdivision composed of two or more *volumes*. The definitions of these subdivisions are found in Table 31-1.

in proportion to changes in airflow. Flow-resistive pneumotachographs contain a resistive element composed of parallel tubes (Fig. 31-3), a wire mesh, or a fibrous, paper-like element. Airflow through the resistive element results in a pressure gradient across the device, which can be measured by a very sensitive differential pressure gauge. In the model depicted in Fig. 31-3, the array of parallel, small-bore tubes maintains a laminar gas flow pattern through the pneumotachograph. As a result, the pressure–flow characteristics of the system can be described by Poiseuille's law:

$$\Delta P = \dot{V}\,\frac{8\eta l}{\pi r^4}$$

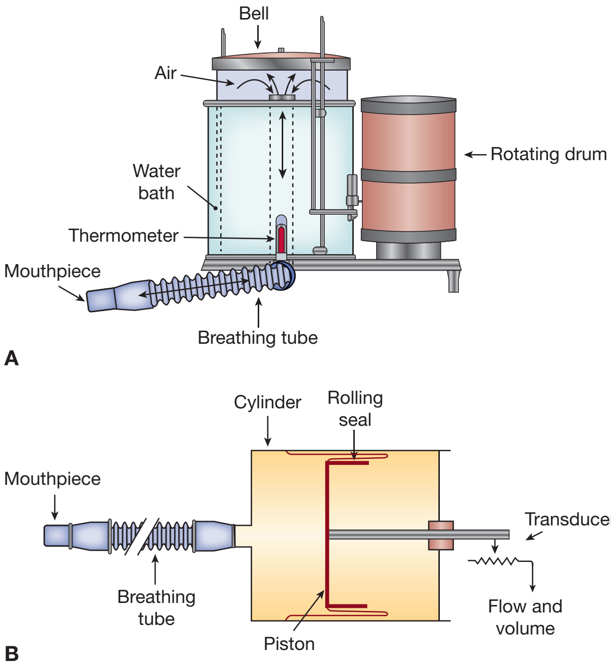

Figure 31-2 Two types of spirometers: water sealed (**A**) and dry rolling seal (**B**). Movement of air through the breathing tube results in movement of the bell (**A**) or piston (**B**). The output signal is either mechanical (pen on rotating drum) or electrical (flow and volume as voltage changes). The primary design criteria for these instruments are that inertia and resistance to airflow must be held to negligible levels, and the calibration must be accurate and stable.

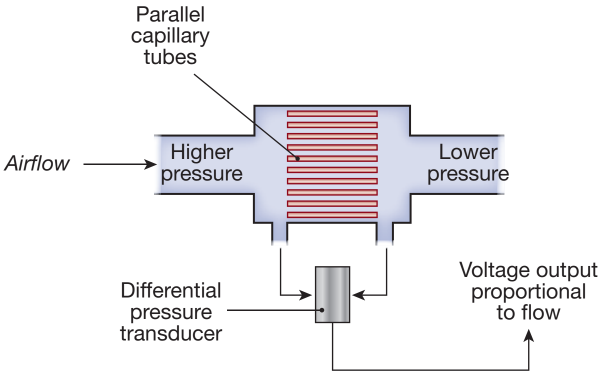

Parallel capillary tubes
Airflow
Higher pressure
Lower pressure
Differential pressure transducer
Voltage output proportional to flow

Figure 31-3 Principle of pneumotachography. During unidirectional airflow, a pressure drop is created across a resistive element made up of an array of parallel capillary tubes. The magnitude of the pressure drop is related to airflow, as described by Poiseuille's law for a laminar flow system. The pressure drop is transduced to a proportional voltage output, which can be recorded. A heating element (not shown) maintains the temperature of the expired gas near body temperature.

where

ΔP = pressure drop across the resistive element, dyn/cm^2
$\dot{V}$ = gas flow, cm^3/s
η = viscosity of gas, dyn s/cm^2
l = length of resistive element, cm
r = radius of resistive element, cm

Hence, under laminar flow conditions, the flow of gas in each tube is proportional to the pressure drop across the tube. The calculation for the overall pressure drop across the entire resistive element is based on the parallel arrangement of the array of tubes. The pressure drop across the resistive element is sensed by a pressure transducer and converted to a voltage output that is proportional to flow. The flow signal can be integrated electronically to yield volume. The output signals for flow and volume are displayed on a monitor and recorded. Minimal standards have been established by the American Thoracic Society (ATS) and the European Respiratory Society (ERS) (Table 31-2) for spirometers used either for diagnostic purposes or patient monitoring.[8–10]

In a diagnostic setting, spirometers are used to (1) evaluate symptoms, signs, or abnormal laboratory tests; (2) measure the effect of disease on pulmonary function; (3) screen persons at risk of having pulmonary disease; (4) assess preoperative risk; (5) assess prognosis; and (6) assess health status before enrollment in strenuous physical activity programs.

On the other hand, spirometers used for patient monitoring are used to (1) assess therapeutic interventions, including bronchodilator therapy, management of congestive heart failure, etc.; (2) characterize the course of diseases affecting lung function (e.g., obstructive or interstitial lung diseases, congestive heart failure, or neuromuscular diseases); (3) track pulmonary function in persons working in occupations or receiving medications known to affect the lung; (4) evaluate large numbers of people in disability assessments; and (5) provide data as part of epidemiologic surveys.[10]

In general, the diagnostic spirometer is used to assess a patient's lung function for purposes of comparison with values expected in a normal population. The monitoring spirometer, which is less expensive and more portable, is used to evaluate a patient's performance over time and to study large numbers of people for epidemiologic or other purposes.

■ The Vital Capacity and Its Subdivisions

Two methods of performing a vital capacity maneuver can be used: closed-circuit and open-circuit methods. In the closed-circuit

TABLE 31-2 Minimal Recommendations for Diagnostic Spirometry

Test	Range/Accuracy (BTPS)	Flow Range (L/s)	Time (s)	Resistance and Back Pressure	Test Signal
VC	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	30		3-L cal syringe
FVC	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	15	<1.5 cmH_2O/L/s	24 standard waveforms 3-L cal syringe
FEV_1	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	1	<1.5 cmH_2O/L/s	24 standard waveforms
Time zero	The time point from which all FEV_t measurements are taken			Back extrapolation	
PEF	Accuracy: ± 10% of reading or ± 0.30 L/s, whichever is greater Precision: ± 5% of reading or ± 0.15 L/s, whichever is greater	0–14		Mean resistance at 200, 400, 600 L/s must be <2.5 cmH_2O/L/s	26 flow standard waveforms
$FEF_{25–75\%}$	7.0 L/s ± 5% of reading or ± 0.200 L/s, whichever is even greater	±14	15	Same as FEV_1	24 standard waveforms
Instantaneous flows	±5% of reading or 0.200 L/s, whichever is greater	0–14		<1.5 cmH_2O/L/s	Proof from manufacturer
MVV	250 L/min at TV of 2 L within ± 10% of reading or ± 15 L/min, whichever is greater	±14 ± 3%	12–15	<1.5 cmH_2O/L/s	Sine wave pump

BTPS, body temperature and pressure, saturated with water vapor; VC, vital capacity; FVC, forced expiratory vital capacity; FEV_1, forced expiratory volume in 1 s; PEF, peak expiratory flow; $FEF_{25–75\%}$, forced expiratory flow, 25–75%; MVV, maximal voluntary ventilation; TV, tidal volume.
Reproduced with permission from Miller MR, Hankinson J, Brusasco V, et al. Standardisation of spirometry. Eur Respir J. 2005;26(2):319–338.

method, the seated patient, with nose clip in place, breathes quietly into the apparatus. After several breaths to establish the resting end-expiratory level, which serves as a point of reference for all subsequent measurements, the patient is urged to inspire fully and then, after reaching a plateau at maximal inspiration, to expire maximally. This expiration must be performed slowly and evenly; attempts by the patient with obstructive pulmonary disease to maximize flow often reduce expiratory volumes because of dynamic compression of the airways caused by high positive pleural pressures (see Chapter 10). Figure 31-1 illustrates schematically this relaxed or "slow" vital capacity maneuver. From the record, tidal volume, inspiratory reserve volume, expiratory reserve volume (ERV), vital capacity, and IC are calculated. A similar maneuver in which the subject breathes out as rapidly and forcefully as possible after a maximal inspiration provides a measure of the forced vital capacity (FVC). Other timed measurements of expiratory airflow (e.g., the forced expiratory volume in 1 s, or FEV_1) also are determined from this type of record (see "Dynamic Mechanical Properties of the Respiratory System," below).

In the open-circuit method of determining vital capacity, the patient inspires maximally, inserts the mouthpiece, and then exhales with a slow, constant effort to the point of maximal expiration. With this technique, the resting end-expiratory position is not recorded. Thus, only the vital capacity, not its component volumes, can be measured. The open-circuit technique offers some advantages. Since the patient inspires from room air before expiring into the apparatus, concern over acquisition of infection from contaminated inspired air is minimized. In addition, the open-circuit method is generally completed in a shorter time, providing a major advantage when epidemiologic studies are being performed on large numbers of subjects.

■ Functional Residual Capacity and Residual Volume

One compartment of the TLC that cannot be measured by spirometry is RV, the volume of air remaining in the lungs at the end of a maximal expiration. RV is determined indirectly in three steps: (1) FRC is typically measured using one of the three techniques: closed-circuit helium, open-circuit nitrogen, or total-body plethysmograph. (2) ERV is determined spirometrically. (3) RV is calculated as the difference between FRC and ERV. In principle, it is possible to determine the RV using a dilution technique or body plethysmography after maximal expiration. In practice, however, the resting end-expiratory level is a more reproducible starting point for determining FRC than is the maximal end-expiratory level for determining RV.

Closed-Circuit Helium Method

The closed-circuit helium dilution method for determining FRC is a variation of the hydrogen dilution method first used in the early 19th century. Both methods take advantage of the virtual insolubility of the test gas in body tissues and the law of conservation of mass. The development and simplification of this test were accomplished over a 20-year span in the mid-20th century. Schematic depictions of the principle upon which the technique is based and the apparatus used are shown in Fig. 31-4.

When a fully manual device is used for measuring FRC, the system is prepared by the addition of about 2 L of air and sufficient helium to achieve an initial helium concentration of approximately 10% in the apparatus. The patient, with nose clip in place, then breathes room air through the mouthpiece (Fig. 31-4A). After a preliminary period of quiet breathing to familiarize the patient with the mouthpiece, apparatus, and environment, and after the baseline resting end-expiratory level is established, the test begins.

At the end of a normal expiration, the valve at the mouthpiece is turned to connect the patient to the spirometer system (Fig. 31-4B). As the patient rebreathes from the closed circuit, the blower circulates the gas mixture. The CO_2 is absorbed by soda lime (CO_2 absorber), while O_2 is added through a valve and flowmeter at a rate corresponding to the subject's O_2 consumption. As the helium, which was at first contained entirely within the apparatus, mixes with air contained in the lungs, its concentration, as monitored by

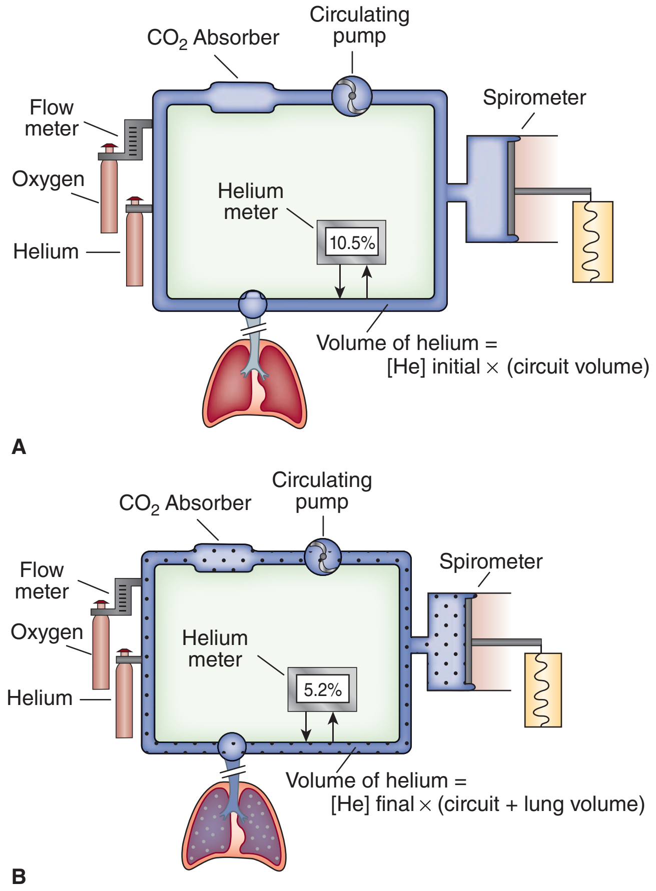

Figure 31-4 Closed-circuit helium dilution method for measurement of FRC. **A.** Spirometer and tubing system with helium before subject begins breathing through the circuit. At the end of an expiration, the mouthpiece valve is turned and the patient rebreathes through the circuit. Expired CO_2 is "scrubbed" out of the system, and O_2 is added to compensate for continued O_2 uptake in the lungs. **B.** During equilibration, the measured helium concentration falls, reflecting a dilutional effect of the additional volume (FRC) on the spirometer circuit.

the helium analyzer, falls. Stabilization of the helium concentration, indicated by a rate of change in concentration of less than 0.02% over a 30-s interval, signals the point at which the helium concentration has equilibrated throughout the lung-breathing circuit system; equilibration, the endpoint of the test, occurs within 7 min in normal persons. However, in patients in whom the distribution of ventilation is abnormal—for example, those with chronic obstructive pulmonary disease (COPD)—equilibration may take much longer. Upon equilibration, the following equation, based on the law of conservation of mass, is applied:

$$F_{0He} \times V_0 = F\mathrm{F}_{He} \times V\mathrm{F}$$

where

F_{0He} = initial concentration of helium
V_0 = initial volume of system, L
$F\mathrm{F}_{He}$ = final concentration of helium
$V\mathrm{F}$ = final volume of system, L

The initial volume of the system is the volume of the spirometer and circuit tubing, whereas the final volume consists of the initial volume plus FRC. The latter value is the only unknown in the preceding equation. Corrections are usually made for the small amount of helium dissolved in body tissues during the test and for slight volume changes caused by a respiratory exchange ratio that is not equal to 1.0.[11] Although the method described here is based on a manually operated device, the same principles hold when all the mechanical and computational steps are accomplished with a computer-controlled system.

Nitrogen Washout Method

Conceptually, the nitrogen washout method is similar to the helium dilution method described previously; however, it relies on an open circuit, rather than the closed circuit, used in the helium dilution method. The open-circuit nitrogen washout method for determining FRC[12] requires that the subject breathe 100% O_2 for 7 min; during this period, the concentration of N_2 in expired gas is monitored. When the expired N_2 concentration falls to zero, all the N_2 present in the lungs at the start of O_2 breathing has been "washed out." The total volume of gas expired and the concentration of N_2 in the expired gas are measured.

The calculation of FRC is based on the reasonable assumption that the volume of N_2 in the lungs at the start of the test (i.e., the product of lung volume and the concentration of N_2 in the lungs) is the same as the total volume of N_2 expired and collected during the period of the test—that is, the product of the total volume of gas expired and the concentration of N_2 in the expired gas:

$$F_{0_{N_2}} \times V_0 = F_{\mathrm{E}_{N_2}} \times V\mathrm{E}$$

where

$F_{0_{N_2}}$ = concentration of N_2 in the lungs
V_0 = volume of gas in the lungs, L
$F_{\mathrm{E}_{N_2}}$ = concentration of N_2 in the expired gas
$V\mathrm{E}$ = volume of expired gas, L

Since the test is started at the end of a quiet expiration, the volume of gas in the lungs is FRC. This volume is calculated by substituting into the above equation the initial concentration of N_2 in the lungs, estimated at 0.81 in fasting and 0.79 to 0.80 in nonfasting subjects, and the measured values for volume and N_2 concentration of expired gas.

Body Plethysmography

The word *plethysmography* is derived from the Greek *plethysmos*, meaning "enlargement." Although the concept of measuring FRC by recording changes in the volume of the body during "enlargement" of the chest was described in 1882, not until 1956 did DuBois and coworkers introduce a practical plethysmographic technique, based on Boyle's law, for determining thoracic gas volume (TGV).[13]

Any of three types of body plethysmographs can be used: (1) the *pressure plethysmograph*, in which pressure during breathing varies while volume remains constant; (2) the *volume plethysmograph*, in which volume varies during breathing while pressure remains constant; and (3) the *pressure-corrected flow plethysmograph*, which couples the pressure plethysmograph's fidelity of response to high-speed events with the volume plethysmograph's ability to follow large changes in volume. Since the conceptual basis for all three devices is similar, only the most popular one—the pressure plethysmograph—will be described.

The pressure plethysmograph (Fig. 31-5) contains a pneumotachograph and transducer for measuring flow and volume, and two strain-gauge transducers, one for sensing pressure at the mouth (Pm) and the other for sensing pressure in the box (Pbx). A solenoid-operated shutter mechanism is situated between the mouthpiece and the pneumotachograph. The three transducers are connected to an amplifying and monitoring system so that box pressure (or lung volume) and mouth pressure are displayed simultaneously on the X and Y axes, respectively, of an oscilloscope (Fig. 31-6).

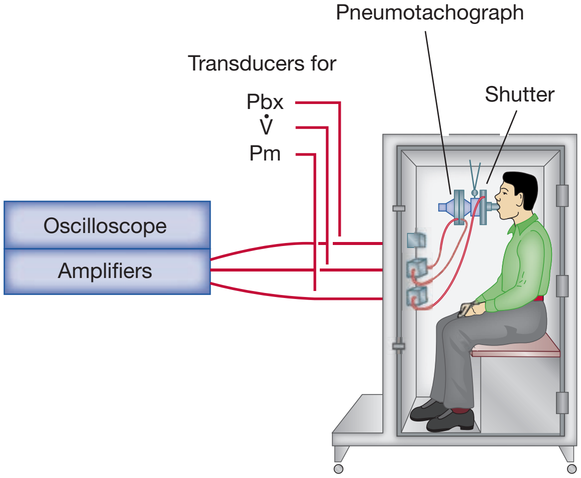

Figure 31-5 Constant-volume, variable-pressure plethysmograph used for measuring functional residual capacity and airway resistance. The device has a fixed volume. Thoracic gas volume changes associated with changes in alveolar pressure are reflected as changes in pressure within the plethysmograph.

In order to determine FRC, the patient, seated comfortably within the box with nose clip in place, is asked to breathe quietly through the mouthpiece. At the end of a quiet expiration, the shutter is closed, and the patient is instructed to pant gently against it. The panting movements cause both mouth pressure and box pressure to change. With each inspiratory effort, as mouth pressure falls and gas in the lungs is rarefied, lung volume increases. Because the plethysmograph is a closed box, the increase in lung volume produces a corresponding increase in box pressure. With each expiratory effort, as lung volume decreases, box pressure falls. Because the shutter is closed while the measurements are made, mouth pressure equals alveolar pressure (PA). These oscillations in mouth pressure and box pressure or lung volume appear on the oscilloscope as a closed loop (Fig. 31-6). Measurement of the slope of this loop is used to determine the volume of gas in the lungs at the time of shutter closure—that is, TGV or V_{TG}. When the occlusion occurs at resting, end-expiratory lung volume, the measurement yields FRC (see below).

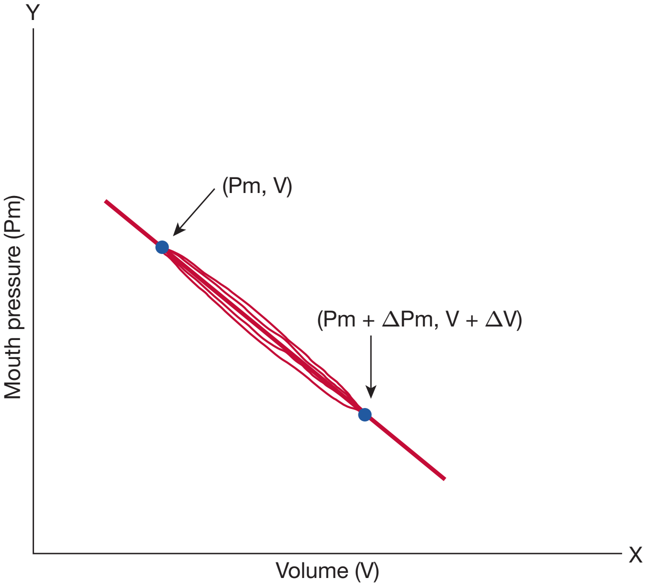

Figure 31-6 Pressure–volume loop obtained from a person seated in a body plethysmograph. Pressure at the mouth represents alveolar pressure; pressure in the box represents thoracic gas volume. After the shutter has closed at end-expiration (Pm, V), the subject attempts to inspire. Pm falls, and the pressure in the box increases. This increase in box pressure is calibrated in terms of an equivalent volume change. The new position of the trace at the end of the inspiratory effort is (Pm + ΔPm, V + ΔV). The slope of the loop depends on the volume of gas in the lungs when the shutter is closed (FRC).

Applying Boyle's law to the plethysmographic determination of lung volume,

$$PV = (P + \Delta P)(V + \Delta V)$$

where

P = pressure in the lungs at end-expiration (atmospheric pressure), cmH_2O
ΔP = change in pulmonary pressure produced by respiratory efforts, cmH_2O
V = volume of gas in the lungs at end expiration (FRC), L
ΔV = change in gas volume in the lungs produced by compression (during expiration) and rarefaction (during inspiration) secondary to respiratory efforts, L

In the pressure plethysmograph, ΔV is sensed as a change in pressure within the box, and ΔP is determined from the change in mouth pressure during breathing efforts against the closed shutter.

Rearranging the above equation and solving for V yields

$$V = \frac{\Delta V}{\Delta P}(P + \Delta P)$$

However, since ΔP is small compared to P (atmospheric pressure), it may be disregarded. The equation then becomes

$$V = P \times \frac{\Delta V}{\Delta P}$$

where

V = functional residual capacity, L
P = atmospheric pressure, cmH_2O
$\Delta V/\Delta P$ = inverse of slope of the loop on the oscilloscope

Therefore, the only unknown in this equation is V, which can be calculated by incorporating values for barometric pressure and the inverse of the slope of the plot of mouth pressure versus box pressure (ΔP/ΔV).

Two methods for measuring static lung volumes using plethysmography have been standardized by the ATS and ERS. One entails shutter closure at FRC, followed by expiration to RV, and then an IC maneuver to TLC; the other method is shutter closure at FRC, followed by an IC maneuver to TLC, and then an expiratory vital capacity maneuver to RV.[14] Application of each method may yield different calculations of lung volumes.[15]

Comparison of Methods

Compared with the dilution and washout techniques, body plethysmography is, by far, the fastest method available for determining FRC. Indeed, it enables several determinations to be made per minute. Although the equipment required for body plethysmography is more expensive than that required for the other methods, in a busy laboratory this technique generally proves to be more economical because of the time saved and the additional uses to which the equipment can be put (e.g., measurement of airway resistance; see "Airway Resistance," below). Technically, the test is only slightly more difficult than the inert gas dilution method.

Sources of error inherent in the use of body plethysmography and discrepancies between results obtained by body plethysmography and the inert gas techniques should be noted. In patients with COPD[16] or asthma,[17] values for FRC obtained by body plethysmography may be artifactually high because of pressure differences between the mouth and alveoli generated during panting across narrowed airways. Consequently, pressures recorded at the mouth during shutter occlusion of the airway underestimate changes in alveolar pressure. Overestimation of TLC using body plethysmography appears to be greatest in patients whose FEV_1 (see below) is less than 30% predicted.[18]

The inert gas dilution and washout methods are similar both in principle and in results. The values for FRC with these techniques match those from the body plethysmograph except in persons in whom considerable areas of the lungs are poorly ventilated, usually due to obstructive airway disease. In these individuals, complete mixing or washout of the indicator gas is very slow, at times requiring 45 min or longer. Because of the slow equilibration of gas concentrations in the poorly ventilated areas, the usual time allotted for the test is inadequate, resulting in a lower value for FRC by the washout methods than by body plethysmography. One strategy commonly used to deal with this problem is to prolong the washout time. The primary advantage of these techniques over body plethysmography is that they can be used in persons for whom the plethysmograph is impractical—for example, those with marked obesity, skeletal abnormalities, or claustrophobia.

Temperature Correction Factors

By convention, all lung volumes previously described and airflows (see below) are expressed in terms of body temperature and pressure, saturated with water vapor (BTPS). This practice enables direct comparison of pulmonary function data from laboratories operating at different ambient temperatures and altitudes. To convert the volume of gas collected in a volume-type spirometer under ambient conditions (i.e., ambient temperature and pressure, saturated with water vapor, or ATPS) to BTPS, a conversion factor is applied (Table 31-3). Previously, it was presupposed that air entering a spirometer was cooled *immediately* to ambient temperature and remained saturated with water vapor (ATPS). Under this assumption, only ambient temperature was considered in determining the appropriate correction factor. However, studies have addressed the assumption that expired gas is immediately cooled,[19,20] as well as the practical consequences of temperature correction errors. The ATS recommends temperature correction of results from volume-type spirometers based on *measured* gas temperature at the time of testing.

TABLE 31-3 Factors for Converting Volumes from ATPS to BTPS at Barometric Pressure of 760 mm Hg[a]

Ambient Temperature (°C)	Multiplier to Convert Volumes to BTPS[b]
20	1.101
21	1.096
22	1.091
23	1.085
24	1.080
25	1.074
26	1.069
27	1.062

[a] *Based on Boyle's, Charles's, and Dalton's laws.*
[b] *Volume at ATPS × multiplier = volume at BTPS.*
ATPS, ambient temperature and pressure, saturated with water vapor; BTPS, body temperature and pressure, saturated with water vapor.

Radiographic Assessment of Lung Volume

Although initial reports describing use of radiographic techniques to measure lung volumes date back over 40 years, these methods have not found widespread use in adult populations. More sophisticated computed tomographic (CT) applications have demonstrated good correlation with plethysmographic and gas dilution techniques in normals. However, significant differences may be observed in patients with COPD,[21] in whom TLC determinations using plethysmography may be up to 2 L greater than TLC assessed with CT scanning.[22]

STATIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

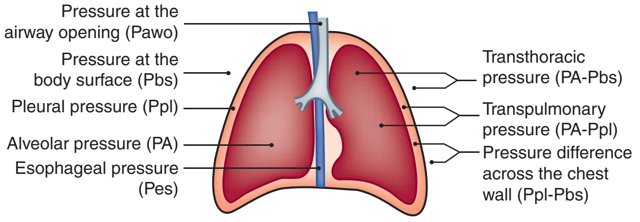
Exploration of the elastic properties of the respiratory system and their effect on lung volumes and work of breathing began in earnest during the earlier part of the 20th century. Although the groundwork had been laid centuries before (by Robert Hooke's *The Theory of Springs* in 1678), between 1923 and 1956 investigators provided a wealth of information about the elastic properties of the respiratory system and its components and the work done in overcoming these elastic forces during breathing.

Static Compliance of the Lungs

The elastic properties of the lungs are determined by relating the change in the volume of air contained in the lungs to the corresponding change in the recoil force of the lungs. Change in lung volume is most easily measured by determining the volume of gas inspired or expired at the mouth. Although expedient, this approach to determining the elastic properties of the lungs can underestimate the change in lung volume when incorporated into techniques (see below) that require the subject to expire gently against a closed shutter, a maneuver that compresses thoracic gas. However, the problem can be circumvented by placing the subject in a volume plethysmograph that uses a spirometer attached to the plethysmograph to record changes in TGV due to gas compression.

The recoil force of the lungs, measured as the transpulmonary pressure (Fig. 31-7), is the difference between the alveolar and pleural pressures (PA and Ppl, respectively). Alveolar pressure is determined as the pressure at the airway opening (Pao)—that is, the mouth—when airflow is arrested and the glottis is open. The pleural pressure is determined indirectly by measuring the pressure in the esophagus using an esophageal balloon catheter. This technique, first introduced in 1949, has been improved over the years and provides accurate reflections of changes in pleural pressure at all lung volumes except those below FRC.[23]

A thin rubber balloon, about 10 cm long, is placed over a small-diameter polyethylene catheter. Several holes in the terminal portion of the catheter allow pressure to be transmitted from the balloon, through the catheter, to a transducer. The balloon is positioned in the lower third of the esophagus, where esophageal pressure and,



Pressure at the airway opening (Pawo)
Pressure at the body surface (Pbs)
Pleural pressure (Ppl)
Alveolar pressure (PA)
Esophageal pressure (Pes)
Transthoracic pressure (PA-Pbs)
Transpulmonary pressure (PA-Ppl)
Pressure difference across the chest wall (Ppl-Pbs)

Figure 31-7 Schematic representation of the chest depicting pressure terms and gradients used in analysis of the mechanics of breathing. The expressions for individual pressure measurements on the left are relative to atmospheric pressure. Pleural pressure (Ppl) is not routinely measured directly but is approximated by esophageal pressure (Pes) measured with a balloon catheter.

therefore, balloon pressure accurately reflect the pressure acting on the lung surface (pleural pressure). Use of an elongated balloon of low volume helps to minimize changes in pressure due to esophageal contractions. By conveying mouth pressure and esophageal pressure to opposite sides of a differential pressure transducer, an output signal is generated that is proportional to the difference between these two pressures—that is, the transpulmonary pressure (PA – Ppl).

To determine the elastic properties of the lungs, the patient, with esophageal balloon in place, is seated in a closed body plethysmograph. The patient then breathes ambient air through a tube to the outside until the volume trace, inscribed by the plethysmograph spirometer, indicates that the end-expiratory level is stable. At this juncture, the patient is instructed to first inspire slowly to TLC and then to expire slowly to the resting end-expiratory level (FRC). This maneuver is then repeated; during the second expiration, the shutter is activated to occlude the airway intermittently. Since each closure of the shutter interrupts the expiration briefly, the recorded trace of expiratory volume versus time displays a staircase pattern (Fig. 31-8A). The plateau resulting from each closure of the shutter marks a finite period of zero change in lung volume as the lungs empty during expiration. Associated with each plateau is a corresponding plateau in transpulmonary pressure.

The relationship between the change in volume and the change in pressure is a measure of the *recoil force* of the lungs at each of the lung volumes that are registered (Fig. 31-8B). The resulting curve provides several useful indices of the elastic behavior of the lungs. The slope of the curve over the range corresponding to the tidal volume is the *static lung compliance.* The transpulmonary pressure attained at TLC is the *maximal static recoil pressure.* The ratio of the maximal static recoil pressure to the corresponding maximal lung volume is the *coefficient of retraction.* However, since these values are derived from only small segments of the curve, inspection of the total static pressure–volume curve remains the most comprehensive means of assessing the elastic properties of the lungs.

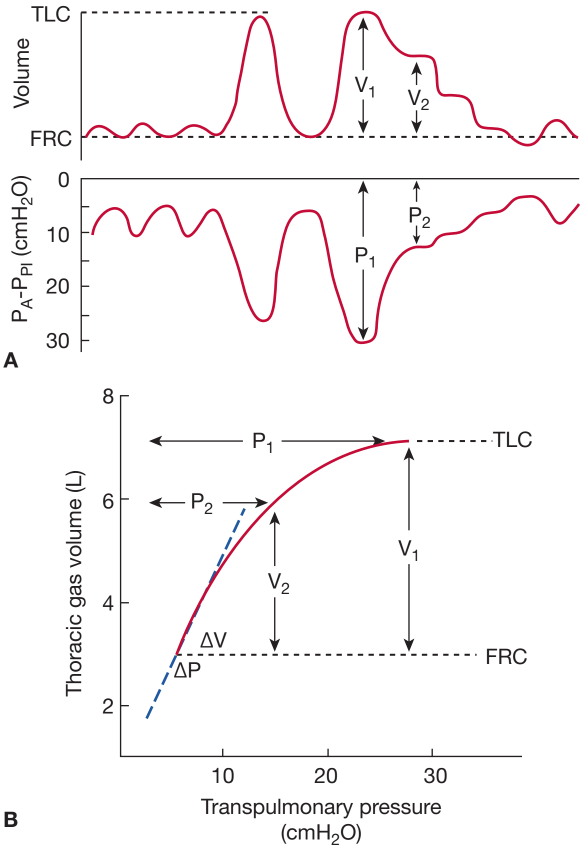


Figure 31-8 Measurement of the elastic properties of the lungs. **A.** Recordings of changes in lung volume and transpulmonary pressure (PA − Ppl) using the esophageal balloon technique described in the text. Simultaneous measurements of volume and pressure are obtained during periods of arrested airflow at lung volumes ranging from TLC to just below FRC. **B.** Thoracic gas volume is plotted on the ordinate and transpulmonary pressure on the abscissa. The curve formed by the plot using values from **A** describes the elastic properties of the lungs. The slope of the line, ΔV/ΔP, over the range of the tidal volume is the static compliance of the lungs.

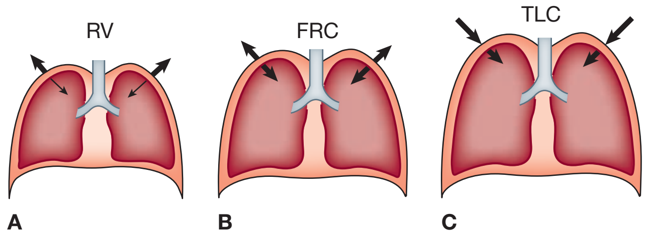

Figure 31-9 Schematic depiction of elastic recoil vectors across the lung and chest wall as determined by the level of inflation. **A.** At RV, the outwardly directed recoil pressure of the chest wall is large and the inwardly directed recoil pressure of the lung is small. **B.** At FRC, the recoil pressures of the lung and chest wall are equal and in opposite directions. **C.** At TLC, both recoil pressures are directed inward, and each contributes substantially to the overall recoil pressure of the respiratory system.

■ Static Compliance of the Chest Wall

Functionally, the chest wall includes the bony thorax, intercostal muscles, overlying soft tissue, pleura, and diaphragm. The chest wall is distensible and has its own distinctive elastic properties. In the normal, end-expiratory, resting position of the respiratory system (FRC), the inward recoil of the lung is balanced by the outward recoil of the chest wall (Fig. 31-9B). As the volume of the thoracic cavity enlarges progressively during inspiration from FRC to TLC, the outward recoil pressure of the chest wall lessens, becoming zero at approximately 70% of TLC; beyond this point, the chest wall begins to recoil inwardly (Fig. 31-9C). Conversely, as the chest wall is compressed below FRC by the action of the expiratory muscles, the natural outward recoil tendency is increased (Fig. 31-9A).

In practice, assessment of the elastic properties of the chest wall is accomplished by first determining the compliance curve of the respiratory system as a whole and then subtracting the contribution of the lungs. For a given lung volume, the pressure across the chest wall, Ppl − Pbs (Fig. 31-7), is simply the difference between the transthoracic (PA − Pbs) and transpulmonary (PA − Ppl) pressures. As indicated above, Ppl is determined using an esophageal balloon catheter.

■ Elastic Properties of the Respiratory System as a Whole

The elasticity of the respiratory system as a whole is determined by measuring the change in volume resulting from a change in pressure applied to the system—that is, the transthoracic pressure (PA − Pbs)—*while the respiratory muscles are completely relaxed.*

The first method used for this evaluation employed the relaxation technique described by Rahn and associates.[24] The subject breathes quietly into an apparatus consisting of a spirometer, a shutter, and a pressure transducer connected to the subject's side of the shutter (Fig. 31-10). After a period of quiet breathing, the subject is instructed to inspire maximally; the shutter is closed at peak inspiration, and the subject is then asked to relax the respiratory muscles completely while keeping the glottis open. Periodically, the shutter is opened, allowing a small volume of air to move from the subject into the spirometer; the shutter is then closed again. This maneuver is repeated until FRC is reached. During the periods of arrested airflow,

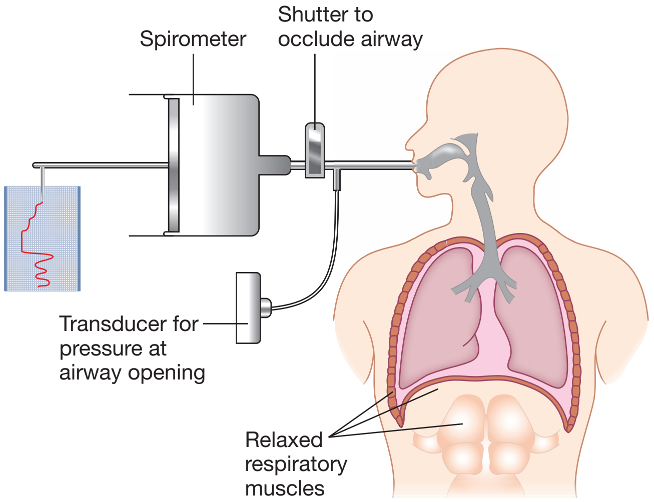

Figure 31-10 Relaxation technique for measurement of elastic recoil pressure of the respiratory system. After a period of normal tidal volume breathing, the subject inspires to TLC. A shutter in the airway is closed, and the subject relaxes his or her respiratory muscles. The shutter is periodically opened, permitting exhalation of a small volume of air measured by the spirometer. Airway pressures are recorded at times of shutter closure (i.e., during no airflow, when mouth pressure equals alveolar pressure). A pressure–volume curve is then constructed from the simultaneously recorded values for pressure and volume.

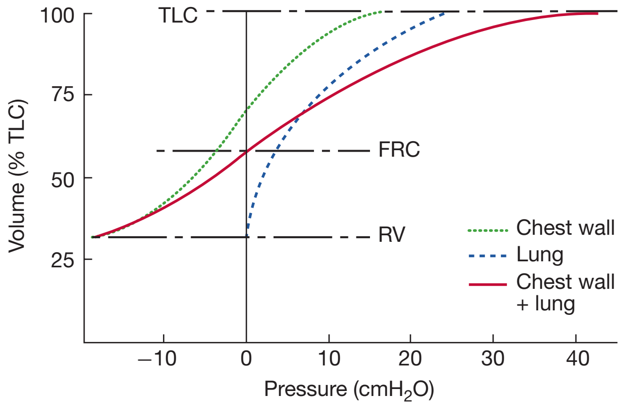

Figure 31-11 The pressure–volume curves of the respiratory system and its components. The elastic recoil pressures of the total respiratory system *(solid line)* over the vital capacity range are the sum of the recoil pressures of the lung *(dashed line)* and chest wall *(dotted line)*. At FRC, the chest wall recoil pressure is counterbalanced by the lung recoil pressure. The net result is a total system recoil pressure of 0. The total system recoil pressure is obtained by relaxation pressure or continuous positive-pressure breathing techniques. The chest wall recoil pressure is calculated as the difference between the recoil pressure of the entire respiratory system and the recoil pressure of the lungs.

pressure at the mouth (Pao) is equal to the pressure in the alveoli (PA). Provided the pressure at the body surface is atmospheric and the respiratory muscles are completely at rest, this value represents transthoracic pressure. In practice, however, full relaxation of the respiratory muscles is difficult, and a contribution by them to the pressure at the airway opening is frequently unavoidable.

A more practical technique entails the application of continuous positive pressure to the airways during spontaneous breathing. The subject breathes quietly into a water-sealed spirometer until a constant end-tidal level is achieved. A weight is then placed on the spirometer bell to increase the pressure in the respiratory system and, thereby, to raise the resting end-expiratory lung volume. This procedure is repeated using several different weights so that a pressure–volume curve of the total respiratory system can be constructed.

The individual pressure–volume curves for the lungs and chest wall and the composite curve for the intact respiratory system are shown in Fig. 31-11. As illustrated, the elastic recoil of the chest wall alone is determined by subtracting the recoil pressure of the lung from that of the total respiratory system. Chest wall elasticity is an important determinant of the subdivisions of lung volume and the overall compliance of the respiratory system; the latter is, in turn, an important determinant of the work of breathing.

Several features of the pressure–volume relationships shown in Fig. 31-11 are worth emphasizing. As lung volume approaches RV, the elastic recoil pressure of the respiratory system is largely due to the outwardly directed recoil pressure of the chest wall. At RV, the contribution of the lung to the recoil pressure of the respiratory system is minimal. At the other extreme of lung volume, TLC, elastic recoil pressure is high and directed inwardly, due to the combined elastic recoils of the lung and chest wall. At FRC, the outwardly directed recoil of the chest wall balances the inwardly directed recoil of the lung, and the transthoracic pressure is zero (i.e., PA − Pbs = 0). Indeed, the system "comes to rest" at FRC because of the counterbalancing of these forces at that volume. Since alveolar pressure at FRC is zero, no pressure gradient exists for airflow. Therefore, the system remains stationary until acted upon by the muscles of inspiration or expiration.

■ Elastic Properties of the Respiratory System in Health and Disease

The elastic properties of the respiratory system are altered by a wide variety of diseases that can affect the lung parenchyma or chest wall, either selectively or in concert. Most instances of clinically significant reductions in static compliance are due to abnormalities in the lung. The two standard clinical measures of the elastic properties of the lung are static lung compliance and maximal static recoil pressure.

Static lung compliance, Cst,L, is determined over the linear portion of the pressure–volume curve, between FRC and a lung volume corresponding to FRC plus 0.5 L. Normal values vary among laboratories, ranging from 0.147 to 0.375 L/cmH$_2$O, with a mean of 0.262 L/cmH$_2$O. Some variability is related to age and sex; Cst,L decreases with age and is higher in males than in females.

Maximal static recoil pressure is the recoil pressure at TLC. Once again, normal values vary. Data from one series of 51 normal subjects[25] are shown in Table 31-4.

TABLE 31-4 Normal Maximal Static Recoil Pressures for Adults (cmH$_2$O)

	Male Age (Years)			Female Age (Years)		
	25–35	36–64	65–75	25–35	36–64	65–75
Mean ± SD	35.9 ± 8.5	33.0 ± 8.7	33.0 ± 2.9	36.4 ± 5.8	25.7 ± 4.0	23.7 ± 3.9
Range	24.0–48.0	21.5–48.0	17.0–42.2	21.0–48.0	20.0–30.0	18.0–31.6

Data from Knudson RJ, Clark DF, Kennedy TC, et al. Effect of aging alone on mechanical properties of the normal adult human lung. J Appl Physiol. 1977;43(6):1054–1062.

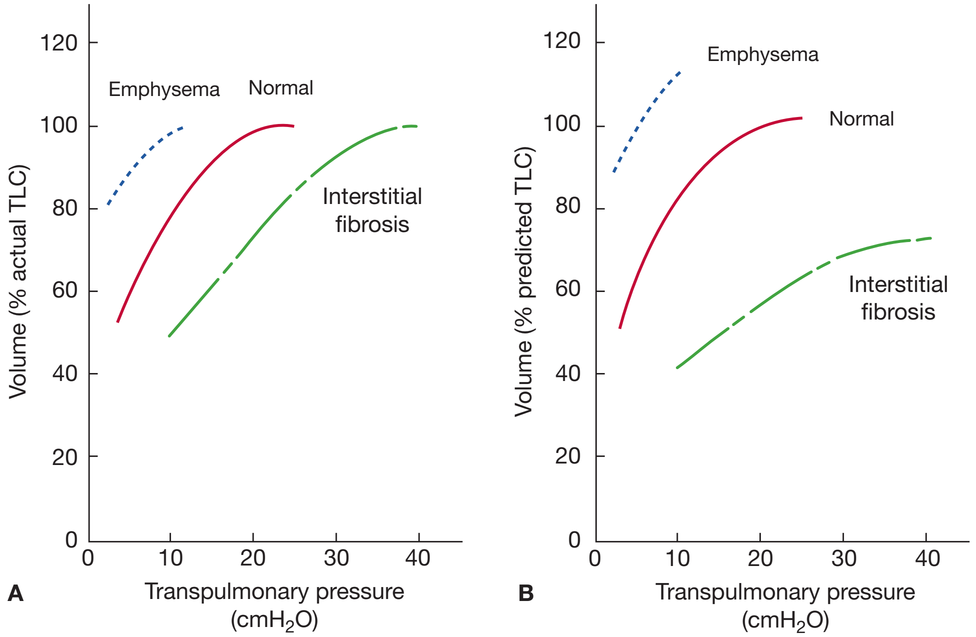

Figure 31-12 Pressure–volume curves of the lungs in health and disease. **A.** Volume expressed as percent of actual TLC. Differences in transpulmonary pressures in normal and diseases states are evident. Changes in lung volume that occur with disease are demonstrated on the plots. **B.** Volume expressed as percent of predicted TLC. In addition to the differences in transpulmonary pressures, alterations in lung volumes in the disease states are evident.

In disease states characterized by an increased elastic recoil pressure, such as diffuse interstitial fibrosis, the pressure–volume curve is shifted to the right and the static lung compliance decreases (Fig. 31-12). The increased elastic recoil pressure contributes to a decrease in FRC and TLC. By expressing the volume axis of the pressure–volume curve in terms of *percent predicted TLC* (Fig. 31-12B), instead of *absolute TLC* (Fig. 31-12A), the reduction in maximal lung volume is clearly evident; that is, maximal recoil pressure is increased, despite the reduced TLC.

In contrast to the effects of fibrosis, emphysema, which destroys alveolar walls and enlarges alveolar spaces, reduces lung elastic recoil pressure (Pel). This change increases both TLC and FRC. The shift of the pressure–volume curve upward and to the left (Fig. 31-12) indicates that lung compliance increases and that the maximal recoil pressure decreases. If the volume axis is expressed as percent predicted TLC (Fig. 31-12B), the increase in lung volume is more clearly demonstrated.

As noted previously, disorders affecting primarily the chest wall can also significantly alter the elastic properties of the respiratory system. Among these are obesity, kyphoscoliosis, and fibrothorax. These disorders limit chest wall excursion and lung expansion and reduce FRC. In addition, they produce decreases in static compliance of the lung and chest wall and maximal recoil pressure.

RESPIRATORY MUSCLE STRENGTH

Ventilatory performance depends not only on the mechanical properties of the lungs and chest wall, but also on the strength of the respiratory muscles. Evaluation of respiratory muscle strength was undertaken as early as the mid-19th century. Subsequently, using simplified methods of measurement, Black and Hyatt established normal values (Table 31-5).[26]

The maximal pressure generated by an isometric contraction varies directly with the resting length of the muscle. Consequently, values for maximal inspiratory and expiratory pressures depend on the lung volume at which the tests are performed (Fig. 31-13).[27] When TLC is less than 70% of the predicted value, the maximal expiratory pressure will be low. Similarly, when RV exceeds 40% of the predicted TLC, the maximal inspiratory pressure will be low.

The only equipment required for measurement of maximal inspiratory or expiratory pressure is an aneroid vacuum and pressure gauge. To determine maximal expiratory pressure, the patient is urged to inspire fully to TLC and then to expire as forcefully as possible into the gauge. The highest pressure attained and held for at least 1 s is the *maximal expiratory pressure* ($P_{E_{max}}$). The *maximal inspiratory pressure* ($P_{I_{max}}$) is determined by having the patient inspire maximally from the gauge after having expired completely to RV. The value recorded is the lowest pressure attained and held for at least 1 s.

TABLE 31-5 Prediction Equations and Lower Limits of Normal for Maximal Inspiratory ($P_{I_{max}}$) and Maximal Expiratory ($P_{E_{max}}$) Pressures (cmH_2O)[a]

	$P_{I_{max}}$		$P_{E_{max}}$	
	Predicted Mean (cmH_2O)	Lower Limit of Normal	Predicted Mean (cmH_2O)	Lower Limit of Normal[b]
Male	143 − (0.55 × age)	71	268 − (1.03 × age)	111
Female	104 − (0.51 × age)	39	170 − (0.53 × age)	88

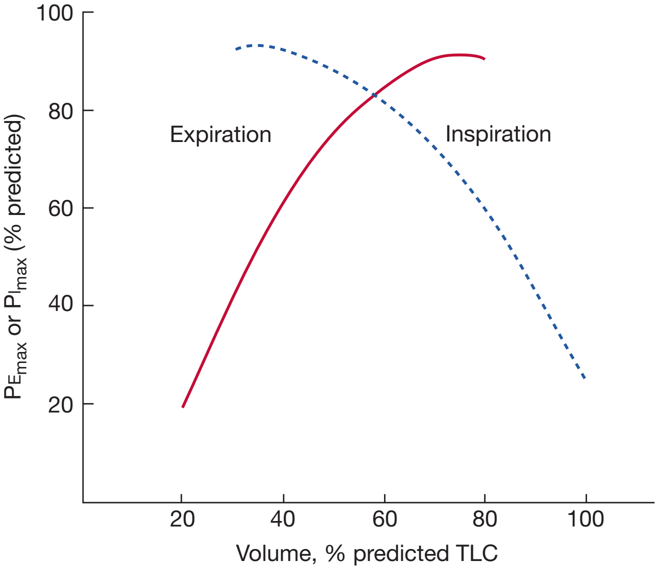

Figure 31-13 Effect of lung volume on maximal inspiratory *(dashed line)* and maximal expiratory *(solid line)* pressures. See text for discussion.

Measurement of maximal static respiratory pressures is particularly important in evaluating respiratory muscle weakness in patients with neuromuscular disease,[28] as described in Chapters 83 and 84. In such patients, spirometric tests are often normal, despite respiratory muscle weakness, because maximal pressures are not required to achieve maximal expiratory flow rates (see "Flow-Volume Relationships" below).

Another useful function of these measurements is in examining patients whose coordination in performing spirometry or whose degree of motivation is suspicious. In such patients, determination of maximal pressures is often helpful in determining whether optimal efforts are being expended during pulmonary function testing (see "Approach to Interpreting Commonly Performed Pulmonary Function Tests," below).

DYNAMIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

The static tests of pulmonary function described in the previous section are based on measurements of volume and pressure made while airflow is arrested. These static tests are particularly useful in defining the elastic properties of the respiratory system. Considerable additional information can be gained from tests done during airflow—that is, under "dynamic" conditions.

Although measurements of static lung volumes began about 300 years ago, the assessment of pulmonary function during airflow began in 1933, when the test now known as the *maximal voluntary ventilation* (MVV) was first proposed. This test did not become popular until a few years later, when Cournand and Richards developed regression equations to determine normal values. Subsequently, investigators proposed that the volume of air expired during specific time intervals be determined. In 1955, determination of the average airflow during the middle half of a forced expiratory vital capacity was described. Determination of these indices of dynamic lung function is now generally part of the battery of tests, both static and dynamic, included under the designation *spirometry.*

The more practical tests of dynamic function can, for convenience, be divided into four categories: FVC, flow–volume curves, MVV, and airway resistance. Other dynamic tests, including assessment of airway reactivity and the function of small airways, will be considered separately.

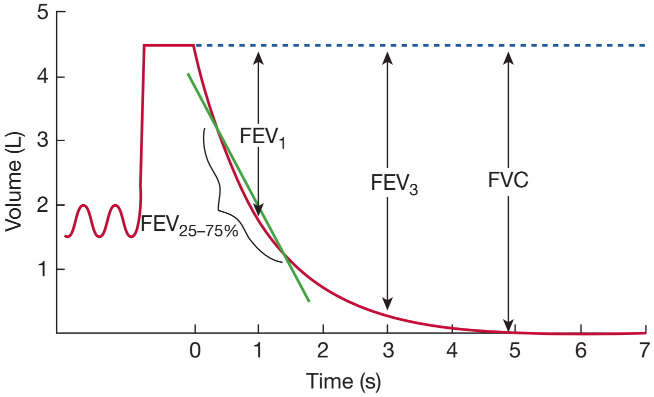

Figure 31-14 Forced expiratory vital capacity maneuver. After an initial period of tidal volume breathing, the patient inspires maximally to TLC and then exhales as rapidly and as forcefully as possible into a spirometer. Shown on the left of the tracing are a series of tidal volume breaths and the maximal inspiration to TLC. The forced expiration begins at time 0. Nearly all the volume is exhaled in the first 3 s of the maneuver. The values for FVC, FEV_1, and FEV_3 are measured from the maximal inspiratory level. The $FEF_{25-75\%}$ is the slope of the line connecting the points on the volume–time trace that correspond to 25% and 75% of the FVC.

Forced Vital Capacity

Both expiratory and inspiratory measurements of the FVC are routinely made in pulmonary function laboratories. Unless otherwise specified, FVC refers to the forced *expiratory* maneuver.

Forced Expiratory Vital Capacity

The forced expiratory vital capacity is measured during expiration. The maneuver entails two steps: a full inspiration to TLC, followed by a rapid, forceful, maximal expiration (to RV) into a spirometer. The forced expiratory vital capacity (FVC) is normally equal to the relaxed or slow vital capacity (VC). However, a discrepancy between FVC and VC appears in obstructive disease of the airways: the FVC is less than the VC.

The relationship between expired volume and time during an FVC maneuver is used to determine airflow during expiration and the volume of air expired within designated intervals; these values provide an indirect measure of the flow-resistive properties of the lung. The FVC is displayed in one of the two ways: expired volume plotted against time (Fig. 31-14) or airflow plotted against lung volume—that is, an expiratory "flow–volume curve" (see below). The normal volume–time display of the FVC consists of a smooth curve with a gradually and progressively decreasing slope. Irregularities in the curve suggest either a failure of coordination or a suboptimal effort. At times, the onset of the forced expiration is unclear (Fig. 31-15) because of hesitation on the part of the patient. When this occurs, the start of expiration ("zero time") is determined with the "back extrapolation" method (Fig. 31-15).[10] A tangent taken through the part of the curve with the steepest slope is extrapolated back to the maximal inspiratory volume; the point of intersection is considered to be the time of onset of expiration.

Several values are commonly determined from the volume–time plot of the FVC (Table 31-6, Fig. 31-14): (1) the *volume expired in the first second*, expressed either as an absolute volume (FEV_1) or as a percentage of the FVC (FEV_1/FVC%); (2) *the volume expired in the first 3 seconds*, expressed either as an absolute volume (FEV_3) or as a percentage of the FVC (FEV_3/FVC%); and (3) *the forced midexpiratory flow rate* ($FEF_{25-75\%}$). The $FEF_{25-75\%}$ is determined by locating the points on the volume–time curve corresponding to 25% and 75% of the FVC and then calculating the slope of a straight line

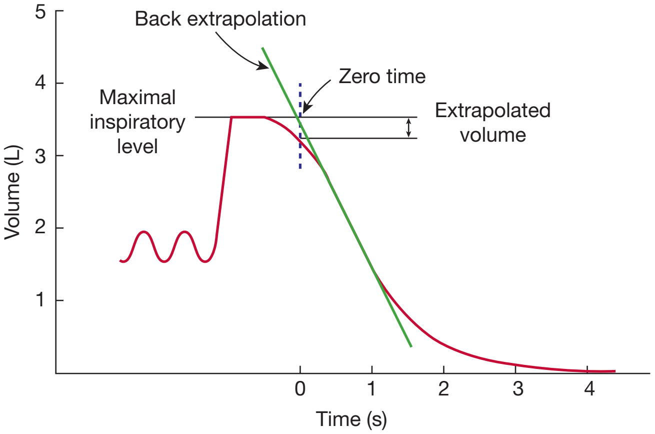

Figure 31-15 Technique of back extrapolation for determining the zero time in calculation of FEV_1. Zero time is determined as the point of intersection of a tangent drawn through the steepest portion of the spirogram and a line drawn horizontally through the maximal inspiratory level.

passing through those two points. The slope of this line represents the average airflow over the midportion of the FVC.

Although the *relaxed* or *slow vital capacity* (VC) may be normal or only modestly reduced in patients with obstructive disease of the airways, the volume–time relationship of the FVC maneuver is usually distinctly abnormal in such patients (Fig. 31-16A and B). Most obvious is a flattening of the slope of the curve at any given lung volume, reflecting the reduced airflow. In addition, the duration of the forced expiratory maneuver is prolonged. Normally, expiration is complete within 6 s; in obstructive airway disease, expiratory airflow may continue for 10 to 12 s. These changes in the expiratory airflow reduce the FEV_1 and FEV_3, the FEV_1/FVC%, the FEV_3/FVC%, and the $FEF_{25–75\%}$.

Restrictive lung disorders reduce the slow vital capacity. However, the *configuration* of the volume–time relationship may not be abnormal (Fig. 31-16C). Although the FEV_1 and FEV_3 are reduced because of the reduced vital capacity, the FEV_1/FVC% and FEV_3/FVC% remain normal or even exceed normal values. Often, because of the reduced vital capacity, the $FEF_{25–75\%}$ is also less than predicted.

Forced Inspiratory Vital Capacity

Measurement of the forced inspiratory vital capacity (FIVC) consists of two steps: (1) full expiration to RV, followed by (2) a rapid maximal inspiratory effort (Fig. 31-17). The rate of airflow over the middle half of the forced inspiratory vital capacity ($FIF_{25–75\%}$) is determined using a procedure similar to that described previously for the $FEF_{25–75\%}$.

TABLE 31-6 Values Obtained from Forced Expiratory Volume–Time Curves

FVC (BTPS) (L)	Forced vital capacity; the total volume expired
FEV_1 (BTPS) (L)	Volume of air expired in the first second
FEV_1/FVC%	Volume of air expired in the first second, expressed as percent of the FVC
FEV_3/FVC%	Volume of air expired in the first 3 s, expressed as percent of the FVC
$FEF_{25–75\%}$ (BTPS) (L/s)	Forced midexpiratory airflow

BTPS, body temperature and pressure, saturated with water vapor.

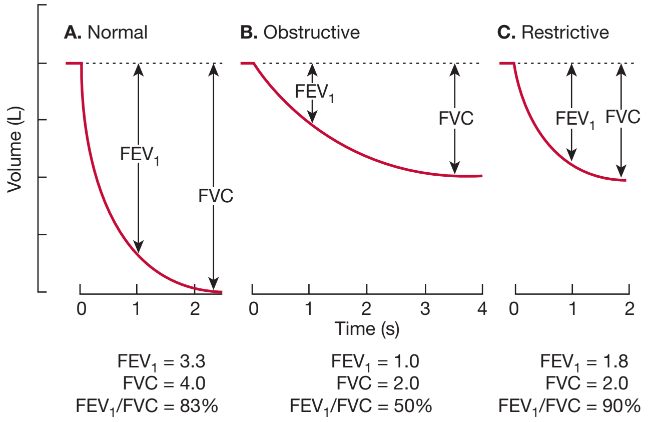

Figure 31-16 Representative spirograms from a normal subject (**A**), a patient with obstructive lung disease (**B**), and a patient with restrictive lung disease (**C**), obtained during a forced expiratory vital capacity maneuver. In the normal subject, expiration is completed within 3 s, and 83% of the volume is expired in the first second ($FEV_1/FVC\% = 83$). In the patient with obstructive disease, expiration is prolonged, and only half the volume is expired in the first second ($FEV_1/FVC\% = 50$). In the patient with restrictive disease, although the magnitude of the reduction in exhaled volume is the same as in the obstructed patient, most of the volume is exhaled within the first second ($FEV_1/FVC\% = 90$).

In normal subjects, the $FIF_{25–75\%}$ is greater than the $FEF_{25–75\%}$. Since inspiratory flow is more dependent on effort than is expiratory flow, a fall in the $FIF_{25–75\%}$ is usually a more sensitive indicator of respiratory muscle dysfunction or a suboptimal effort than is the $FEF_{25–75\%}$. When airway resistance is high, a disproportionate fall in $FIF_{25–75\%}$ relative to $FEF_{25–75\%}$ suggests an extrathoracic site of airway obstruction (see “Approach to Interpreting Commonly Performed Pulmonary Function Tests,” below).

Flow–Volume Relationships

In addition to analysis of the relationship between volume and time depicted on a spirogram, examination of the relationship between flow and volume provides useful information about lung function. A flow–volume curve, which shows the relationship between lung volume and maximal airflow as lung volume changes during a forced expiration, is shown in Fig. 31-18. The test comprises four phases of breathing into a spirometer: (1) tidal breathing for several breaths, (2) a maximal inspiratory effort to TLC, followed by (3) a maximal expiration to RV

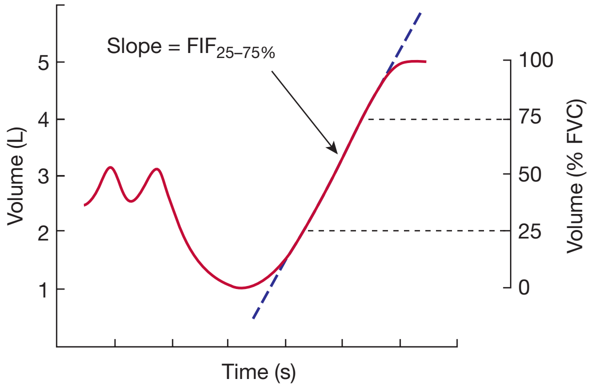

Figure 31-17 Forced inspiratory volume–time curve. The $FIF_{25–75\%}$ is the slope of a line between the points on the trace corresponding to 25% and 75% of the inspired volume.

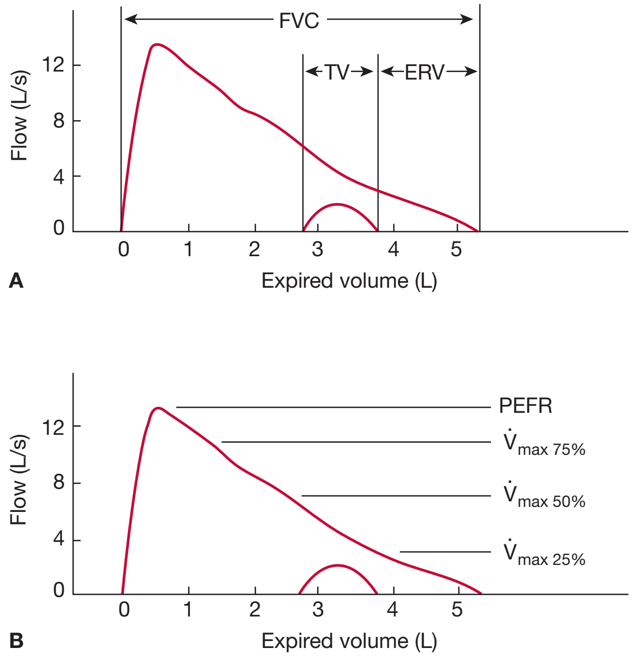

Figure 31-18 Flow–volume plots during forced expiration *(outer trace)* and quiet expiration *(inner trace)*. **A.** The subdivisions of lung volume. **B.** The common flow measurements. PEFR = peak expiratory flow rate; $\dot{V}_{max,75\%}$, $\dot{V}_{max,50\%}$, and $\dot{V}_{max,25\%}$ = flows at 75%, 50%, and 25% of the vital capacity, respectively.

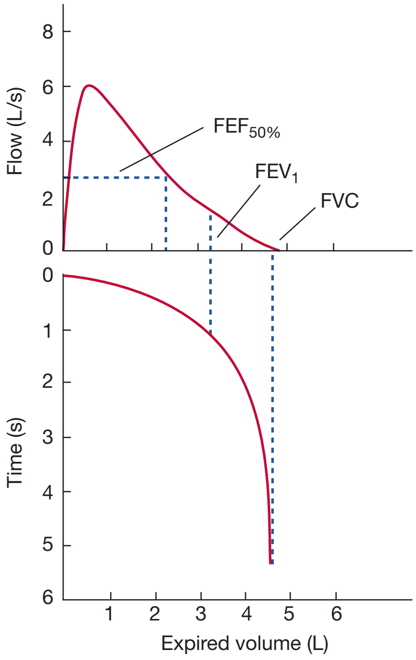

Figure 31-20 Flow–volume and volume–time curves depicting the same forced expiration aligned along a common volume axis (abscissa). Points corresponding to the FEV$_1$, FVC, and FEF$_{50\%}$ obtained from the volume–time plot are shown on the flow–volume curve.

done as forcefully and quickly as possible, and (4) another maximal inspiratory effort to TLC. Volume is displayed on the horizontal axis and airflow on the vertical axis. Airflow is measured at the mouth using a pneumotachograph; volume is measured either by integrating the pneumotachographic record during expiration or as a change in TGV, determined by a pressure-corrected flow plethysmograph. The records obtained by the two techniques for determining volume differ because the body plethysmograph senses compression of intrathoracic gas during a forced expiration, whereas measurements of volume made at the mouth do not (Fig. 31-19). Differences between curves obtained with the two techniques for measuring volume are most marked in patients with airway obstruction in whom considerable gas compression occurs during a forced expiration.

For the sake of comparison, tracings of flow versus volume and volume versus time, recorded during the same FVC maneuver and aligned by using a common volume axis as the abscissa, are shown in Fig. 31-20. Selected measurements are more evident in one tracing or the other—for example, maximal expiratory flow in the flow–volume curve and volume expired in 1 s (FEV$_1$) in the volume–time curve.

Comparison of serial curves from a single person or curves from different subjects requires that the curves be aligned on the volume (horizontal) axis so that points of maximal inspiration or maximal expiration coincide. As may be seen in Fig. 31-21A, which illustrates typical curves from a normal subject and two patients, one with pulmonary fibrosis and the other with obstructive airway disease, the

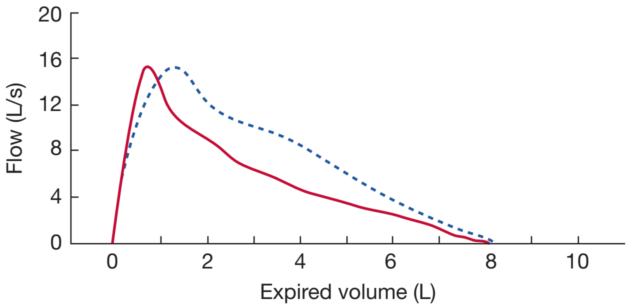

Figure 31-19 Comparison of the flow–expired-volume curve *(solid line)* with a simultaneously recorded flow–thoracic-gas-volume curve *(dashed line)*. The difference between the two curves results from the compression of gas in the lungs during a forced expiration.

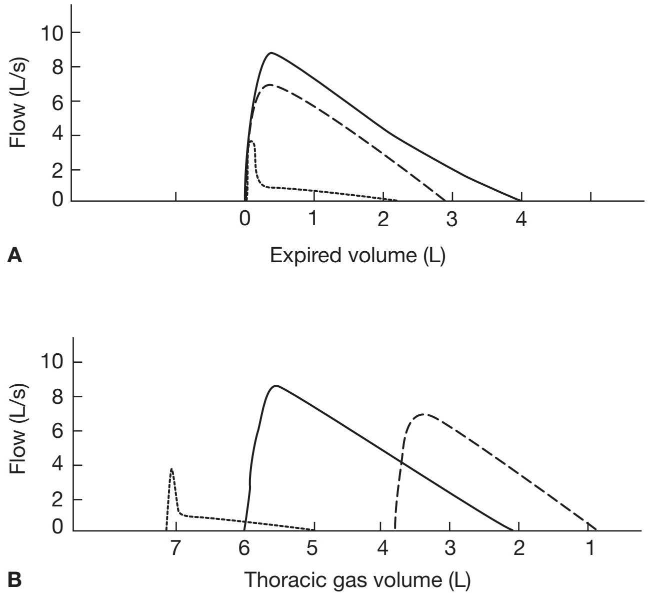

Figure 31-21 Airflow at different lung volumes. **A.** Flow–volume curves aligned at TLC. **B.** Flow–volume curves displayed relative to thoracic gas volume. Although the curves aligned at TLC (**A**) show striking differences in the pattern of airflow, they provide no insight into the relationship between lung volumes and airflow. See text for discussion.

information provided by this form of representation is limited—that is, the vital capacities and airflows from the patients are abnormally low. The limitation stems from the fact that the change in volume during expiration is shown relative to the *maximal inspiratory level* rather than to an *absolute volume* of gas in the lungs—that is, RV or TLC. When RV or TLC is known so that absolute volumes can be plotted on the horizontal axis (Fig. 31-21B), additional insight is gained into the flow–volume relationship depicted in Fig. 31-21A. The patient with obstructive disease of the airways manifests a reduction in expiratory airflow at elevated lung volumes, which should enhance airflow. In contrast, the reduced rate of airflow in the patient with pulmonary fibrosis is normal, or even supranormal, when the lung volume at which the airflow occurs is taken into account; that is, the reduced airflow is primarily a function of the reduced lung volume, rather than of airway obstruction.

Maximal Voluntary Ventilation

The previous considerations of dynamic lung function focus on a single timed maximal expiratory or inspiratory maneuver. In contrast, the MVV depends on the movement of air into and out of the lungs during continued maximal effort throughout a preset interval (Fig. 31-22). The MVV is a simple, informative test that provides an overall assessment of effort, coordination, and the elastic and flow-resistive properties of the respiratory system.[29,30]

In performing the test, the patient is urged to breathe as hard and as fast as possible. As a rule, the patient automatically adjusts frequency and tidal volume for optimal performance. However, extremes of frequency or tidal volume are to be avoided, since neither panting nor slow deep breathing leads to the highest possible values. The total volume that is expired during a 12-s interval, expressed in liters per minute (BTPS), is the MVV. In some patients the test cannot be done because of an inability to continue the necessary effort for 12 s.

A normal value for MVV indicates that the overall integrated performance of the respiratory system is intact, thereby excluding moderate to severe restrictive or obstructive disease. In addition, a normal value suggests that the elastic and flow-resistive properties of the respiratory system, respiratory muscle strength, coordination of respiratory performance, and motivation of the patient are all normal. Although this test is very useful in detecting overall disturbances in integrated performance and diffuse tracheobronchial and pulmonary parenchymal diseases, other tests are required to pinpoint specific disorders.

The difference between the MVV and the resting minute ventilation is the *breathing reserve*. At one time, a low breathing reserve was correlated with the breathlessness in lung diseases. However, this determination is now primarily of historic interest.

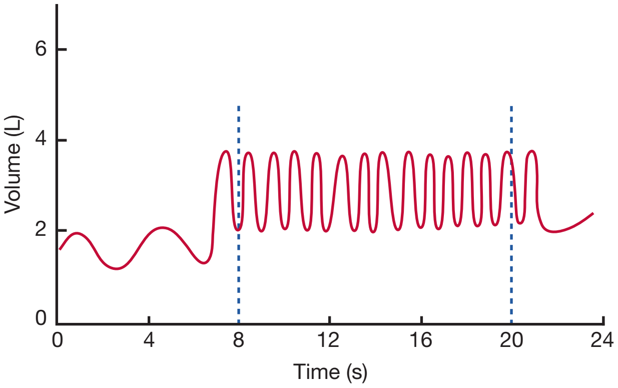

Figure 31-22 Maximal voluntary ventilation (MVV). After a period of relaxed breathing, the subject breathes rapidly and as forcefully as possible. The total volume of air inspired over 12 s and expressed in L/min is the MVV.

Respiratory Resistance

Total respiratory resistance (Rrs) is the resistance to airflow and chest expansion offered by the airways (Raw), chest wall (Rw), and lung tissue (Rti):

$$\text{Rrs} = \text{Raw} + \text{Rw} + \text{Rti}$$

The overall resistance of the respiratory system can be determined with a technique employing forced oscillation (see "Small-Airway Function," below). However, further methodologic refinements permitting determination of *pulmonary resistance*—the sum of airway and tissue resistances (Raw + Rti)—have not proved to be worthwhile clinically, particularly since measurement of transpulmonary pressure with an esophageal balloon is necessary. Other variations of the determination of resistance measurements also have been explored. However, the only clinically useful measurement of resistance is airway resistance, which is now routinely determined in pulmonary function laboratories.

Airway Resistance

Airway resistance (Raw) is defined as the ratio of the driving pressure (P) for flow to the actual rate of airflow ($\dot{V}$) along the airways—that is, the mouth, nasopharynx, larynx, and central and peripheral airways:

$$\text{Raw} = \frac{\Delta P}{\dot{V}}$$

where ΔP, the drop in pressure over the entire length of the airways, is determined as the difference between alveolar pressure (P_A) and pressure at the mouth (Pm) or airway opening (Pao).

Although airflow and pressure at the airway opening are easily measured, the difficulty in measuring alveolar pressure prevented the routine determination of airway resistance until DuBois and colleagues introduced the plethysmographic technique in 1956.[31]

With this technique, the patient, seated in the body plethysmograph, pants at a rate of about two breaths per second while airflow is measured using a pneumotachograph. During inspiration and expiration, gas in the alveoli is alternately rarefied and compressed, causing changes in pressure within the sealed plethysmograph. The relationship between plethysmograph pressure and airflow during the panting maneuver is displayed on the X and Y axes of an oscilloscope (Fig. 31-23).

While the panting continues, a shutter at the airway opening is closed so that airflow is transiently interrupted. Using the technique employed in the determination of FRC, changes in pressure in the plethysmograph (equivalent to changes in lung volume) and at the mouth are displayed on the X and Y axes, respectively, of the

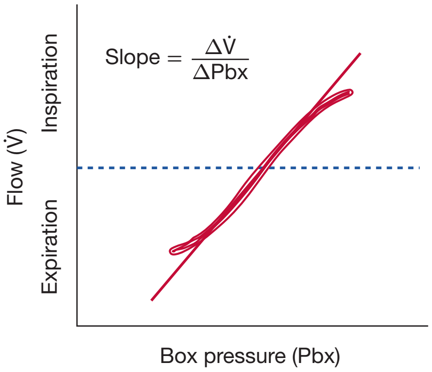

Figure 31-23 Plot of airflow ($\dot{V}$) versus body plethysmograph pressure (Pbx). The slope of this curve, in the range of 0 to 0.5 L/s of inspiratory flow, divided into the slope of the loop obtained when the shutter is closed (see Fig. 31-7) provides a measure of airway resistance (Raw).

oscilloscope (Fig. 31-6). However, since airflow is zero while the shutter is closed, the pressure at the mouth equals alveolar pressure (Pao = PA).

Panting while the shutter is open allows the determination of the relationship between airflow ($\dot{V}$) and plethysmograph pressure (Pbx)—that is, $\dot{V}$/Pbx. Similarly, panting against a closed shutter enables the determination of the relationship between alveolar pressure (PA) and plethysmograph pressure—that is, PA/Pbx. Airway resistance is calculated by dividing the slope of the loop obtained by plotting PA versus Pbx while the shutter is closed by the slope obtained by plotting $\dot{V}$ versus Pbx while the shutter is open:

$$\mathrm{Raw} = \frac{\mathrm{PA}/\mathrm{Pbx}}{\dot{V}/\mathrm{Pbx}} = \frac{\mathrm{PA}}{\dot{V}}$$

where

Raw = airway resistance, $cmH_2O/L/s$
PA = alveolar pressure, cmH_2O
$\dot{V}$ = airflow, L/s

Raw is measured during a panting maneuver for several reasons:[32] (1) The rapid respiratory frequency in panting circumvents the poor low-frequency response characteristics of many plethysmographs. (2) The small inspired and expired volumes minimize temperature fluctuations in the plethysmograph that would otherwise occur as tidal breaths of air at body temperature are exchanged with breaths of air at room temperature. (3) During panting, the glottis remains open, thereby minimizing its contribution to overall airway resistance. Use of plethysmographs linked to microprocessors that automatically correct for temperature-related volume differences has made possible the determination of airway resistance during quiet breathing instead of during panting.

Airway resistance varies inversely with lung volume; it is low at large lung volumes and increases curvilinearly as lung volume and, consequently, airway diameters are reduced (Fig. 31-24A).[33] In contrast, the inverse of airway resistance, airway *conductance,* is linearly related to lung volume (Fig. 31-24B). Interpretation of a given value for airway resistance or airway conductance requires that the lung volume at which the measurement is made be taken into account. *Specific conductance* (SGaw) is calculated by dividing airway conductance by the lung volume.

Defining the range of normal for Raw is difficult because of the lack of data obtained from populations sorted into smoking and nonsmoking groups and because of the inter- and intraindividual variations of Raw with lung volume. One classification scheme proposed for defining normal and abnormal Raw in adults in whom FRC exceeds 2 L is given in Table 31-7.

At times, an apparent discrepancy occurs between forced expiratory flow rates and values for airway resistance. For example, although the FEV_1 and $FEF_{25-75\%}$ may be abnormally low (suggesting some degree of airway obstruction), Raw may be within normal limits (arguing against appreciable airway obstruction). This apparent contradiction arises because Raw is determined during *inspiration,* when airways are enlarged because of surrounding negative pleural pressure, whereas FEV_1 and $FEF_{25-75\%}$ are determined during a forceful *expiration,* when airways are compressed by high positive pleural pressures. Therefore, the discrepancy is simply a manifestation of dynamic airway obstruction in which the narrowing is confined to expiration.

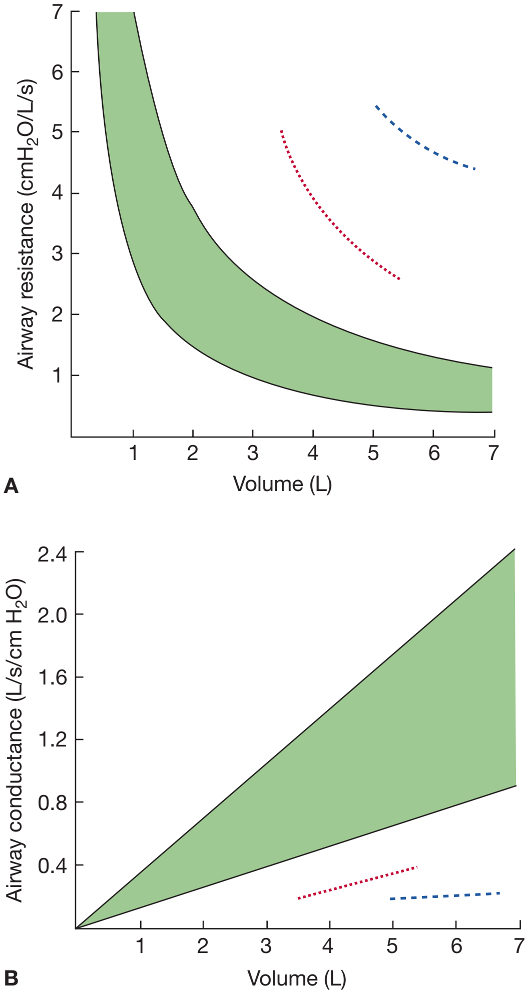

Figure 31-24 The relationship between airway resistance (**A**) and airway conductance (**B**). The shaded area represents the predicted normal range. Values are shown for an asthmatic patient before *(dashed line)* and after *(dotted line)* bronchodilator therapy. Airway resistance increases as lung volume decreases. Conversely, airway conductance, the inverse of resistance, decreases as lung volume decreases.

■ Measurement of Exhaled Nitric Oxide

Over the last two decades, the important role of nitric oxide (NO) in a variety of biologic processes has been described.[34] The concept that NO is a marker of airway inflammation, and, hence, has a potential role as a measure of airway function in the setting of inflammatory airway diseases, has been investigated.[35,36] Studies have demonstrated that, at least in asthma, levels of exhaled NO are elevated during exacerbations (when other measures of airway inflammation show activity), even in the absence of symptoms or changes in spirometry.[37,38] Exhaled levels of NO may also be helpful in classifying the severity of asthma.[39] Levels of NO decrease with inhaled corticosteroid use and rise with corticosteroid tapering. Many advocate measurement of exhaled NO as part of routine chronic asthma management.[34,40]

Standards have been developed for measuring exhaled NO levels,[34] and equipment for measuring exhaled NO is becoming

common in outpatient settings in which patients with asthma are managed.

AIRWAY REACTIVITY

The dynamic tests of airway function described previously are designed to determine intrinsic properties of the airways in a subject breathing room air at rest. In many clinical situations, such as evaluation of chronic cough, assessment of airway hyperresponsiveness is desirable. This section reviews *bronchoprovocation testing* (BPT),[41–45] which assesses reactivity of the airways to selected pharmacologic or environmental agents.

Background

One test of bronchial reactivity that has been incorporated into routine pulmonary function testing is determination of the effect on airflow of administration of a nebulized bronchodilator agent. However, bronchoprovocation tests are designed to quantify the degree of bronchoconstriction following the application of a particular stimulus. A number of tests of bronchial reactivity are currently in clinical use (Table 31-8). Among the agents used for inhalation challenges are methacholine, histamine, carbacholine, and specific antigens chosen in accord with the patient's history. In addition to the inhalation challenge tests in which pharmacologic agents are used, tests of bronchial reactivity may be based on inhalation of cold or dry air, isocapnic hyperventilation, or exercise.

Indications for Bronchoprovocation Testing

The principal indication for BPT is a history suggestive of bronchospasm induced by an environmental or occupational agent, generally in the setting of normal pulmonary function tests (including determination of airflow before and after administration of an inhaled bronchodilator). For example, comparison of FEV_1 before and after administration of a pharmacologic agent such as methacholine or histamine can be useful in establishing the diagnosis of asthma. Also, inhalation of a suspected specific antigen may be useful in uncovering asthma when skin tests are equivocal, or in proving that asthma is occupation related. In some instances, exercise testing may disclose airway hyperreactivity in persons who are free of bronchoconstriction while at rest. Airway hyperresponsiveness to methacholine may presage an accelerated decline in pulmonary function.[46] However, the impact of therapy with agents like inhaled bronchodilators or corticosteroids in preventing progression is unclear.

Methods of Bronchoprovocation Testing

Several methods of BPT are in general clinical use. These include methacholine challenge, exercise challenge, and antigen challenge, each of which is described briefly in subsequent sections.

Inhalation Challenge: Methacholine

Inhalation challenge using methacholine has become popular because of standardization of the technique, ease and safety of performing the test, and high sensitivity of the test in detecting asthma.[47,48] Methacholine is a synthetic cholinergic agent that evokes airway smooth muscle constriction. Because baseline pulmonary function and breathing pattern influence the site of deposition of the inhaled methacholine particles and, thereby, the response, a standard method for aerosolizing the agent is used to ensure reproducible results.[49]

One method in common use is that of intermittent aerosol generation. Standardization entails the delivery of a 0.6-s pulse of airflow at 20 lb/in.^{2} to a nebulizer, which, in turn, discharges particles that range from 0.3 to 4 μm in diameter into the airways. Methacholine for delivery by aerosol is prepared in concentrations ranging from 0.1 to 25 mg/mL using bicarbonate-buffered isotonic saline (containing 0.4% phenol) as the diluent. The cumulative dose delivered is expressed in inhalation units. One inhalation unit is equivalent to the single inhalation of a solution containing 1 mg of methacholine per milliliter (Table 31-9).

At the outset, the patient is challenged with five inhalations containing only aerosolized diluent. The necessity of the diluent step has been recently questioned. In addition to adding time and expense, it may force a greater absolute drop in FEV_1 needed to prove bronchial hyperreactivity. A fall in FEV_1 below 90% of the baseline value (i.e., the pre-challenge control FEV_1) establishes that the airways are hyperreactive, and therefore, the test is terminated. However, if the FEV_1 does not fall below 90% of the control value, increasing concentrations of methacholine are given in stepwise increments of five-breath inhalations. The breaths are taken slowly from FRC to TLC. Then, 1 to 1.5 min after each dose, an FVC maneuver is performed. The interval between each increase in concentration is kept to a minimum because the response is judged in terms of the *cumulative* dose. However, the deep inspiration that immediately precedes the expiratory portion of the FVC maneuver may decrease bronchomotor tone in airways narrowed by methacholine. This effect lasts up to 6 min, thus limiting the shortest acceptable interval between dosage steps.[50] If the postchallenge FEV_1 falls below 80% of the control FEV_1, or if the patient experiences cough or chest tightness at any step, the

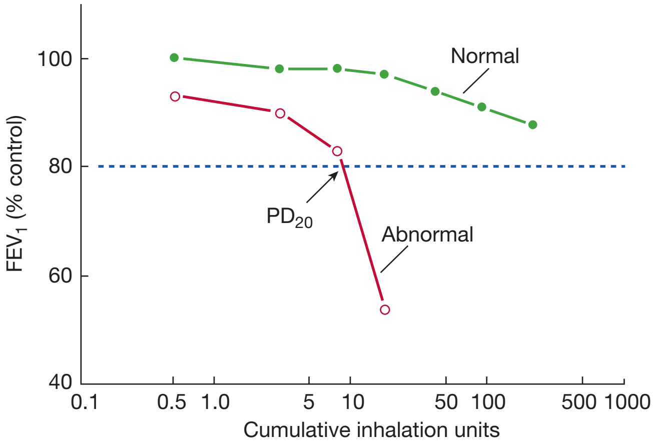

Figure 31-25 Plot of FEV$_1$,% control versus cumulative dose of methacholine administered by inhalation (logarithmic scale), to a normal subject and a subject with hyperreactive airways. The PD_{20} is the cumulative dose, which results in a 20% drop in the FEV$_1$ from the baseline measurement (after inhalation of diluent alone). In the subject with normal airway reactivity, the maximal cumulative dose of methacholine administered fails to elicit a 20% drop in FEV$_1$.

test is stopped. The magnitude of the bronchoconstrictor response to inhalational challenge is related to the control FEV$_1$. A lower baseline FEV$_1$ (even in the normal range) correlates with increased bronchial reactivity.[51–54] Additional measurements of dynamic airway function (e.g., specific conductance) may provide supplemental data but also prolong the study. Another dosing option in use is the 2-min tidal breathing protocol. This protocol typically yields results similar to the one described previously.

The results are plotted on four-cycle semi-log graph paper: the number of cumulative inhalation units, expressed logarithmically, against the FEV$_1$, as percent of control (Fig. 31-25). A curve is constructed through the points; the dose corresponding to the point at which the FEV$_1$ is 80% of the control FEV$_1$ is designated as the *provocation dose,* or PD_{20} FEV$_1$.

Exercise Challenge

Persons without a history of asthma who develop cough, wheezing, or dyspnea after exercise may have exercise-induced bronchospasm (EIB). In these individuals, an exercise test may prove useful in establishing the diagnosis. Such exercise testing in asthmatics can be useful to assess the degree of impairment during exercise, or the impact of therapies.

Several factors that may influence the outcome of the test should be kept in mind. The temperature and humidity of the laboratory should be tightly controlled. Some centers use dry air inhalation during exercise. In addition, the duration of the test needs to be monitored. The goal of testing for EIB is to produce at least 4 min of exercise at the target heart rate and ventilation. Exercise should not continue for more than 6 to 8 min, in order to avoid "run-through" of the bronchospasm—that is, reversal at the end of the test.

The type of exercise also influences the outcome. As a rule, the more intense the exercise, the more likely is bronchoconstriction to occur. Free-range running provides the most potent stimulus for bronchoconstriction, followed by treadmill running, bicycle ergometry, swimming, and walking. An asthmatic may swim comfortably at a level of exercise that is incapacitating on the treadmill. The motor-driven treadmill or electromagnetically braked cycle ergometer are the preferred modes of exercise for formal testing.

The FEV$_1$ is the most useful measurement made during testing for EIB. Measurements are made just before and immediately after the exercise and at 5-min intervals for the following 30 min. A decrease in FEV$_1$ of 10% or more below the pre-exercise value constitutes a positive test. Some have suggested that a decrement of 15% is of greater diagnostic value. False-positive responses can occur in patients with vocal cord dysfunction or abnormal posterior arytenoid motion.

Inhalation Challenge: Antigen

Compared with the relatively safe methacholine challenge test, BPT using a specific antigen is unpredictable and potentially hazardous. Since establishing the minimum dose required to induce bronchoconstriction is difficult, too much of the antigen may be given. A late response, far more severe than the initial one, often develops about 6 h after the challenge. Despite these reservations about antigen challenge, testing is warranted under certain circumstances: to uncover a particular agent in the environment that causes bronchoconstriction, to establish the diagnosis of occupational asthma, to prove that bronchoconstriction is caused by a particular antigen after routine skin tests have failed to support the clinical suspicion, and to convince a skeptical patient about the cause of his or her asthma. Recommendations for preparing concentrations of antigens and the technique of antigen challenge testing are specific to the antigen in question and may be found in the literature. These tests should be performed only in laboratories that have considerable experience in BPT.

■ Precautions and Contraindications

Although the overall risk of serious complications is low, bronchoprovocation tests may be unnecessary, invalid, or even dangerous in some circumstances (Table 31-10). For example, the patient who manifests appreciable airway obstruction by conventional testing may develop life-threatening airway narrowing during a bronchoprovocation test. In such a patient, a simple bronchodilator study would be more appropriate and informative. If bronchodilators fail to reverse the increase in airway resistance, and if it is important to prove that bronchial hyperreactivity does exist, BPT is sometimes done, with extreme caution, on another day, as antigen dosages are titrated carefully and details of the procedure monitored closely.

Absolute contraindications include severe airways obstruction (FEV$_1$ <50% predicted), myocardial infarction or stroke in the preceding 3 months, uncontrolled hypertension, or known aortic aneurysm. Moderate airflow limitation, pregnancy, lactation, and concurrent use of cholinesterase inhibitor medication represent relative contraindications.

A recent viral upper respiratory tract infection can cause airway hyperreactivity for up to 6 weeks in normal subjects. Similarly, influenza vaccination increases responsiveness to inhalation challenges in asthmatics for a few days to a week. In these conditions, BPT should not be undertaken until the sensitization effects of the infection or vaccination have worn off. Also, bronchodilators,

TABLE 31-10 Bronchoprovocation Testing: Precautions and Contraindications

- Baseline FEV$_1$/FVC% <60 (relative) or <50 (absolute)
- Recent upper respiratory tract infection
- Recent influenza vaccination
- Recent administration of bronchodilator
- Ingestion of caffeine within 6 h before testing
- Cold-air breathing, hyperventilation, exercise within 6 h before testing
- Recent acute myocardial infarction or cerebrovascular accident, uncontrolled hypertension, or known aortic aneurysm

including caffeine, should be withheld for at least 6 h before a bronchoprovocation test, if possible, in order to prevent blunting of the bronchoconstrictor response. Finally, cold air, hyperventilation, and exercise should be avoided for at least 6 h before testing in order to prevent the induction of a refractory period or late response that would overlap the test results.

SMALL-AIRWAY FUNCTION

Up to this point, discussion of tests of dynamic lung function has addressed the tracheobronchial tree as a unit. However, in a variety of common clinical settings, including asthma, COPD, cigarette smoking, lung transplantation complicated by bronchiolitis obliterans syndrome, ARDS, and cystic fibrosis,[55,60–63] structural (and functional) abnormalities of the airways may be centered primarily in the small, peripheral airways—that is, those 2 mm or smaller in diameter. Because of their small contribution to airway resistance, estimated to be about 10% to 38% (at a lung volume equivalent to 50% of VC), the small airways can undergo considerable damage before the usual tests of either static or dynamic lung function become abnormal.[64,65] Consequently, efforts have been made to utilize tests aimed at early detection of small-airway disease in the hope of early intervention to limit progression of the disease.[66]

Once obstructive disease of the peripheral airways arises, the small airways' contribution to overall resistance increases, and abnormalities in their function may be detected using specialized tests (see below), or, in some cases, analysis of selected aspects of the expiratory VC maneuver. In particular, abnormal values for $FEF_{25-75\%}$, in conjunction with normal values for FVC and FEV_1, are often useful in identifying small-airway disease. The basis for this approach is that $FEF_{25-75\%}$ measures airflow during the effort independent part of the FVC, when the small airways contribute substantially to the limitation of airflow.

A number of specialized tests of small airways' function have been developed over the last several decades, and some have found resurgent use in evaluating selected patient populations.[55] Several, along with their underlying physiologic basis, are described in subsequent sections.

Forced Oscillation Technique and Impulse Oscillometry

The forced oscillation technique (FOT) and a variation of FOT, impulse oscillometry, are based on assessment of airway impedance and a component of airway impedance, airway resistance.[56–59]

Using a loudspeaker applied to the airway opening and measuring pressure and flow over a range of oscillation frequencies, airway resistance can be measured and compartmentalized into segments reflecting resistance in medium-to-large and small airways. In normals, over an oscillatory range of 5 to 25 Hz, respiratory resistance and its major component, airways resistance, are frequency independent. With development of airways obstruction, respiratory resistance becomes frequency-dependent. Furthermore, as small airways narrow or close, a component of impedance distinct from resistance—reactance (a concept which refers to the "out-of-phase" relationship between pressure and flow during oscillation and which is ascribed to energy storage, as determined by the elastic properties of the respiratory system)—is significantly affected, particularly when measured during the expiratory phase of respiration.[55,62,63,67]

Dynamic Compliance

Dynamic compliance, defined as the change in lung volume during airflow produced by a given change in transpulmonary pressure, is normally independent of breathing frequency. However, under conditions of nonuniformity of ventilation throughout the lung, increases in breathing frequency are associated with a fall in dynamic compliance. This frequency dependence of compliance was first noted in a patient with emphysema.[68,69]

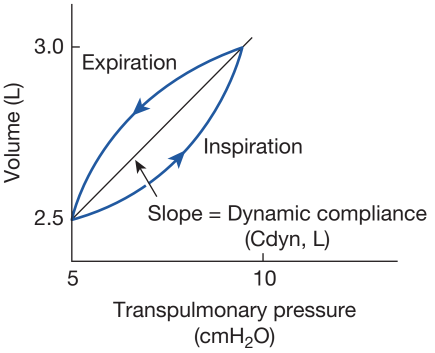

Figure 31-26 Measurement of dynamic lung compliance (Cdyn,L). During the inspiratory and expiratory phases of the respiratory cycle, a loop relating volume to transpulmonary pressure is generated. The slope of a line drawn through the points of zero airflow (at end inspiration and end expiration) is the dynamic compliance. Determination of Cdyn,L can be done at a variety of respiratory frequencies to assess the frequency dependence of compliance (Fig. 31-27).

During the test, the patient, with an esophageal balloon in place, first inspires maximally to TLC and then expires to the resting end-expiratory position (FRC); the patient then breathes at a normal tidal volume and respiratory rate (15 breaths per minute). In order to enable the patient to monitor these parameters, tidal volume and the resting end-expiratory level are displayed on an oscilloscope within sight of the patient. At the same time, changes in tidal volume and transpulmonary pressure are displayed on another oscilloscope (Fig. 31-26). The slope of the line connecting the end-inspiratory and end-expiratory points on the pressure–volume loop—that is, the points of zero airflow—is the dynamic compliance. This procedure is repeated with breathing frequencies of 30 and 60 breaths per minute. Values for dynamic compliance (Cdyn,L) at the various frequencies are expressed as a ratio of the dynamic compliance to the static inspiratory compliance (Cst,L) or as a percentage of Cst,L (Fig. 31-27) for the same range of tidal volumes.

In normal subjects, Cdyn,L/Cst,L remains above 0.8, even at frequencies greater than 60 breaths per minute. However, in the

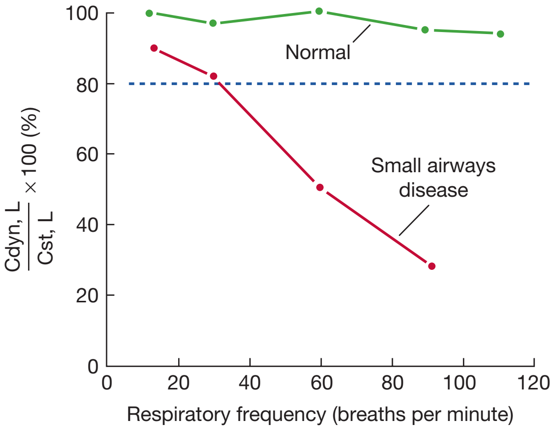

Figure 31-27 Determination of frequency dependence of dynamic compliance. Dynamic compliance is determined as shown in Fig. 36-26 and is expressed as a percentage of static lung compliance (Cdyn, L/Cst, L × 100,%) at a variety of respiratory frequencies. Normally, Cdyn,L is ≥80% of Cst,L and is independent of respiratory frequency. In patients with obstructive airway disease, including those with disease limited to the small airways, Cdyn,L falls relative to Cst,L as respiratory frequency increases.

presence of obstructive disease of the small airways, Cdyn,L/Cst,L falls progressively to values below 0.8 as breathing frequency increases. It is worth emphasizing that interpretation of frequency dependence of compliance with regard to small-airway disease is valid only if the static compliance and overall airway resistance are normal. Abnormalities in these other measurements indicate disease that is not likely to be confined to the small airways and for which frequency dependence of dynamic compliance is another manifestation. The physiologic basis for the fall in Cdyn,L/Cst,L as respiratory frequency increases is the presence of unequal time constants throughout the lung (see above).

■ Single-Breath Nitrogen Washout, Multiple Breath Nitrogen Washout, and Closing Volume

In 1949, Fowler described the single-breath nitrogen washout test for assessing the uniformity of ventilation throughout the lungs. In performing this test, the patient first expires maximally to RV before filling his or her lungs by taking a maximal breath of 100% O_2. During the subsequent expiration, the concentration of nitrogen at the mouth is continuously recorded and plotted against the volume of expired gas. Originally, interest focused on the initial part of the tracing that depicts the changing concentration in expired nitrogen as the first 750 to 1200 mL of gas is exhaled. Over this range, the change in nitrogen concentration in persons with normal lungs is less than 2.5%. In contrast, when disease of the lungs or tracheobronchial tree results in abnormal intrapulmonary distribution of inspired gas, the change in nitrogen concentration exceeds 2.5%.

Almost 20 years later, Fowler's test was modified to include a bolus of xenon at the beginning of inspiration and to record the concentration of xenon during the following expiration.[70] Abrupt changes in the concentration of expired xenon as RV was approached suggested that important information about the small airways could be obtained from the terminal portion of the curve.

These observations with xenon rekindled interest in Fowler's original technique and also directed attention to the terminal portion of expiration. The procedure is depicted in Fig. 31-28. To perform the maneuver for this measurement, the seated patient takes two deep breaths of air and then expires to RV. At the end of this maximal expiration, a valve is opened so that the patient can take a full breath of 100% O_2 to TLC. The patient then expires slowly to RV while N_2 concentration and expired volume are recorded continuously.

Four distinct phases can be identified in the continuous record relating N_2 concentration to expired volume. Phase I, the initial expirate, contains virtually no N_2, since it derives from the O_2-containing dead space. Phase II represents a mixture of gases from the dead space and the alveoli. Phase III is due to a mixture of gases from alveoli located at the apices, midlung fields, and bases. Phase IV, characterized by an upward shift in N_2 concentration, is caused by closure of alveoli in the dependent parts of the lungs at low lung volumes. This final expirate derives from alveoli in the middle and upper regions of the lungs, where N_2 concentrations are higher than at the bases.

The explanation for these phases resides in the intrapulmonary distribution of gases during the respiratory maneuvers used in performing the test. In the normal upright person, a gradient of pleural pressures exists from apex to base, so that pleural pressure is more negative at the apices than at the bases. Because the alveoli at the bases operate on a lower portion of their pressure–volume curve (Fig. 31-11), they expand more than do apical alveoli per unit change in pleural pressure. However, the less negative pleural pressures and decrease in elastic recoil pressure at the bases also cause small airways to close during expiration as lung volume approaches RV. Thus, the pleural pressure gradient from top to bottom of the chest causes nonuniform distribution of gas within the normal upright lungs.

In the single-breath nitrogen washout test, a breath of 100% O_2 is taken, starting from RV. At RV, small basal airways are closed. Therefore, at the start of the O_2 breath, the N_2-containing air remaining in the dead space is preferentially drawn into the middle and apical lung zones as 100% O_2 gradually replaces air in the dead space. As the inspiration continues, the small airways at the bases open. Since their compliances are greater than those in the middle or at the top of the upright lungs, the inspired O_2 is then preferentially distributed to the bases.

During the expiration from TLC, the four phases then represent, as indicated above, the sequential emptying of dead-space gas and a mixture of dead-space and alveolar gas, followed by mixtures of alveolar gases from different parts of the lungs, as determined by the preceding intrapulmonary distribution of inspired O_2.[71]

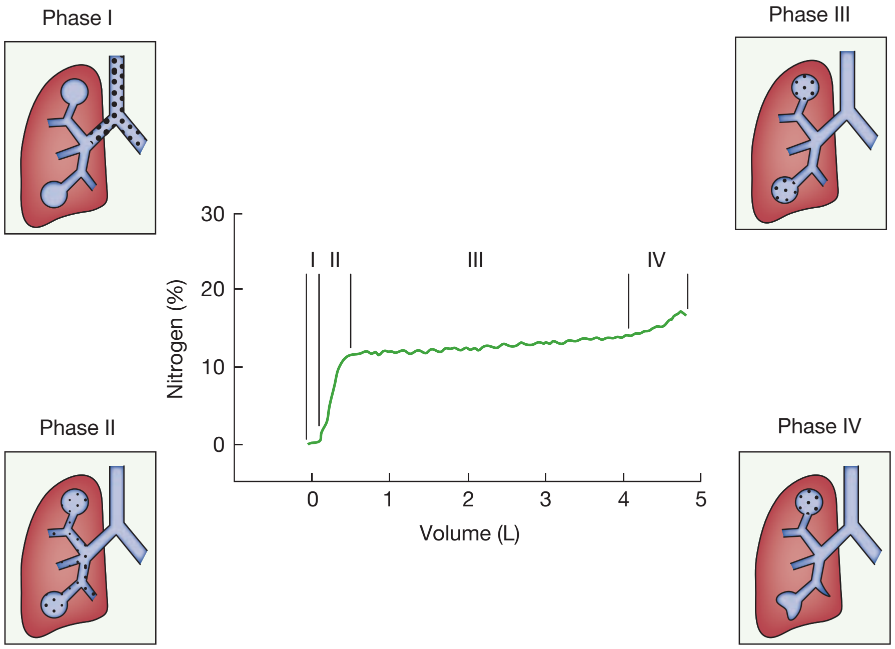

Figure 31-28 Contributions of different lung regions to the nitrogen concentration–volume curve obtained during the single-breath nitrogen washout test. See text for discussion.

The volume from the onset of phase IV to the completion of the full expiratory maneuver is termed the *closing volume* (CV). In healthy young adults, the normal closing volume averages about 10% of the VC. Narrowing or obstruction of small peripheral airways causes closing volume to enlarge. The closing volume also increases progressively as people grow older, so that by the age of 50, the closing volume sometimes reaches 25% of the VC. Cigarette smokers consistently experience an increase in closing volume. In both aging normal persons and cigarette smokers at any age, a decrease in pulmonary elasticity seems to be responsible for the increase in closing volume.

■ Helium–Oxygen Flow–Volume Curves

In 1963, the effects of changes in gas density and viscosity on maximal expiratory

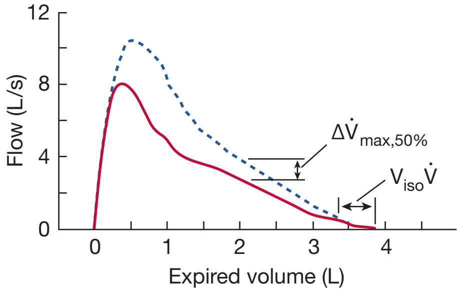

Figure 31-29 Maximal expiratory flow–volume curves generated in breathing room air *(solid line)* and breathing a helium–oxygen mixture *(dashed line)*. The airflows achieved with the less dense helium mixture are higher than those with air at all but the lowest lung volumes. The point of first intersection of these two curves demarcates the volume of isoflow ($V_{iso}\dot{V}$). The difference between the flows achieved when 50% of the vital capacity has been expired is the $\Delta\dot{V}_{max,50\%}$. The use of these measurements as indicators of small-airway disease is described in the text.

flow throughout the vital capacity range were described.[72] Almost 10 years later, gas-density-related and viscosity-related concepts were applied to determine the site of airway obstruction in asthma. These principles were then applied for the specific purpose of detecting obstruction of small airways when other tests of pulmonary function were within normal limits.[73] While application of helium–oxygen flow–volume curves in the assessment of small airways function is physiologically elegant, the test is rarely performed in clinical practice.

The use of a helium–oxygen mixture to detect small-airway disease requires comparison of two maximal expiratory flow–volume curves, one that is generated while the patient breathes air and the other while the patient breathes helium and oxygen (Fig. 31-29). At least three maximal expiratory flow curves are obtained with room air and three with helium–oxygen.[32]

In normal subjects, at lung volumes greater than 10% of the VC, the primary site of resistance to airflow is in the larger airways, where flow is turbulent and, therefore, density dependent. At these lung volumes, the flow attained with the helium–oxygen mixture will be higher than that attained with air. At lung volumes less than 10% of the VC, the primary site of resistance is in the smaller airways, where flow is laminar and, therefore, not density dependent. In this circumstance, the less dense helium mixture has no effect on flow (Fig. 31-29). In disease of the small airways, the primary site of resistance shifts at large volumes from the larger to the smaller airways. As a result, the flow-enhancing effect of the less dense gas disappears at volumes well above 10% of the VC.

In practice, two sets of maximal expiratory flow–volume curves are obtained, one while the subject is breathing air and the other after three VC breaths of the helium–oxygen mixture to replace at least 95% of the alveolar N_2. Comparisons are then made of the superimposed curves (Fig. 31-29). One comparison is made at 50% of the VC in order to compare maximal expiratory flows (i.e., the $\Delta\dot{V}_{max,50\%}$); the other is at the volume at which the flows become identical—that is, the *volume of isoflow* ($V_{iso}\dot{V}$).[74] The curves are superimposed at RV or TLC, as long as the vital capacities of each curve are within 2.5% to 5.0% of the largest VC recorded.[33]

The percentage change in expiratory flow while breathing helium–oxygen compared to air at 50% of the VC, $\Delta\dot{V}\mathrm{E}_{max,50\%}$, is calculated as

$$\Delta\dot{V}\mathrm{E}_{max,50\%} = \frac{\dot{V}\mathrm{E}_{max,50\%}\,(\text{helium–oxygen}) - \dot{V}\mathrm{E}_{max,50\%}\,(\text{air})}{\dot{V}\mathrm{E}_{max,50\%}\,(\text{air})} \times 100$$

where $\dot{V}\mathrm{E}_{max,50\%}$ (helium–oxygen) and $\dot{V}\mathrm{E}_{max,50\%}$ (air) are the expiratory flows at 50% of the VC during helium–oxygen and air breathing, respectively. As noted previously, the volume of isoflow is normally less than 10% of the VC; when it is increased, it indicates small-airway obstruction. The $\dot{V}\Delta\mathrm{E}_{max,50\%}$ is also specific for small-airway disease, and unlike the closing volume, it is considered to be unaffected by changes in the elastic properties of the lung. Questions remain, however, about the validity and sensitivity of tests of density dependence of flow in assessing small-airway disease. Although they are conceptually attractive, the practical value of helium–oxygen flow–volume curves in detecting small-airway disease is debatable.

GAS EXCHANGE FUNCTIONS

Traditional measurements of the gas exchange functions of the lung include oxygen uptake ($\dot{V}_{O_2}$), carbon dioxide elimination ($\dot{V}_{CO_2}$), respiratory dead space (VD), alveolar gas composition ($P\mathrm{A}_{O_2}$ and $P\mathrm{A}_{CO_2}$), diffusing capacity for carbon monoxide ($D\mathrm{L}_{CO}$), and arterial blood gas tensions (Pa_{O_2} and Pa_{CO_2}). These determinations require a steady state of the ventilation and circulation and constant body stores of O_2 and CO_2. A steady state with respect to O_2 implies that O_2 uptake measured at the mouth equals the rate of O_2 transport across the alveolar membrane, and that, in turn, both rates are equal to O_2 consumption by the tissues. The same type of definition applies to CO_2 exchange in the tissues, in the alveolar capillaries, and at the mouth.

Ventilation, Oxygen Uptake, and Carbon Dioxide Elimination

The total volume of air breathed per minute ($\dot{V}\mathrm{E}$) is the *minute ventilation*. It is equal to the product of the tidal volume (VT) and the breathing frequency (f). As a rule, minute ventilation is determined by measuring the volume of expired gas relative to time. When the measurement is performed manually, the necessary equipment includes gas-collecting bags, low-resistance directional valves, a stopwatch, and a device for measuring gas volume. In practice, the patient, with nose clip in place, breathes through a mouthpiece for at least 3 to 5 min while expired gas is vented to the atmosphere. This preliminary period is intended to put the patient at ease and to achieve a steady state of respiration and circulation. When a steady heart rate and breathing pattern are achieved, a valve is turned without the patient's knowledge, and expired gas is collected for 3 min.

The minute ventilation is determined by dividing the total volume of expired gas collected in the spirometer by the time of collection (3 min). The average tidal volume is obtained by dividing $\dot{V}\mathrm{E}$ by the number of breaths per minute. Values for minute ventilation and tidal volume are expressed in terms of body conditions (BTPS). In the resting adult, the minute ventilation is typically 6 to 8 L/min; the corresponding tidal volume is 0.4 to 0.6 L.

The quantity of CO_2 in inspired air is negligible. Consequently, the amount of CO_2 produced per minute ($\dot{V}_{CO_2}$) can be calculated as the product of the expired volume of ventilation ($\dot{V}\mathrm{E}$) and the concentration of CO_2 in the expired air ($F\mathrm{E}_{CO_2}$):

$$\dot{V}_{CO_2} = \dot{V}\mathrm{E} \times F\mathrm{E}_{CO_2}$$

Oxygen uptake ($\dot{V}O_2$) is calculated as the difference between the amounts of O_2 in inspired and expired air:

$$\dot{V}O_2 = (\dot{V}\mathrm{I} \times F\mathrm{I}_{O_2})\ (\dot{V}\mathrm{E} \times F\mathrm{E}_{O_2})$$

where

$\dot{V}\mathrm{I}$ = inspired volume of ventilation, L/min
$F\mathrm{I}_{O_2}$ = concentration of O_2 in the inspired air
$F\mathrm{E}_{O_2}$ = concentration of O_2 in the expired air

In the steady state, O_2 uptake by alveolar capillary blood exceeds CO_2 output from alveolar capillary blood. As a result, the expired volume of gas is less than the corresponding inspired volume. Since N_2 does not undergo exchange in the lungs, the difference between CO_2 output and O_2 uptake results in a higher concentration of N_2

in expired air than in inspired air. Based on the change in nitrogen concentration, the inspired volume of ventilation can be calculated from the expired volume of ventilation:

$$\dot{V}I = \dot{V}E\,\frac{FE_{N_2}}{FI_{N_2}}$$

where

FE_{N_2} = concentration of N_2 in expired air
FI_{N_2} = concentration of N_2 in inspired air

In the normal, resting subject who is tested after several hours of fasting, the ratio of CO_2 output to O_2 uptake, the *respiratory exchange ratio* (R), is about 0.8. The respiratory exchange ratio at any instant is calculated by simultaneously determining the P_{O_2} and P_{CO_2} in an alveolar gas sample. As indicated above, in the steady state, the R determined by sampling alveolar gas equals the R of alveolar capillary blood, which, in turn, equals the R of the tissues. The steady-state R, when alveolar gas, blood, and tissue are all in dynamic equilibrium, is the *respiratory quotient* (RQ). Hence, in the steady state, when the O_2 and CO_2 stores of the body are not changing, the RQ, reflecting cellular metabolism, can be determined by analyzing alveolar gas for O_2 and CO_2.

Unlike tidal volume and ventilation, which are expressed in terms of BTPS, $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ are given in terms of standard temperature and pressure, dry (STPD).

■ Dead Space

Not all of the air breathed participates in gas exchange. Part of each breath remains in the mouth, nose, pharynx, larynx, trachea, bronchi, and bronchioles. This volume, the *anatomic dead space,* is about equal, in milliliters, to the subject's ideal body weight, in pounds (e.g., about 150 mL in a typical adult male). Inspired air reaching alveoli that are not exposed to pulmonary capillary blood also does not participate in gas exchange. This volume plus the anatomic dead space equals the *physiologic dead space.* In a normal person, the anatomic and physiologic dead spaces are virtually identical and constitute about one-third of the tidal volume.

Determination of the physiologic dead space has proved to be of practical importance in a variety of clinical conditions. It is calculated by considering each breath (VT) to consist of dead space (VD) and an alveolar volume that participates in gas exchange (VA):

$$VT = VD + VA$$

Physiologic dead space can be calculated using a modification of the *Bohr equation*, which recognizes that all of the test gas expired derives from two sources: the physiologic dead space and the alveolar gas-exchanging volume. If we use CO_2 as the marker gas, the total amount of CO_2 eliminated per minute equals the sum of the CO_2 coming from the dead space per minute and from the alveolar compartment per minute:

$$\dot{V}E \times FE_{CO_2} = (\dot{V}D \times FI_{CO_2}) + (\dot{V}A \times FA_{CO_2})$$

where

$\dot{V}E$ = minute ventilation, L/min
FE_{CO_2} = fractional concentration of CO_2 in expired gas
$\dot{V}D$ = minute dead space ventilation, L/min
FI_{CO_2} = fractional concentration of CO_2 in inspired gas
$\dot{V}A$ = minute alveolar ventilation, L/min
FA_{CO_2} = fractional concentration of CO_2 in alveolar gas

Since, in a subject breathing room air, FI_{CO_2} is practically zero, the last equation is generally simplified as follows.

$$VE \times FE_{CO_2} = VA \times FA_{CO_2}$$

where VE and VA represent volumes of ventilation, rather than rates.

Recalling that VA = VT − VD and substituting partial pressures for the fractional concentration terms, the relationship becomes

$$VE \times PE_{CO_2} = (VT - VD)\,PA_{CO_2}$$

where PE_{CO_2} and PA_{CO_2} are the partial pressures of CO_2 in mixed expired gas and alveolar gas, respectively.

Assuming that arterial blood and alveolar gas are in equilibrium with respect to CO_2, when Pa_{CO_2} is substituted for PA_{CO_2} and the equation rearranged, it becomes

$$VD = VT\,\frac{Pa_{CO_2} - PE_{CO_2}}{Pa_{CO_2}}$$

Thus, if arterial blood is sampled during collection of expired gas, and if the partial pressures of CO_2 in expired gas and arterial blood are determined, the physiologic dead space can be calculated. In order for the physiologic dead space to be separated from the total dead space determined by the above equation, the dead space of the apparatus is subtracted from the value for total dead space.

■ Alveolar Gas Composition

In normal subjects, values for PO_2 and P_{CO_2} in an end-tidal sample approximate mean alveolar values. However, when imbalances exist in alveolar ventilation and blood flow because of lung disease, inhomogeneity in alveolar gas composition often invalidates the use of end-tidal gas tensions as a measure of mean alveolar gas composition.

In practice, mean alveolar P_{O_2} ($\bar{P}A_{O_2}$) and mean alveolar P_{CO_2} ($\bar{P}A_{CO_2}$) are often determined indirectly. Arterial P_{CO_2} is assumed to equal mean alveolar P_{CO_2} on the grounds of the narrow arteriovenous difference for P_{CO_2} across the lungs, the high solubility of CO_2, and the presumed role of pulmonary capillary blood as a tonometer. Mean alveolar P_{O_2} is calculated using the alveolar gas equation:

$$\bar{P}A_{O_2} = \bar{P}I_{O_2} - \bar{P}A_{CO_2}\left[FI_{O_2} + \frac{1 + FI_{O_2}}{R}\right]$$

The alveolar gas equation takes advantage of the fact that the total pressure of gases in the alveoli is equal to the sum of the partial pressures of the individual gases. This equation simply states that the mean alveolar P_{O_2} is the difference between inspired P_{O_2} and mean alveolar P_{CO_2}, allowing for a correction factor when the respiratory exchange ratio differs from 1.0.

■ Diffusing Capacity

The diffusing capacity of the lung for carbon monoxide (DL_{CO}) can be determined by steady-state, rebreathing, and single-breath methods. The most frequently used method is a modification of the single-breath method first described in 1915 and subsequently modified in 1957.[75] Although the single-breath test has been shown to exhibit a large interlaboratory variation, it has proved to be a valuable measure of lung function in a wide variety of disease states. In fact, with continuing refinement of the standards,[8,76,77] the variability, which may be as much as 12% or greater, is likely to decrease; however, the variability will probably not be reduced to the range for vital capacity measurements (about 4%).

The diffusing capacity is intended to provide an estimate of the rate at which test molecules—usually CO—move by diffusion from alveolar gas to pulmonary capillary blood. Factors that influence the measurement are the physicochemical properties of the test gas, the extent and thickness of the alveolar capillary barrier, the resistance to diffusion offered by the red blood cell membrane, and the reaction rates of the test gas and hemoglobin, and pulmonary capillary blood volume. As a rule, the diffusing capacity is interpreted as an index of the surface area engaged in alveolar capillary diffusion. Clinical entities that can reduce the diffusing capacity include parenchymal lung diseases, particularly interstitial lung disease, emphysema, pulmonary hypertension, and anemia. Polycythemia and alveolar hemorrhage syndromes, on the other hand, may increase the diffusing capacity.

Carbon monoxide has emerged as the most practical test gas because of its affinity for hemoglobin. The diffusing capacity for CO is defined as the amount of CO transferred per minute per mm Hg of driving pressure:

$$\mathrm{DL_{CO}} = \frac{\dot{\mathrm{V}}_{\mathrm{CO}}}{\bar{\mathrm{P}}\mathrm{A_{CO}} - \bar{\mathrm{P}}\mathrm{C_{CO}}}$$

where

$\mathrm{DL_{CO}}$ = the diffusing capacity of the lung for CO, mL/min/mm Hg (STPD)
$\dot{\mathrm{V}}_{\mathrm{CO}}$ = the amount of CO transferred, mL/min
$\bar{\mathrm{P}}\mathrm{A_{CO}}$ = the mean alveolar PCO, mm Hg
$\bar{\mathrm{P}}\mathrm{C_{CO}}$ = the mean capillary PCO, mm Hg

Since the blood Pco in nonsmokers is essentially zero, the term $\bar{\mathrm{P}}\mathrm{C_{CO}}$ is customarily neglected. In practice, $\mathrm{DL_{CO}}$ is determined by calculating $\dot{\mathrm{V}}_{\mathrm{CO}}$ as the difference between inspired and expired samples and estimating the mean alveolar Pco. Generally, one of the two techniques is used to determine $\mathrm{DL_{CO}}$: the single-breath or the steady-state technique.

The Single-Breath Method

The breathing maneuvers required for the single-breath method consist of tidal breathing for a few breaths, unforced expiration to RV, and then a single full, rapid inspiration of a gas mixture containing approximately 0.3% CO and an inert gas—traditionally, 10% helium (some newer systems use methane). The breath is held for 10 ± 2 s and then rapidly expired. An inspiratory time of less than 4 s, and a sample collection of no more than 3 s, are required. Longer expiratory times and sample collection time greater than 3 s should be noted in the test report. The initial portion of the expirate containing dead-space gas is discarded; the remainder is collected, and the concentrations of CO and helium are measured.[75] A variety of automated systems are commercially available for performing the single-breath diffusing capacity.[78] However, the essential components in all systems are a source of the special inspired gas mixture, a device for measuring the volume of gas inspired and expired, rapid response analyzers to measure the concentration of gases (see below), a timer, and appropriate valving and collection devices to trap the desired portion of the expirate.

The diffusing capacity of the lung for CO is calculated according to the following equation.

$$\mathrm{DL_{CO}} = \frac{\mathrm{VA} \times 60}{(\text{barometric pressure} - 47)} \times \text{time} \times \ln \frac{\mathrm{FA_{CO}},\ \text{initial}}{\mathrm{FA_{CO}},\ \text{final}}$$

where

VA = alveolar volume
$\mathrm{FA_{CO}}$, initial = alveolar concentration of CO at the start of breath hold
$\mathrm{FA_{CO}}$, final = alveolar concentration of CO at the end of breath hold

The concentration of CO in the alveoli at the start of the period of breath holding ($\mathrm{FA_{CO}}$, initial) is calculated from the inspired concentration of CO and, for helium-based systems, the inspired concentration of helium and the expired concentration of helium, according to the equation

$$\mathrm{FA_{CO,}}\ \text{initial} = \frac{\mathrm{FE_{He}}}{\mathrm{FI_{He}}} \times \mathrm{FI_{CO}}$$

where

$\mathrm{FE_{He}}$ = expired concentration of helium
$\mathrm{FI_{He}}$ = inspired concentration of helium
$\mathrm{FI_{CO}}$ = inspired concentration of CO

The concentration of CO in the alveoli at the end of the breath-holding period ($\mathrm{FA_{CO}}$, final) is equal to the concentration of CO in the expired gas. The alveolar volume (VA) is determined in one of two ways. Originally, VA was calculated as the sum of the RV, determined by the closed-circuit helium or body plethysmograph techniques described previously, and the volume of inspired gas, as recorded on the spirometer. Later, VA came to be calculated from the single-breath dilution of helium that occurs during the determination of $\mathrm{DL_{CO}}$. Finally, the time of breath holding is measured (in seconds) from the spirometer recording of the maneuver.

Although the single-breath method is relatively simple and has the advantage of requiring no blood samples, breath holding is clearly artificial, and the maneuver is difficult for dyspneic patients. Therefore, a steady-state method is sometimes used.

The Steady-State Method

In the steady-state method, a gas mixture containing 0.1% carbon monoxide is breathed until the rate of CO uptake from the lung is constant.[79] CO uptake ($\dot{\mathrm{V}}_{\mathrm{CO}}$) is determined from the difference between the amount of CO in the inspired and expired gas using an equation similar to that presented previously for calculation of O_2 consumption.

Comparison of Single-Breath and Steady-State Methods

Certain differences between the single-breath and steady-state techniques merit special mention.[32] The single-breath method is more popular because it is relatively easy to perform; it is well standardized, and it is less effected by nonuniformity of ventilation in comparison to the steady-state method. However, one drawback is that the patient is required to perform an inspiratory vital capacity maneuver of at least 88% of the VC and to hold his or her breath for 10 s. Another is that the test is extremely difficult to perform during exercise. The steady-state method is more attractive intrinsically than the single-breath method, since it requires no respiratory maneuvers and can be done during exercise. However, it does require an arterial blood sample (for determination of $\mathrm{P_{CO_2}}$), and it is technically more difficult to perform.

The steady-state method for determining diffusing capacity tends to give lower values for the resting subject than does the single-breath method. The discrepancy is generally attributed to the fact that the surface area for diffusion is smaller during the quiet tidal breathing employed in the steady-state method than during the full inspiration to TLC, as required in the single-breath method. Also, during quiet breathing, some areas of the lung receive considerably less ventilation than during a breath hold at TLC.

Factors Other than Diffusion That Influence Test Results

A low $\mathrm{DL_{CO}}$ need not indicate a diffusion defect. A number of additional respiratory and nonrespiratory factors may reduce or increase the $\mathrm{DL_{CO}}$. A reduction in the lung volume alone can reduce the $\mathrm{DL_{CO}}$. Therefore, some laboratories “normalize” the diffusing capacity for lung volume by dividing $\mathrm{DL_{CO}}$ by alveolar volume—a manipulation that assumes a linear relationship between $\mathrm{DL_{CO}}$ and VA, which is not the case.

Anemia artificially decreases the $\mathrm{DL_{CO}}$ as determined by either method, but the effect of low hemoglobin concentration can be adjusted by application of a correction factor.[80] Conversely, polycythemia and intrapulmonary hemorrhage tend to increase the value for $\mathrm{DL_{CO}}$. In fact, an unexpectedly high value for $\mathrm{DL_{CO}}$ may be a helpful clinical clue in detecting radiographically occult pulmonary hemorrhage.

Although the equation for $\mathrm{DL_{CO}}$ assumes that the CO back pressure in blood is negligible, the blood of a heavy smoker sometimes contains as much as 10% carboxyhemoglobin. Such levels of carboxyhemoglobin will be accompanied by appreciable concentrations of dissolved CO in the plasma. The resulting back pressure of CO will reduce the DL_{CO}. A correction equation may be applied to adjust the DL_{CO} for this effect.

Altitude also affects the DL_{CO}.[8] Pa_{O_2} falls with increasing altitude above sea level. The reduction in Pa_{O_2} allows CO to diffuse more rapidly into the blood. A specific adjustment should be made for inspired oxygen partial pressure.

Measurement of diffusing capacity is quite useful in the evaluation of patients with a number of pulmonary conditions. Decrement in DL_{CO} has been shown to predict exertional hypoxemia. In addition, DL_{CO} levels have been correlated with disease severity and prognosis in primary pulmonary hypertension, idiopathic pulmonary fibrosis, and alveolitis associated with systemic sclerosis.

■ Arterial Blood Gas Composition

The determination of arterial P_{O_2} and P_{CO_2} provides useful information about the overall efficiency of external gas exchange. Heavy reliance is placed upon them for this purpose in managing acute respiratory failure, particularly in intensive care units. Less dramatic, but important, is their use in a variety of other settings (e.g., exercise testing) and for assorted calculations (e.g., the alveolar–arterial O_2 gradient and respiratory dead space).

Technique for Sampling Arterial Blood

Arterial blood is sampled either through an indwelling arterial catheter or by percutaneous arterial puncture. Sampling through an indwelling catheter avoids the acute changes in ventilation that sometimes result from apprehension and pain associated with percutaneous puncture.

Three anatomic sites are generally used for obtaining arterial blood samples: the radial, brachial, and femoral arteries. For several reasons, the radial artery is the preferred sampling site. Because of its superficial location at the wrist, the radial artery is easy to palpate and easy to compress by direct pressure, facilitating hemostasis when sampling is complete. In addition, no large veins lie in its immediate vicinity. Furthermore, the ulnar artery usually provides an adequate collateral circulation to the hand in the rare instance of postsampling thrombosis of the radial artery.

Arterial blood samples are drawn anaerobically into plastic or glass syringes coated with heparin. Because room air at sea level has a P_{O_2} of approximately 150 mm Hg and a P_{CO_2} of approximately zero mm Hg, air bubbles in the syringe will artificially increase the arterial P_{O_2} and reduce the arterial P_{CO_2}. The sample either is immediately analyzed or is placed on ice in order to minimize the metabolism of blood cells, particularly the white cells. If the icing precaution is neglected and the analysis is delayed, the Pa_{CO_2} of the sample will increase and the Pa_{O_2} and pH will decrease; the rate of change depends on the temperature of the sample and the elapsed time before analysis (Table 31-11).[81]

Interpretations

Analysis of arterial blood gases as part of pulmonary function testing is based primarily on determination of Pa_{O_2}, Pa_{CO_2}, and pH. As a rule, these parameters are measured directly. Other values, including O_2 saturation, bicarbonate concentration, and base excess (or deficit), are usually calculated. This section deals with the interpretation of Pa_{O_2}, Pa_{CO_2}, and pH. Additional consideration of arterial blood gases, with particular reference to acid–base balance, is found in Chapter 17.

Arterial P_{O_2} (Pa_{O_2}) The physiologic determinants of normal Pa_{O_2} have been described elsewhere. For example, normal values for arterial P_{O_2} depend on altitude (Table 31-12). Therefore, normal values for arterial P_{O_2} in Denver (altitude of approximately 1500 m) are less than those at sea level by about 20 mm Hg.

TABLE 31-11 In vitro Changes in Arterial Blood Gas Values at 37°C

Measurement	Change Over 10 min
pH (units)	−0.01
P_{CO_2} (mm Hg)	+1.000
O_2 content (vol%)	−0.001

Data from Kelman GR, Nunn JF. Nomograms for correction of blood P_{O_2}, P_{CO_2}, pH, and base excess for time and temperature. J Appl Physiol. 1966;21(5):1484–1490.

Arterial P_{O_2} also decreases with age. A regression equation can be used to predict the decrease:[82]

$$Pa_{O_2} = 109 - 0.43 \text{ (age in years)}$$

The standard deviation of this relationship is ± 4.10 mm Hg.

A third physiologic influence is body position. Assumption of the supine position causes abdominal contents to displace the diaphragm cephalad, thereby closing small airways at the lung bases and creating ventilation-perfusion inhomogeneities that decrease Pa_{O_2}.

Many more pathologic conditions than physiologic states can lower Pa_{O_2}. In each instance, however, arterial hypoxemia may be attributed to one or more of the following generic mechanisms: alveolar hypoventilation, ventilation-perfusion mismatch, diffusion impairment, and venous admixture ("shunt"). Considerations of the individual disorders within these categories and the mechanisms leading to hypoxemia are found throughout this book.

Arterial P_{CO_2} (Pa_{CO_2}) and pH In a steady state, the level of Pa_{CO_2} reflects the level of alveolar ventilation. In the absence of a disorder in metabolic acid–base balance, an increase or decrease in Pa_{CO_2} beyond normal limits indicates a primary disorder in alveolar ventilation. A summary of these disorders and useful criteria for distinguishing among them, based on arterial blood gas composition, are given in Table 31-13.

Acute *respiratory alkalosis,* produced by alveolar hyperventilation, is characterized by hypocapnia (Pa_{CO_2} < 36 mm Hg) and an appropriately elevated pH (>7.44). In time (e.g., 24 h or more), renal compensation occurs, and the concentration of bicarbonate in serum decreases. If alveolar hyperventilation continues, a chronic respiratory alkalosis, partly or completely "compensated," ensues.

TABLE 31-12 Effect of Altitude on Mean Alveolar and Arterial O_2 Pressures

Altitude (Feet)	Barometric Pressure (mm Hg)	Ambient P_{O_2} (mm Hg)	Alveolar P_{CO_2} (mm Hg)
0	760	159	103
1000	733	154	98
2000	707	148	94
3000	681	143	90
4000	656	138	85
5000	632	133	81
6000	609	128	77
8000	565	118	69
10,000	523	110	61
12,000	484	101	54

Data from Wasserman K. Cardiovascular manifestations of respiratory insufficiency. Clin Notes Respir Dis. Fall; 1973;12(2):3–10.

TABLE 31-13 Classification of Primary Respiratory Disorders of Acid–Base Balance

Disorder	Definition
Acute respiratory alkalosis (acute alveolar hyperventilation)	Pa_{CO_2} below lower limit of normal (<36 mm Hg), with accompanying alkalemia (pH >7.44)
Chronic respiratory alkalosis (chronic alveolar hyperventilation)	Pa_{CO_2} below lower limit of normal, with pH normal (or near normal) due to renal compensation and lowered serum bicarbonate concentration (<19 mEq/L)
Acute respiratory acidosis (acute alveolar hypoventilation)	Pa_{CO_2} above upper limit of normal (>44 mm Hg), with accompanying acidemia (pH <7.36)
Chronic respiratory acidosis (chronic alveolar hypoventilation)	Pa_{CO_2} above upper limit of normal, with pH normal (or near normal) due to renal compensation and elevated serum bicarbonate concentration (>30 mEq/L)

A low Pa_{CO_2} is not necessarily indicative of a primary disturbance in alveolar ventilation. Instead, it may be a consequence of respiratory compensation (partial or complete) for metabolic acidosis; this possibility is signaled by the coexistence of hypocapnia and a low pH (<7.36). Since the kidney and respiratory system do not overcompensate for acid–base derangements, the coexistence of hypocapnia and acidemia suggest the presence of two primary disturbances.

Acute respiratory acidosis, caused by alveolar hypoventilation, is characterized by an abnormally high Pa_{CO_2} (>44 mm Hg) and a subnormal pH (<7.36). Again, in time (24 h or more), renal compensation for the primary respiratory disorder restores the serum bicarbonate concentration and blood pH toward normal. A high value for Pa_{CO_2} may also reflect respiratory compensation for a primary metabolic alkalosis ($[HCO_3^-] > 30$ mEq/L). In this circumstance, however, blood pH will be abnormally high (pH >7.44), rather than low. In general, the elevation in Pa_{CO_2} in compensation for metabolic alkalosis does not exceed about 55 mm Hg. A Pa_{CO_2} exceeding this value in the setting of a metabolic alkalosis suggests the likely coexistence of a primary respiratory acidosis.

This discussion has been limited primarily to alterations in arterial blood gas values in primary respiratory acidosis or alkalosis. Metabolic derangements often complicate the picture. These disorders are considered elsewhere (Chapter 17).

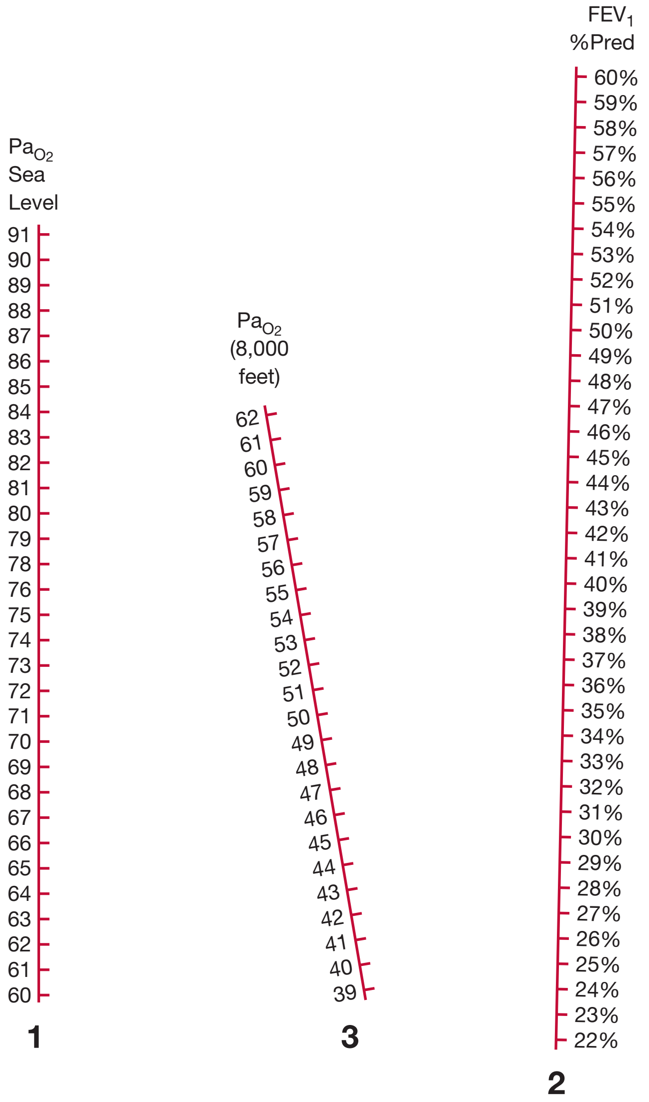

Figure 31-30 Nomogram for predicting in-flight oxygen tension. Using a straight edge, the patient's resting Pa_{O_2} at sea level (*column 1*) is aligned with his or her FEV_1 percent of predicted (*column 2*). The expected in-flight Pa_{O_2} (*column 3*) is estimated as the value where the line crosses the center scale. *(Data from Dillard TA, Berg BW, Rajagopal KR, et al. Hypoxemia during air travel in patients with chronic obstructive pulmonary disease. Ann Intern Med. 1989;111:362–367; and Knudson RJ, Slatin RC, Lebowitz MD, et al. The maximum expiratory flow-volume curve: Normal standards, variability, and effects of age. Am Rev Respir Dis. 1976;113:587–600.)*

■ Testing for Air Travel–Related Hypoxemia

Travel in commercial jet airliners typically results in exposure of passengers and crew to conditions equivalent to about 6000 to 8000 ft above sea level. For individuals with normal pulmonary gas exchange, the resulting Pa_{O_2} falls within a clinically acceptable range. However, for many patients with lung disease, the resulting Pa_{O_2} may well be problematic, even in those patients who do not require supplemental oxygen at sea level. Consequently, assessment of patients with chronic lung diseases, particularly COPD and interstitial lung diseases, has become part of the repertoire of tests offered by many pulmonary function laboratories.[83–87] One approach to estimating the resultant Pa_{O_2} during air travel is based upon use of regression equations (Fig. 31-30). Using the patient's resting Pa_{O_2} at sea level and his or her FEV_1 percent of predicted, the expected in-flight Pa_{O_2} can be estimated. Some experts advocate use of the nomogram for determining which patients ought to undergo hypoxia inhalation testing (HIT), while others advocate performance of HIT for all traveling patients at risk for in-flight hypoxemia.

HIT is based on the observation that exposure to hypoxic gas mixtures can reproducibly mimic the Pa_{O_2} arising under true hypobaric conditions. Exposure to 15.1% oxygen for 20 min reliably duplicates the resultant Pa_{O_2} at 8000 ft. During performance of the test, the patient, with nose clips in place, breathes from a reservoir though a mouthpiece. The electrocardiogram is monitored, and arterial blood gases are obtained at the conclusion of the test. Supplemental oxygen can then be titrated and prescribed according to the findings.

The British Thoracic Society (BTS) has published recommendations for use of supplemental oxygen during air travel, based on the patient's oxygen saturation at sea level and the presence or absence of risk factors.[84]

The BTS recommends no in-flight supplemental oxygen if the oxygen saturation at sea level is >95%; if the oxygen saturation is 92% to 95%, supplemental oxygen is recommended if additional risk factors are present, including hypercapnia, FEV_1 <50% predicted, lung cancer, interstitial lung disease with fibrosis, chest wall or respiratory muscle disorders, need for mechanical ventilation, cardiac or cerebrovascular disease, or travel within 6 weeks of hospital discharge following an acute exacerbation of chronic lung or heart disease. Supplemental oxygen is also recommended if oxygen saturation is <92% or if the patient uses supplemental oxygen at sea level, for whom an increase in oxygen flow during flight is advised.

The BTS also recommends supplemental oxygen for patients whose Pa_{O_2} on challenge testing (using an $F\text{I}_{O_2}$ of 15% for 20 min) is <50 mm Hg and, possibly, for those whose Pa_{O_2} is between 50 and 55 mm Hg; in the latter group, a walk test may be helpful.[84]

CONTROL OF BREATHING

The rate, depth, and pattern of breathing reflect a complex interplay of neurohumoral and chemical regulatory mechanisms that drive the respiratory apparatus. Tests used to evaluate the control of breathing, based on assessment of the ventilatory response to controlled hypercapnia or hypoxia, are uncommonly performed in the clinical setting. However, since these tests highlight important physiologic mechanisms that affect the level and pattern of ventilation, they are summarized in subsequent sections.

■ Ventilatory Response to CO_2

The ventilatory response to changes in Pa_{CO_2} is linear over a broad range (Fig. 31-31). Determination of the ventilatory response to controlled hypercapnia generally is based on one of the two methods: the steady-state method[88] or the rebreathing method.[89]

Steady-State Method

After a control period in which CO_2-free air is breathed to establish a baseline, the patient is subjected to two or more periods of breathing CO_2-enriched air. Care is taken to achieve a steady state of ventilation and circulation during each exposure. Especially at the higher concentrations of inspired CO_2, at least 10 to 20 min is required for a steady state to be reached in alveoli, arterial blood, cerebrospinal fluid, and the chemosensitive areas of the brain. The ventilatory response to CO_2 is then determined from a plot of $\dot{V}\text{E}$ versus Pa_{CO_2}. In patients without underlying lung disease, end-tidal CO_2 concentration is often substituted for Pa_{CO_2}. In addition, in order to eliminate the influence of variations in arterial PO_2 on the ventilatory response to CO_2, the inspired gas is enriched with O_2 during the control and test periods.

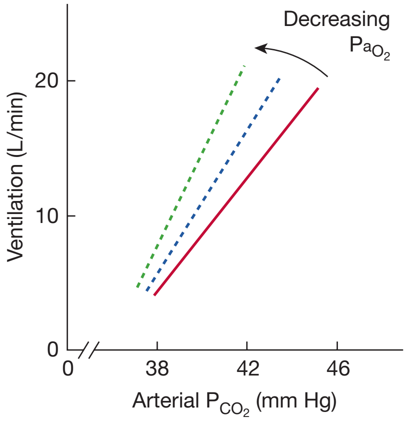

Figure 31-31 Linear relationship between minute ventilation ($\dot{V}\text{E}$) and arterial P_{CO_2}. The dashed lines show the increased slope of the relationship of $\dot{V}\text{E}$ versus P_{CO_2} as Pa_{O_2} decreases.

TABLE 31-14 Factors Associated with an Altered Ventilatory Response to CO_2

Depressed Response
Endurance training
Aging
Genetic/racial predilection
Metabolic alkalosis
Narcotics, barbiturates, and other CNS depressants
Neurologic disorders (encephalitis, brain stem disease)
Myxedema
Obesity-hypoventilation syndrome
Chronic obstructive pulmonary disease (COPD)
Accentuated Response
Metabolic acidosis
Drugs (e.g., aminophylline, salicylates, thyroxine, progesterone)

Rebreathing Method

This method entails rebreathing a CO_2-enriched gas mixture from a bag for approximately 4 min. The validity of the approach requires rapid equilibration of CO_2 among alveolar gas, arterial and mixed venous blood, and the chemosensitive areas of the brain. The bag is filled at the outset with a mixture of 7% CO_2 in O_2; O_2 is substituted for air in this mixture to avoid the ambiguity of a hypoxic stimulus to ventilatory drive.

The result of the CO_2 rebreathing test is described by the use of two terms: (1) the *slope* of the line relating change in ventilation response to change in end-tidal P_{CO_2} ($\Delta\dot{V}\text{E}/P_{CO_2}$), determined by using the method of least squares linear regression analysis, and (2) the *x-intercept* of the relationship between $\dot{V}\text{E}$ and end-tidal P_{CO_2}.

Normal Response to CO_2 and Modifying Influences

As indicated above, the normal increase in ventilatory response to increasing concentrations of inspired CO_2 is linear. Normal responses are categorized as low (<1.5 L/min/mm Hg), intermediate (1.5–5.0 L/min/mm Hg), or high (>5.0 L/min/mm Hg). Most normal persons (about 80%) have an intermediate ventilatory response. A variety of factors, both genetic and environmental, seem to influence the ventilatory response to CO_2 (Table 31-14).

■ Ventilatory Response to Hypoxia

The response to acute hypoxia in normal persons is largely determined by the peripheral arterial chemoreceptors, as long as the level of hypoxia is mild to moderate. Even at sea level, the level of arterial P_{O_2} in normal persons provides an appreciable chemoreceptor drive, accounting for about 10% of the minute ventilation. Unlike the linear response of $\dot{V}\text{E}$ to progressive hypercapnia, the response to hypoxemia is curvilinear (Fig. 31-32). The magnitude of the ventilatory response to a decrease in arterial P_{O_2} depends on the Pa_{CO_2}, increasing as the concentration of CO_2 in arterial blood is increased.

As may be seen from the hyperbolic curves in Fig. 31-32, the rate of change in ventilation is greater over the lower range of oxygenation (when Pa_{O_2} falls below 60 mm Hg). Not shown in Fig. 31-32 is the depression of ventilation brought about by severe hypoxemia, presumably because of the central depressing effect of severe hypoxia on respiratory neurons.

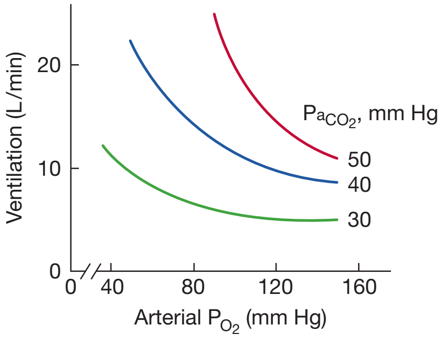

Figure 31-32 The curvilinear relationship between ventilation and arterial P_{O_2} at various levels of arterial P_{CO_2}. The rate of change of ventilation as P_{O_2} falls (slope) increases precipitously at a P_{O_2} of approximately 60 mm Hg when P_{CO_2} is 40 mm Hg. The abrupt increase in ventilation occurs at a higher P_{O_2} when the level of P_{CO_2} is elevated, and at a lower P_{O_2} when the prevailing P_{CO_2} is lower.

Although tests for assessing the ventilatory response to hypoxia are less well standardized than those for measuring the hypercapnic response, they, too, may be conveniently categorized into steady-state and non-steady-state methods. In one steady-state method,[88] successive ventilatory responses are determined to a series of increasingly severe hypoxic gas mixtures, each administered for at least 10 min; Pa_{CO_2} is kept constant by the addition of CO_2 to the inspired gas mixture as hypoxia-induced hyperventilation develops. In another, the effect of hypoxia on the slope of the plot of $\dot{V}_E$ versus P_{CO_2} as P_{O_2} is lowered from hyperoxic (at least 200 mm Hg) to hypoxic (40 mm Hg) levels is determined. The normal response to diminished inspired oxygen concentrations is characterized by an increase in sensitivity (slope) without a change in the CO_2 threshold.

Three non-steady-state techniques are currently in use. In the hypoxic rebreathing test,[90] the subject rebreathes a hypoxic gas mixture containing 7% CO_2. As arterial hypoxemia intensifies, causing an increase in ventilation and in CO_2 elimination into the closed circuit, the P_{CO_2} in the system is held constant at a predetermined level by the diversion of a fraction of the expired gas through a CO_2 absorber. The ventilatory response is determined at two or more levels of P_{CO_2}, since the hypoxic response is influenced by P_{CO_2}.

An alternative rebreathing test[91] induces progressive hypoxemia by adding N_2 to the inspired gas mixture over a 20-min period.

Finally, in a relatively simple test,[92] the patient induces a transient drop in arterial P_{O_2} by inhaling pure N_2 for a few breaths. The relationship between $\dot{V}_E$ and Pa_{O_2} is plotted; the slope of the relationship is the sensitivity to hypoxia. Because the duration of the hypoxia is brief, presumably only the peripheral chemoreceptors are stimulated. No adjustment is made for the drop in P_{CO_2} that occurs during the hypoxia-stimulated increase in ventilation.

Normal Responses to Hypoxia and Modifying Influences

The normal ventilatory response to acute hypoxia varies among individuals. Several factors may influence the relationship (Table 31-15). A high ventilatory response to CO_2 may be associated with a high sensitivity to hypoxia; in addition, higher levels of arterial P_{CO_2} are associated with a higher ventilatory response to hypoxia. Interestingly, a long duration of hypoxia before the test period, as is the case for example, in native residents at high altitude and persons with cyanotic congenital heart disease, a blunted response to acute hypoxia is observed. Finally, a variety of other clinical disorders, including myxedema and hypothyroidism, autonomic nervous system dysfunction, chronic narcotic addiction, and the chronic use of methadone, are characterized by a reduced hypoxic response.

TABLE 31-15 Factors Associated with an Altered Ventilatory Response to Hypoxia

Depressed Response
Long-standing hypoxia
High-altitude dwelling
Congenital cyanotic heart disease
Aging
Hypothyroidism
Riley–Day syndrome
Chronic use of methadone
Following carotid endarterectomy
Accentuated Response
Heightened CO_2 response
Hypercapnia

■ Nonventilatory Measures of Ventilatory Drive

Measurement of ventilation in response to acute hypoxia or hypercapnia provides a useful index of respiratory output when the ventilatory apparatus (thorax, diaphragm, abdominal muscles, lung, and airways) is normal. This situation obviously does not apply in certain neuromuscular disorders in which the thorax and diaphragm behave abnormally. In addition, it does not apply in some instances of pulmonary disease, notably obstructive airway disease, in which the respiratory apparatus may not be capable of responding normally, even though it is intact and chemosensitivity is normal. In this instance, a decrease in ventilatory response may be attributable to the excessive mechanical load placed on the muscles of respiration.

When ventilation fails to provide a reliable measure of the ventilatory drive (efferent discharge from the respiratory neurons), the diaphragmatic electromyograph (EMG) or the pressure generated by the inspiratory muscles during the first 0.1 s of an occluded inspiration (the $P_{0.1}$)[93] has been used for the clinical assessment of the control of breathing.

The electrical activity of the diaphragm is directly related to neural activity of the phrenic nerve. Therefore, it provides a measure of efferent neural traffic to the diaphragm. The diaphragmatic EMG may be recorded in patients by placing the tip of an esophageal catheter, containing bipolar electrodes, at the level of the diaphragm.

The second approach to obtaining a nonventilatory measure of ventilatory drive is the determination of $P_{0.1}$, which is the negative pressure generated by the inspiratory muscles during the first 100 ms of an inspiratory effort made against an occluded airway. During this brief period, contraction of the respiratory muscles is virtually isometric, and the force generated correlates with activity recorded by the diaphragmatic EMG.

In performing the test, airflow in the inspiratory line of the breathing circuit is randomly interrupted during the preceding expiration. The 100-ms period has proved to be so brief as to be imperceptible, thereby obviating any corrective action by the subject during the breath against the occlusion. However, the $P_{0.1}$ is far from foolproof. A major concern is that $P_{0.1}$ is affected by resting lung volume: $P_{0.1}$ is reduced when FRC is abnormally high, a common occurrence in obstructive disease of the airways.

ASSESSMENT OF INTEGRATED FUNCTIONS: 6-MINUTE WALK TEST

A complete evaluation of a patient with respiratory symptoms often requires assessment of exercise capacity, in addition to traditional pulmonary function tests and radiographic studies. A number of exercise studies can be employed, including cardiopulmonary exercise tests (Chapter 32), cardiac stress tests, and exercise-induced bronchospasm protocols. One of the most widely used, practical modalities is the 6-minute walk test (6MWT). Despite its simplicity, the 6MWT has become a powerful tool in the evaluation of functional status and prognosis of patients with a variety of functional impairments.[94]

■ Technical Aspects

The 6MWT is performed indoors. There is an initial period of rest in a chair for at least 10 min, during which baseline vital signs are taken. The patient then stands and is asked to rate baseline dyspnea and overall fatigue using the Borg scale (from 1 to 10). The patient, walking at a comfortable pace, completes 60-m laps on a walking course that is 30 m in length. Cones are used to mark the turnaround points. For patients using supplemental oxygen, the oxygen is delivered at standard rate, or as prescribed by a physician, or as determined by protocol. The patient should not carry or push the oxygen source during testing. The number of laps and a postwalk Borg scale assessment are recorded, as is the total distance walked over 6 min (6MWD).

Although pulse oximetry during the 6MWT is considered optional, it has become standard at many institutions. In some cases, pulse oximetry can be used to titrate levels of oxygen supplementation. Obtaining a high-quality oximeter signal is imperative.

A number of sources of variability are inherent in 6MWT. A modest training effect has been reported when two studies are performed within 1 week. Concomitant medication use also can impact the 6MWT. Improved test performance, for example, occurs after bronchodilator use in patients with COPD. Shorter height, female sex, and higher body weight are associated with reduced performance.[95] Despite these factors, the 6MWT has been found to have excellent reproducibility, especially when performed in evaluation of specific clinical entities, such as idiopathic pulmonary fibrosis.[96,97]

Several modifications of the 6MWT are in clinical use. During a *shuttle-walking test*, the patient walks on a 10-m course while the walking speed is increased every minute until the patient cannot reach the turnaround point within the set time. The *timed walk test (TWT),* which has been designed for patients with idiopathic pulmonary fibrosis, has three stopping criteria based on changes in oxyhemoglobin saturation.

Absolute contraindications to performing the 6MWT include unstable angina or myocardial infarction within 1 month of the study. Resting tachycardia of greater than 120 beats per minute, systolic blood pressure greater than 180 mm Hg, or diastolic blood pressure greater than 100 mm Hg are relative contraindications. The study should be terminated if the patient develops chest pain, severe dyspnea, leg cramps, diaphoresis, or profound oxyhemoglobin saturation.

■ Interpretation

Although the 6MWT is limited in its inability to provide objective measures of functional capacity, such as oxygen uptake, the test provides very useful clinical information. In addition, it realistically represents the patient's functional capacity during physical effort that more closely reflects his or her daily activity. Reliable reference equations establishing standard performance during a 6MWT in healthy patients are not currently available.

The 6MWT has several indications, including, most notably, measurement of the response to a number of medical and surgical interventions. Pulmonary rehabilitation clearly improves 6MWT performance in patients with COPD, while pharmacologic interventions for pulmonary arterial hypertension and heart failure, among other disorders, have also been shown to favorably affect test results. Lung transplantation (unilateral and bilateral) and lung volume reduction surgery for emphysema have been shown to significantly improve results of the 6MWT.

The 6MWT has also been used to assess functional status in patients with COPD, cystic fibrosis,[98] heart failure, and peripheral vascular disease, and in determining eligibility for, and timing of, lung transplantation. In the absence of well-established reference standards, the clinical value of performing a single test in these patient groups is limited. Serial studies are likely to be more useful than a single 6MWT.

Recently, a number of publications have established the value of the 6MWT in predicting morbidity and mortality from heart and lung disease. Results from the test have been shown to have an inverse relationship with mortality in severe COPD. Walk distance and velocity, as well as magnitude of oxyhemoglobin desaturation, are correlated with survival in idiopathic pulmonary fibrosis. Similar correlations have been made in heart failure and primary pulmonary hypertension.

Finally, at some institutions, results of the 6MWT are utilized to not only establish the presence of exertional hypoxemia, but also to titrate supplemental oxygen with activity.

QUALITY CONTROL IN THE PULMONARY FUNCTION LABORATORY

Meaningful interpretation of pulmonary function tests requires confidence in the accuracy and reproducibility of results provided by the pulmonary function laboratory. Previously, it was tacitly assumed that all data from all laboratories, especially when reported as "percent predicted," were equally reliable. In recent years, the fallacy of this assumption has been explicitly recognized, and steps have been taken to standardize equipment and procedures and to ensure accuracy, reproducibility, and uniformity in testing and reporting.[8,10] To accomplish this goal, both analytical and nonanalytical factors must be taken into account.

■ Nonanalytical Factors in Quality Control

A familiar example of a confounding influence that may distort test results is the anxious patient who pauses outside the laboratory door to "calm the nerves" by smoking one or more cigarettes before undergoing pulmonary function testing. Cigarette smoking before the diffusing capacity of the lungs is determined can generate enough carboxyhemoglobin to reduce a normal value to subnormal levels.

Another example of a nonanalytical factor is the failure to achieve patient understanding and comfort for tests that usually require patient cooperation. Unfortunately, a preliminary explanation before the patient arrives at the laboratory or prior exposure of the patient to the laboratory and its personnel is usually impractical. Use of explanatory sheets or descriptive brochures may prove helpful. If such materials are not available, laboratory personnel are obligated to make the patient comfortable and even perform "practice runs" before undertaking final testing.

When the patient arrives at the pulmonary function laboratory, an assessment should be made of his or her prior experiences. Did the patient undergo other tests or procedures that could alter the outcome of the pulmonary function tests in question? Is the patient fatigued or in pain? Should a period of rest precede the tests in order to ensure optimal performance? If delay is impractical, the test report should include the fact that the patient was fatigued or in pain.

Medication use before pulmonary function testing can seriously affect the results. For example, self-administration of bronchodilators before testing can artificially enhance tests of airflow. If medications have been taken before the patient arrives at the laboratory, the time of administration should be part of the record. Also, a request for pulmonary function test results for patients who regularly

AL GRAWANY

take bronchodilators should indicate whether the tests are to be done without interruption of the regular schedule of medications, whether bronchodilators are to be discontinued before the test is done, or whether regular bronchodilators are to be discontinued so that the effects of bronchodilation can be tested. Appropriate comments about bronchodilators are part of the report.

A major nonanalytical cause of misinterpreting results is the inappropriate application of predicted normal values to the patient population by the laboratory (see "Approach to Interpreting Commonly Performed Pulmonary Function Tests," below). For example, normal values based on data obtained using physically fit hospital personnel do not necessarily apply to those who have a sedentary existence. Noncomparable race, as well as lifestyle, may complicate comparisons. Anthropologic differences among control and test populations are not easily reconciled. Extraordinary height, weight, or age cannot be easily extrapolated if corresponding subjects are not represented in the control group. Using patient-reported height, rather than making measurement of patient height, may introduce an error in the selection of appropriate normal values.[99] Comparison of control and test results at different altitudes can be invalid if due regard is not paid to the influence of hypoxia on certain measurements (e.g., diffusing capacity).

Analytical Factors in Quality Control

Performance of pulmonary function tests is replete with opportunities for error. The equipment, techniques, use of control values, and calculations are potential sources of error. In an attempt to minimize errors, standardization of techniques has been advocated. For example, with respect to performing the FVC maneuver, guidelines have been established for the number of attempts required, acceptable variability between efforts, and methods for selecting test data in order to arrive at acceptable results. To avoid misuse of spirometers, criteria have been set for minimal performance with respect to capacity, accuracy, and frequency response of various spirometers; in addition, standards have been developed for determining the single-breath diffusing capacity. Potential sources of discrepancies—such as breath-holding time, concentration of hemoglobin, dead space of the equipment and the patient, $\mathrm{FIO_2}$, volume of the alveolar sample, number of tests, and acceptable variability in results—are taken into account.

Quality Control of Test Results

Guidelines for standardization play a major role in reducing discrepancies between laboratories. However, measures are also required to ensure accuracy and reproducibility within any given laboratory. Among the elements of control that merit consideration are calibration, validation of calibration, and performance of a control measurement. *Calibration* is the adjustment of an instrument's output so that it validly reflects a known input. *Verification of calibration* entails introduction of the same known input and demonstration that the correct output is reproduced. *Performance of a control measurement* refers to the testing of a substrate that has known properties, similar to those usually tested, to prove the accuracy of the instrumentation.

One example of the application of these principles is blood gas analysis. Use of control measurements derived from tonometered blood or commercially prepared buffer solutions is now widespread. Another example is assessment of diffusing capacity[100] and routine incorporation of simulator testing in its measurement.[101]

Unfortunately, similar controls do not exist for pulmonary function tests. Therefore, laboratory technologists have the responsibility for continuing to be alert, not only with respect to faithful observance of guidelines for standardization, but also to detect in-house sources of error—for example, a leak in the system, malfunction of gas analyzers, faulty analog-to-digital converters, and faulty electronics that reduce frequency response.

Responsibility and Cost in Quality Control

All who work in the laboratory must be concerned with quality control[102] and resist the frequent temptation to cut corners. Time has to be set aside for the technologist to care for and calibrate equipment, to establish proper control values for the laboratory, to search for inconsistencies in the data and interpretation, and to keep up with changing standards. Also, equipment and supplies, including calibrating syringes and calibrating gases, are expensive. However, when put into the balance, the cost and waste of producing erroneous results exceed, by far, the expense of practicing quality control.

Infection Control

Given the relatively close contact between patients and technical staff during performance of pulmonary function tests, the issue of infection control is one that must be carefully considered. To date, the role of pulmonary function equipment in transmission of disease appears to be minimal. Although the presence of potential pathogens on laboratory mouthpieces, valves, and tubing has been well documented, implication of these organisms in the transmission of disease has not been established. Nevertheless, the potential hazards should be recognized, and appropriate care exercised.

Infection control begins with practice of the basic principles of hygiene. Hand washing between patients and use of protective gloves by staff when they are handling potentially contaminated equipment are important considerations. Care must be taken in working with mouthpieces, nose clips, and any other implements that come in contact with mucosal surfaces. These devices, if reused, should be disinfected or sterilized after each use. Other equipment—manifolds, tubing, etc.—should be sterilized on a regular basis. In fact, guidelines from the ATS call for the disinfection or sterilization before reuse of any equipment surface with visible condensation from expired air.[8,103]

Because of recent growing concern over cross-contamination among patients and laboratory personnel, manufacturers now produce a variety of in-line filters and disposable pneumotachographs. Care should be taken, however, to assure that response characteristics of the test equipment are not driven to unacceptable levels by use of these devices. Current literature on this topic should be consulted regularly.

Concern over transmission of infection, to both patients and laboratory personnel, came into sharp focus in 2019 during the COVID-19 pandemic. General guidelines were established for prioritizing patients most in need of testing, use of personal protective equipment for laboratory personnel, and strict attention to laboratory air circulation times and room cleaning protocols.[104–106]

APPROACH TO INTERPRETING COMMONLY PERFORMED PULMONARY FUNCTION TESTS

A standard battery of pulmonary function tests is commonly used to identify and quantify abnormalities in the performance of the respiratory system. An organized approach to interpreting these studies is critical.[107–109]

Once a patient's baseline values are established, the tests are valuable in tracking the course of the disorder and its response to treatment.

Results of pulmonary function tests are interpreted by comparing individual patient data with reference or predicted values for normal subjects.[110,111] Ideally, predicted values should be generated from large groups of well-defined, normal or healthy subjects with proper distribution of anthropometric characteristics such as sex, age and height, and ethnic background. Despite dedicated attempts to improve prediction formulas, however, many still fail to take into account important sources of discrepancy, such as the racial and ethnic backgrounds of the patients and the control population, the effects of altitude and exposure to air pollution, and effects of inordinate body size or old age. As a result, not all sets of predicted normals are applicable in pulmonary function laboratories outside the immediate vicinity of the patient populations from whom the data were collected.[112] Extrapolation beyond the characteristics of the reference population should be avoided.

Published guidelines from a joint Task Force of the ATS and ERS recommended that in the United States, ethnically appropriate reference equations from the National Health and Nutrition Examination Survey (NHANES) III be used for individuals aged 8 to 80 years. The Task Force did not recommend any specific set of reference equations for laboratories in Europe, but it suggested the need for an investigation conducted throughout Europe to derive contemporary equations for prediction of normal lung function.

The same ATS/ERS Task Force recommended that each pulmonary function test result falling below the fifth percentile of the frequency distribution of values measured in the reference population be considered abnormal. If normal test results fall in a normal distribution, values below the fifth percentile can be estimated using Gaussian statistics. If the distribution of normal values is non-Gaussian, the lower limit of normal is estimated using a nonparametric technique, for example, the 95th percentile method. Traditionally, but without a sound statistical basis, most laboratories have used an arbitrary cutoff of 80% predicted to define normal. While this method may be reasonable in children, errors may arise if it is applied to adult test results.

Interpretation Scheme and Classification of Abnormal Patterns

A variety of schemes have been proposed for sorting out abnormalities in pulmonary function test results. Many are based on initial categorization of findings reflective of one of the four basic patterns described in the following paragraphs.

An *obstructive* pattern stems from narrowing of any portion of the airways—from upper airway to bronchioles less than 2 mm in diameter—that results in a reduction of maximal airflow in relation to maximal volume.

A *restrictive* pattern is elicited by diseases of the lung, chest wall, pleural space, or neuromuscular respiratory apparatus that reduce lung volumes, particularly TLC, and vital capacity.

A *combined obstructive–restrictive* pattern results from pathologic processes that reduce lung volumes, vital capacity, and airflow, and that also include an element of airway narrowing.

Finally, *abnormal gas transfer* may be noted as part of one of the aforementioned patterns or in isolation and reflects an abnormality in the alveolar capillary membrane, impairing oxygen uptake from alveolar gas to pulmonary capillary blood.

Overlap among categories is not uncommon. For example, widespread interstitial disease, as in idiopathic pulmonary fibrosis, often shows a pattern that indicates important components of both restrictive disease and abnormal gas transfer.

One useful sequence recommended by the ATS/ERS Task Force for analyzing a conventional battery of pulmonary function test results is illustrated in Fig. 31-33.

Analysis begins with evaluation of the ratio of FEV_1 to VC. While, historically, the ratio of FEV_1 to FVC (FEV_1/FVC%) served as the basis for distinguishing obstructive disorders from normality or restrictive disease, the ATS/ERS Task Force currently recommends using as the denominator the FVC, *or* the VC (“slow” VC or SVC), *or* the FIVC, whichever is greatest. If the ratio is less than the lower limit of normal (i.e., below the fifth percentile) and the VC (defining VC as any of the three previously noted vital capacity measurements) is at or above the lower limit of normal, the pattern is obstructive. If TLC is not at or above the lower limit of normal, a mixed obstructive–restrictive pattern is suggested. Distinction between asthma and chronic bronchitis on the one hand, and emphysema on the other, is based upon whether the DL_{CO} is normal (asthma or chronic bronchitis) or reduced (emphysema). The previous practice of using a value for FEV_1/FVC% of less than 70% to define obstruction results in misdiagnosis of airway obstruction in men over 40 years and women over 50 years of age, as well as overdiagnosis of COPD in elderly, asymptomatic nonsmokers.

If FEV_1/VC and VC are each equal to or greater than the respective lower limits of normal, spirometry is considered normal; measurement of the DL_{CO} can then help distinguish between normal pulmonary function and pulmonary vascular disorders. If VC is below the lower limit of normal, a reduced TLC supports a diagnosis of restriction, while a normal TLC indicates an obstructive pattern. Once again, in the setting of a restrictive pattern, measurement of DL_{CO} can be used to distinguish between pulmonary parenchymal disorders and disorders of the chest wall or respiratory muscles. Note that according to these guidelines, an obstructive pattern may be diagnosed in the setting of a *normal* FEV_1/VC, if VC is reduced and TLC is normal or elevated.

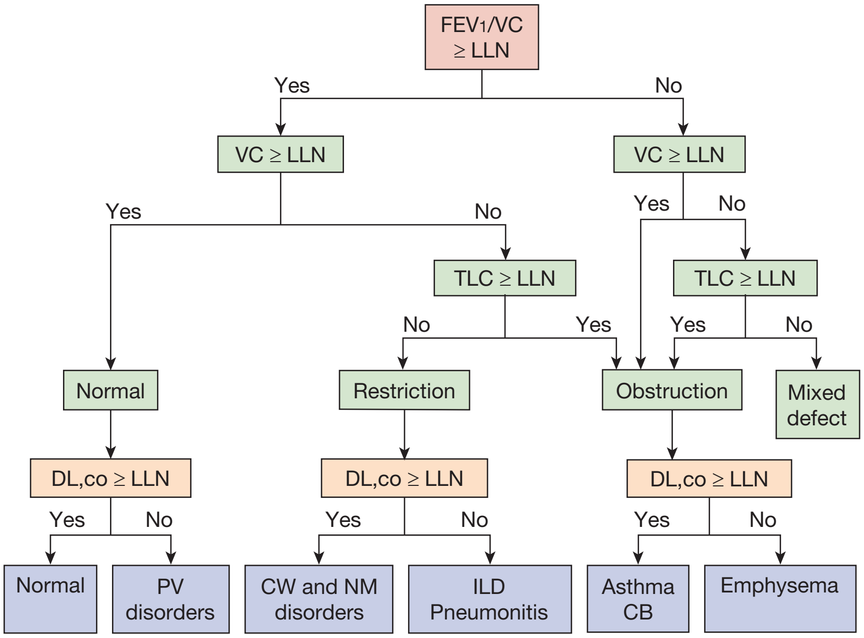

Figure 31-33 Proposed sequence of test review in the interpretation of pulmonary function tests. See text for discussion. CB, chronic bronchitis; CW, chest wall; ILD, interstitial lung disease; LLN, lower limit of normal; NM, neuromuscular; PV, pulmonary vascular. *(Reproduced with permission from Pellegrino R, Viegi G, Brusasco V, et al. Interpretive strategies for lung function tests. Eur Respir J. 2005;26(5):948–968.)*

TABLE 31-16 Grading of Severity of Abnormal Spirometry Based on FEV_1

Severity	FEV_1 Percent Predicted
Mild	>70
Moderate	60–69
Moderately severe	50–59
Severe	35–49
Very severe	<35

Modified with permission from Pellegrino R, Viegi G, Brusasco V, et al. Interpretive strategies for lung function tests. Eur Respir J. 2005;26(5):948–968.

TABLE 31-17 Conditions Associated with Reduced Peak Inspiratory (PI_{max}) and Expiratory (PE_{max}) Pressures

Condition	PI_{max}	PE_{max}
Poor effort	↓	↓
Fatigue	↓	↓
Neuromuscular disease	↓	↓
Increased lung volume	↓	N
Decreased lung volume	N	↓

↓, decreased; N, normal.

Once the predominant abnormality is defined with initial pulmonary function testing, the whole battery may not be necessary in following the course of the disease or in assessing its response to treatment. For example, particular determinations, such as spirometry, may suffice in patients with airway diseases. Notably, according to the ATS/ERS guidelines, the severity of the abnormality in each of the obstructive, restrictive, or mixed patterns is expressed on the basis of the FEV_1 (Table 31-16). Standards have been established for defining significant changes in results over time: A 15% or greater change in FVC or in FEV_1, or a greater than 10% change in DL_{CO} is considered significant.

Assessing Respiratory Muscle Strength and Effort

One additional measurement that is frequently useful in assessing results of routine spirometry is assessment of respiratory muscle strength. Respiratory muscle strength is expressed in terms of peak inspiratory (PI_{max}) and peak expiratory (PE_{max}) pressures, determined under static conditions.[26] The technique was outlined in a previous section. Any of a number of factors may be responsible for low peak inspiratory or expiratory pressures (Table 31-17): suboptimal effort, fatigue, weakness of the respiratory muscles, deformity of the chest wall, or intrinsic diseases of the lungs or chest wall. Although the first three factors characteristically reduce both peak inspiratory and expiratory pressures, disease of the lungs or chest wall often reduces, selectively, one or the other peak pressure. Thus, diseases that reduce lung volumes (e.g., widespread interstitial fibrosis) and shorten the length of the expiratory muscles at the end-inspiratory position generally reduce maximal expiratory pressure. Conversely, diseases that increase lung volume, such as obstructive airway disease, by decreasing the inspiratory muscle length at end-expiration generally reduce maximal inspiratory pressure.

If airflow during spirometry is reduced, determination of the peak inspiratory and expiratory pressures may be helpful in suggesting the mechanism. Many pulmonary function tests depend on the cooperation of the patient. Poorly reproducible peak flows that are consistently subnormal raise the question of poor effort. Conversely, consistently low values that occur despite maximal effort may signal neuromuscular disease.

Additional Details of Pulmonary Function Test Results in an Obstructive Pattern

Included in the obstructive pulmonary disorders (Table 31-18) are chronic obstructive diseases of the airways (chronic bronchitis and emphysema), bronchiectasis, asthma, small-airway disease, and upper-airway obstruction.

Except for diseases confined to the small airways, as noted previously, the hallmark of the obstructive pattern is a reduction in the $FEV_1/VC\%$. Notably, some healthy subjects have a reduced $FEV_1/FVC\%$ and an FEV_1 in the normal range. The clinical significance of these findings is unclear. Results of additional tests (e.g., lung volumes, DL_{CO}, assessment of bronchodilator responsiveness) may help distinguish those with airway obstruction from true normals.[113] Measurement of airway resistance (Raw) or specific airway conductance (SGaw) may be useful in assessing airway obstruction in subjects unable to perform a maximal forced expiratory maneuver.

Changes in lung volume commonly accompany the abnormal findings on spirometry, but, as indicated in Fig. 31-33, lung volume measurement is not mandatory in establishing the presence of obstruction. Frequently, but not invariably, lung volumes are abnormally high. Typically, all three lung volumes—RV, FRC, and TLC—are increased.

In addition to uncovering the pattern of chronic obstructive airway disease described above, certain additional tests provide insight into the sites and mechanisms of obstructive airway disease.

TABLE 31-18 Causes of an Obstructive Pattern

Disease Process	Anatomic Location of Lesion	Cause of Reduced Airflow
Chronic obstructive pulmonary disease (COPD)		
Chronic bronchitis	Large and small (<2-mm diameter) airways	Narrowing of airways by fibrosis, secretions, edema
Emphysema	Lung parenchyma	Loss of lung elastic recoil
Cystic fibrosis	Large and small airways	Narrowing of airway by fibrosis, retained secretions, edema Loss of elastic recoil
Asthma	Large and small airways	Narrowing of airways by smooth muscle contraction, edema, retained secretions
Small-airway disease	Small airways	Narrowing, stenosis of small airways
Upper-airway obstruction	Major, central airways (trachea, main bronchi)	Anatomic or functional narrowing of upper airway

Reversible versus Irreversible Obstructive Airway Disease

The response to inhaled bronchodilators traditionally has been used to help distinguish between chronic obstructive airway disease (chronic bronchitis and emphysema), in which airway resistance is virtually fixed, and asthma, in which bronchoconstriction is a prominent feature. This is an oversimplification, since a sizable minority of patients with COPD manifest a bronchodilator response. Furthermore, the absence of a bronchodilator response in a laboratory setting does not necessarily predict lack of a clinical response.

A universally agreed upon definition of reversibility is lacking. Expressing change in FEV_1 or FVC as percent of predicted values may be more advantageous than expression of changes in the values relative to baseline. In general, an increase in FEV_1 or FVC of at least 12% above baseline *and* an absolute increment of at least 200 mL is considered evidence of significant bronchodilation. If the increase in spirometric values is not significant, a decrease in lung volumes toward normal may be an indication of bronchodilator responsiveness.

Chronic Bronchitis versus Emphysema

Although chronic bronchitis and emphysema usually coexist, occasionally one or the other exists in virtually pure form. Two pulmonary function tests have proved valuable in distinguishing between the two—diffusing capacity (DL_{CO}), which is routinely measured, and static lung compliance (Cst,L), which is uncommonly measured clinically. Emphysema, characterized by a loss of alveolar units and a decrease in alveolar surface area, is associated with a low DL_{CO}, whereas the DL_{CO} in chronic bronchitis is usually normal or near normal.

The loss of alveolar units in emphysema also causes a decrease in the elastic recoil pressure of the lungs. As a result, Cst,L is increased in emphysema, whereas it is usually not appreciably altered in chronic bronchitis.

Small-Airway Disease

In obstructive disease of the small airways (i.e., those less than 2 mm in diameter), expiratory flow is usually normal, except at low lung volumes; that is, the FEV_3 and $FEF_{25-75\%}$ are abnormally low. Other, uncommonly performed tests for isolated, small-airway disease, including the helium–oxygen flow–volume loop, nitrogen washout test, and frequency dependence of dynamic compliance, would also be anticipated to be abnormal. Lung volumes and DL_{CO} are normal. Bronchodilators are virtually without effect.

The practical value of tests of small-airway function is problematic. At one time, high hopes were held that early detection of small-airway disease might reinforce measures, such as cessation of smoking, that would prevent or arrest progression to irreversible obstructive disease of the airways. However, enthusiasm for testing for small-airway disease has waned, since it is still unclear if small-airway disease is a reversible phase in the evolution of clinically significant obstructive airway disease that affects larger bronchi.

Upper-Airway Obstruction

The designation *upper-airway obstruction* is an umbrella for anatomic or functional narrowing of the large upper airways—the larynx, extra- and intrathoracic trachea, and lobar bronchi. Although upper-airway obstruction of any cause may reduce expiratory or inspiratory airflow, an alteration in the contour of the flow–volume loop has proved to be the most reliable abnormality in conventional pulmonary function testing. The observation from routine spirometry that the ratio of FEV_1 to peak expiratory flow rate (PEFR) exceeds 8 mL/L/min should prompt careful performance and review of the flow–volume loop, as described later.

Upper-airway obstruction can be divided into three major types: (1) fixed obstruction, (2) variable extrathoracic obstruction, and (3) variable intrathoracic obstruction.[114]

A *fixed obstruction,* such as tracheal narrowing by scar tissue at the site of a previous tracheotomy, is one in which the geometry and cross-sectional area of the lesion do not change during the respiratory cycle. Characteristically, both inspiratory and expiratory flows are affected about equally (Fig. 31-34A).

A *variable obstruction* is one in which the configuration of the obstructive lesion changes with the phases of respiration. Depending on its location in the tracheobronchial tree (extra- or intrathoracic), this type of lesion usually affects predominantly either inspiration or expiration.

The inspiratory arm of the flow–volume loop is primarily affected by a *variable extrathoracic* obstruction, leaving the expiratory limb relatively unaffected (Fig. 31-34B). The abnormal configuration of the flow–volume loop is attributable to the following sequence: during forced expiration, tracheal pressure exceeds atmospheric, so that the degree of obstruction decreases; conversely, during forced inspiration, intratracheal pressure becomes less than atmospheric and the trachea tends to collapse.

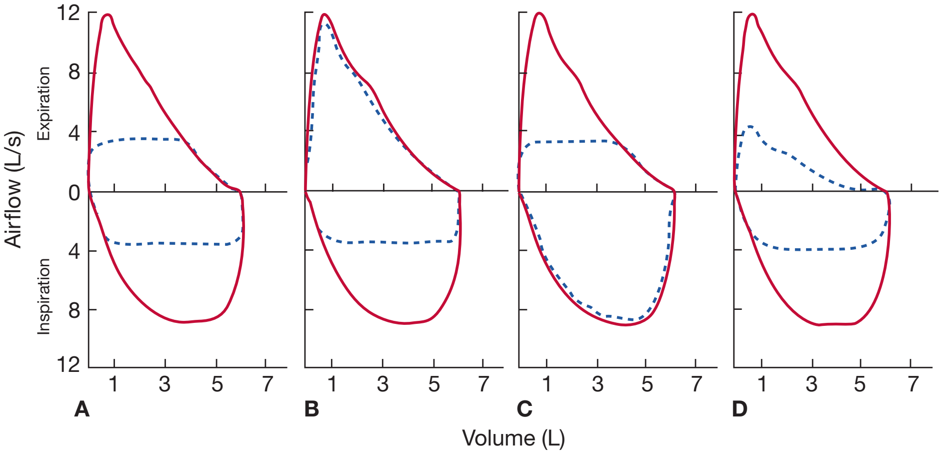

Figure 31-34 Schematic flow–volume loops in four pathologic conditions. **A.** In a fixed upper-airway obstruction, both inspiratory and expiratory limbs are truncated. **B.** In a variable extrathoracic obstruction, the inspiratory limb is flattened while the expiratory limb is not altered. **C.** In a variable intrathoracic obstruction, the expiratory limb is flattened while the inspiratory portion is unchanged. **D.** In chronic obstructive airway disease, although expiratory airflow is reduced, the tapering in airflow during expiration is generally maintained so that the configuration of the loop is different from that in variable intrathoracic obstruction.

TABLE 31-19 Distinguishing Features of Disorders Producing an Obstructive Pattern

Disorder	FEV_1	FVC	FEV_1/ VC%	Response of FEV_1 to Administration of Bronchodilator	Tests of Small-Airway Function	Lung Volumes	D_{LCO}	Flow–Volume Loop
COPD								
Chronic bronchitis	↓	↓	↓	NC	ABN	↑	NL	ABN
Emphysema	↓	↓	↓	NC	ABN	↑	↓	ABN
Asthma	↓	↓	↓	↑	ABN	↑	NL	ABN
Small-airway disease	NL	NL	NL	NC	ABN	NL	NL	NL
Upper-airway obstruction	↓	↓	↓	NC	NL or ABN	NL or ↑	NL	ABN[a]

[a] *Configuration frequently characteristic for upper-airway obstruction.*

↓, decrease; ↑, increase; NC, no significant change; NL, normal; ABN, abnormal.

The expiratory arm of the flow–volume loop is primarily affected by a *variable intrathoracic* obstruction (Fig. 31-34C). The following sequence is responsible for producing this abnormality in the flow–volume loop: during forced expiration, as pleural pressure reaches and then exceeds intratracheal pressure downstream from the lesion (i.e., toward the mouth), the obstruction tends to increase; conversely, during a forced inspiration, as intratracheal pressure exceeds pleural pressure, the intrathoracic obstruction decreases.

Variable intrathoracic lesions often coexist with obstructive airway disease. In considering a variable intrathoracic lesion, the respective roles played by obstructive disease of the airways (i.e., chronic bronchitis, emphysema, and asthma) and an obstructive upper-airway lesion (anatomic or functional) in deforming the flow–volume loop must be determined. Fortunately, this distinction is often possible. Although both upper-airway obstruction and obstructive airway disease (reversible and irreversible) do decrease maximal expiratory flow, the shapes of the flow–volume cures are frequently quite distinctive (Fig. 31-34C and D). Thus, in obstructive airway disease, despite a decrease in airflow, the expiratory limb of the loop generally retains its normal configuration (Fig. 31-34D)—that is, an early peak in flow, followed by gradual tapering. In contrast, in upper-airway obstruction (fixed and variable intrathoracic), the expiratory limb is flat and flow is decreased throughout most of expiration (Fig. 31-34C).

In addition to changes in the shape of the flow–volume loop, clues from routine pulmonary function tests often alert the clinician to the possibility of upper-airway obstruction. As noted previously, when $FEV_1/PEFR > 8$, the possibility of upper-airway obstruction should be considered. Finally, the presence of any of the following may also provide clues: $FEF_{50\%}/FIF_{50\%}$ of at least 1, where $FEF_{50\%}$ and $FIF_{50\%}$ are the forced expiratory flow at 50% of FVC and the forced inspiratory flow at 50% of FIVC, respectively; $FIF_{50\%}$ less than 100 L/min; and $FEV_1/FEV_{0.5}$ at least 1.5.

Distinguishing test features of disorders producing an obstructive pattern are summarized in Table 31-19.

■ Additional Details of Pulmonary Function Test Results in a Restrictive Pattern

The restrictive pattern (Table 31-20) characteristically occurs in several groups of disorders including (1) a primary disorder of the lung parenchyma in which functional tissue is lost through disease (e.g., an alveolar filling process, such as pneumonia, tumor, atelectasis, or fibrosis); (2) surgical removal of lung tissue (e.g., lobectomy); (3) constrictive disease of the pleura and chest wall (e.g., extensive pleural fibrosis, large pleural effusion or pleural mass, kyphoscoliosis, obesity); and (4) neuromuscular diseases, notably those in which the generation of respiratory force is reduced (e.g., disorders of the spinal cord, peripheral nerves, neuromuscular junction, and muscle).

The diagnosis of restriction is based upon the finding of a normal FEV_1/VC and reduced VC in the setting of a decreased TLC. While TLC generally is reduced in most disorders producing a restrictive pattern, FRC is usually preserved in disorders characterized by decreased respiratory force (e.g., the neuromuscular disorders) and is reduced in the others. In neuromuscular disorders, ERV is decreased because of loss of expiratory force, so that RV is often increased. In the other types of restrictive disorders, RV is usually reduced.

Whether the D_{LCO} is reduced in the restrictive disorders depends on the underlying disease process. Primary parenchymal disorders and removal of lung tissue decrease the diffusing surface area and reduce D_{LCO}. Diseases of the pleura and chest wall that limit thoracic excursion during the inspiratory vital capacity maneuver, which is part of the technique for determining D_{LCO}, also reduce this measurement.

■ Additional Details of Pulmonary Function Test Results in a Mixed Obstructive–Restrictive Pattern

Occasionally, a battery of pulmonary function tests demonstrates features of both obstructive and restrictive patterns. Most often, the mixed pattern is characterized by a low FEV_1/VC% (indicating

TABLE 31-20 Causes of a Restrictive Pattern

Disease Process	Anatomic Location of Lesion	Cause of Pulmonary Function Test Abnormality
Primary parenchymal disease	Lung parenchyma	Loss of lung tissue ⟶ reduced volumes and flows
Surgical removal of lung tissue	Lung parenchyma	Loss of lung tissue ⟶ reduced volumes and flows
Diseases of pleura and chest wall	Pleura, chest wall	Limited expansion of thoracic cavity ⟶ reduced volumes and flows
Reduced generation of expiratory force	Central nervous system, peripheral nerves, neuromuscular junction, muscles of respiration	Reduced muscle tension ⟶ reduced expiratory flow, atelectasis

TABLE 31-21 Categorization of Reduction in Efficiency of Gas Transfer: Measurement of $\mathrm{DL}_{\mathrm{CO}}$

Severity	$\mathrm{DL}_{\mathrm{CO}}$, Percent Predicted
Mild	>60, but less than lower limit of normal
Moderate	40–60
Severe	<40

Modified with permission from Pellegrino R, Viegi G, Brusasco V, et al. Interpretive strategies for lung function tests. Eur Respir J. 2005;26(5):948–968.

obstructive airway disease) and VC and reduced TLC (indicating coexisting restrictive disease).

A number of disorders can produce the mixed obstructive/restrictive pattern. Sarcoidosis and interstitial fibrosis, when severe, generally result in this pattern because the parenchymal disease causes restriction and narrowing of the airways by adjacent fibrosis, evoking signs of airway obstruction. The mixed pattern also occurs in complicated situations when there is more than one cause—for example, a lobar pneumonia or large pleural effusion occurring in a patient with underlying chronic bronchitis or emphysema.

Isolated Decrease in the Efficiency of Gas Transfer

An isolated reduction in the $\mathrm{DL}_{\mathrm{CO}}$ suggests one of the two possible abnormalities: (1) interstitial lung disease that is so mild as not to affect measurements of airflow or lung volume, or (2) widespread occlusive disease of the pulmonary microcirculation (e.g., due to an inflammatory process or multiple small emboli). In occlusive vascular disorders, tests of airflow and lung volume are usually normal. Although other disorders can also decrease $\mathrm{DL}_{\mathrm{CO}}$, almost invariably they also reduce airflow, lung volumes, or both. Quantification of the degree to which the $\mathrm{DL}_{\mathrm{CO}}$ is reduced by any of these processes is indicated in Table 31-21. Notably, interlaboratory differences are substantial for measurements of $\mathrm{DL}_{\mathrm{CO}}$.

TABLE 31-22 Characteristic Alterations in Pulmonary Function Tests According to the Major Patterns of Abnormality

Pattern	Airflow (FEV_1/VC%)	Airflow Response to Bronchodilators	Volumes	Lung $\mathrm{DL}_{\mathrm{CO}}$
Obstructive				
Irreversible	↓	↔	↑	↔ or ↓
Reversible	↓	↑	↑	↔
Small-airway disease	↓	↔	↔	↔
Upper-airway obstruction	↓	↔	↔ or ↑	↔
Restrictive				
Parenchymal disease	↔ or ↑	↔	↓	↓
Surgical resection	↔	↔	↓	↓
Pleural, chest wall disease	↔	↔	↓	↔
Reduced expiratory force generation	↔	↔	↓	↔
Mixed obstructive–restrictive	↓	↔ or ↑	↓	↓
Isolated reduction in efficiency of gas transfer	↔	↔	↔	↓

↓, decreased; ↑, increased; ↔, no change or normal.

Summary of Approach to Interpretation

Pulmonary function tests are designed to detect common disorders. Test interpretation relies heavily on recognition of major patterns of abnormality (Table 31-22). These patterns often suggest pathogenetic mechanisms and are helpful to the clinician in arriving at a diagnosis. The degree of abnormality provides a quantitative measure of the extent of involvement at a particular time. Moreover, repeated testing makes it possible to pace and quantify the course of the illness and to assess the effects of therapeutic interventions.[115]

CHAPTER 32

Principles and Application of Cardiopulmonary Exercise Testing

Marco Guazzi
Alice Moroni

INTRODUCTION

Exercise testing using gas exchange analysis, or cardiopulmonary exercise testing (CPET), is a remarkably useful and versatile tool. CPET has evolved over time and, currently, constitutes a unique clinical approach for study of a variety of cardiopulmonary disorders that may be associated with symptoms or limit exercise performance.[1–3] Use of CPET has become more common recently, with increasing recognition that assessment of cardiac and pulmonary function at rest cannot reliably predict functional capacity, and that disease stages and severity correlate better with exercise parameters than with resting measurements. Indeed, CPET provides an overall assessment of the integrated, multiorgan response to exercise involving the oxygen-uptake cascade, including the lung, cardiovascular system, skeletal muscle, and cellular pathways for oxygen utilization.

The precision of the technology used in CPET is remarkable, and the technique provides information that facilitates an understanding of the pathophysiology underlying exercise impairment. Additionally, it enables insight into how therapeutic interventions impact effort limitation, and identifies useful markers of prognosis.[4]

A thorough evaluation of gas exchange parameters in response to various cardiopulmonary disorders was proposed in the early 1980s, including pioneering studies by Weber and Janicki.[5,6] Recently, use of CPET has been expanded considerably. Combination modalities, for example, CPET coupled with echocardiography (CPET imaging),[7] and invasive assessment of systemic and pulmonary hemodynamics have been described.

This chapter provides a conceptually balanced discussion of CPET applications based on expert recommendations, guidelines, and available data.

PRINCIPLES OF GAS EXCHANGE DURING EXERCISE

When physically challenged, for example, during exercise, the body behaves as a "machine in harmony," integrating and promoting the interaction of multiple organs and pathways. O_2 delivery from ambient air to mitochondria is essential to aerobic performance. Optimal O_2 delivery depends on a set of elegant biologic interactions among the functional components of the O_2 transport chain, including oxygenation of blood in the lung (via gas diffusion in the alveoli); O_2 transport in blood, in both hemoglobin-bound and dissolved forms; redistribution of blood flow to working muscles; adequate O_2 release and tissue O_2 extraction in metabolizing tissues; and diffusion of O_2 from capillaries into metabolizing cells (Fig. 32-1).

Direct measurement of oxygen uptake ($\dot{V}O_2$), typically expressed as $\dot{V}O_{2max}$ (in healthy subjects) or as peak $\dot{V}O_2$ (in patients), and normalized for body weight (mL/kg/min), defines maximal exercise performance and related limits of the cardiopulmonary system.[5]

One's ability to perform physical activity is critically related to the cardiopulmonary system's capacity to supply O_2 and clear carbon dioxide (CO_2) from exercising muscle. During this process, delivery of O_2 to mitochondria is essential to performing maximal exercise.[8]

According to *Fick's principle*:

$$\dot{V}O_2 = CO \times (CaO_2 - CvO_2)$$

where CO is cardiac output and (CaO_2 – CvO_2) is the O_2 content difference between arterial and venous blood.

According to *Fick's law*:

$$\dot{V}O_2 = D \times K \times PvO_2$$

where D refers to the diffusive properties of the tissue through which O_2 is diffusing, K is a constant, and PvO_2 is the partial pressure of O_2 in the venous blood draining from the tissue.

The linear increase in $\dot{V}O_2$ during exercise is achieved by matching O_2 delivery to mitochondrial O_2 utilization. In concert with alveolar gas exchange, O_2 delivery is determined by heart rate (HR) and stroke volume (SV) at a given O_2 saturation and Hb concentration. Furthermore, diffusion of O_2 from capillaries to myocytes depends on the diffusion properties of tissues and the contribution of cellular mechanisms of O_2 release to mitochondria.[9,10] Hence, O_2 delivery and extraction are two physiologic processes critical to O_2 utilization at the cellular level.

As noted above, O_2 delivery is determined not only by CO (and its distribution), but also by blood O_2 content and the mechanisms involved in O_2 dissociation from hemoglobin (Hb). Blood O_2 content is calculated as: 1.34 mL O_2/gram Hb/dL × O_2 saturation × Hb concentration (where 1.34 mL is the amount of oxygen bound to each gram of hemoglobin when fully saturated), plus O_2 dissolved in plasma, calculated as PaO_2 × 0.0031 mL O_2/dL/mm Hg (where 0.0031 is the solubility coefficient of O_2 in blood). The relationship of O_2 delivery, or "convection" (as described by the Fick principle), and diffusion (as described by Fick's law) can be represented in a diagram relating $\dot{V}O_2$ and PvO_2 (Fig. 32-2).[11]

As proposed by Wagner,[12] the diagram relates $\dot{V}O_2$ to venous PO_2 in muscle, from rest to peak exercise. The convection and diffusion lines intersect, defining the point of maximal O_2 consumption, that is, $\dot{V}O_2$ max.

O_2 extraction in tissues is the net result of O_2 delivery to peripheral tissues and O_2 utilization and is dependent on the ability of O_2 to diffuse from capillaries to cells, as well as the function of mitochondria (Fig. 32-3).

Normally, healthy adults can increase $\dot{V}O_2$ up to 6-fold during exercise. The relative contribution of the individual determinants in Fick's equation to increases in $\dot{V}O_2$ are approximately 1.2 for stroke volume, 2.5 for heart rate, and 2.5 for arteriovenous O_2 content difference. In health, multiple steps limit O_2 utilization in achieving $\dot{V}O_{2max}$. Cardiac output appears to be most important at sea level, while at higher altitudes, diffusion of O_2 in lung and muscle are more important.[13]

Heart failure (HF) represents a prototypical condition in which O_2 delivery and diffusion are impaired, as demonstrated in a study in humans with HF characterized by reduced ejection fraction (HFrEF).[14] The study addressed the relative contributions of convection versus diffusion using two different exercise modalities: incremental exercise to a maximum and, therefore, accompanied by a need for increased CO, versus isolated knee extension, with the requirement for an increase in local O_2 extraction (Fig. 32-4A). The study included analysis of muscle fiber types, mitochondrial volume, and capillary-to-muscle fiber ratios. Interestingly, in normal individuals, skeletal muscle and mitochondria contributed minimally to the limitation in O_2 utilization, supporting the concept that mitochondrial oxidative capacity largely exceeds O_2 delivery at peak $\dot{V}O_2$. However, patients with HF, when compared with controls, exhibited attenuation of both convective and diffusive components of O_2 transport during both maximal exercise and isolated knee extension (Fig. 32-4B).

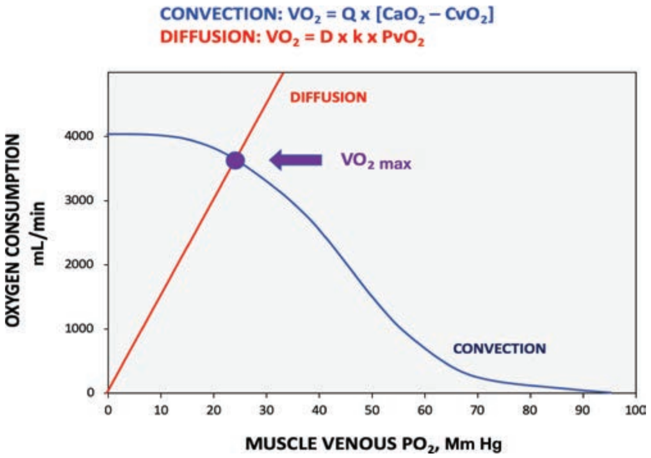

Figure 32-2 The relationship between O_2 diffusion and convection. As proposed by Wagner,[11] during exercise, $\dot{V}O_2$ relates to muscle venous PO_2 from rest to peak exercise. Shown are the line *(blue)* for $\dot{V}O_2$ convection (i.e., O_2 delivery) from rest at a high muscle venous PO_2, to a peak at a low muscle venous PO_2, and the line for O_2 diffusion *(red)*. The diffusion line goes through the origin of the plot; its slope varies according to the muscle venous PO_2; a line shifted upward and to the left represents greater diffusion. The point of intersection of the two curves is $\dot{V}O_{2max}$, the point where convection and diffusion result in maximal O_2 utilization.

More uncertainty exists regarding the limiting steps in O_2 transport and utilization in the functional response of patients with HF who have a preserved ejection fraction (HFpEF). Many of these patients are elderly and anemic and, therefore, have impaired O_2 carrying capacity.[15] In addition, they may have a defect in O_2 diffusion, as well as a lower (CaO_2 – CvO_2). To better understand the specific roles of various steps in limiting O_2 uptake pathways, phenotypic mapping may be useful and aid in delineating the high rate of interindividual variability.[16]

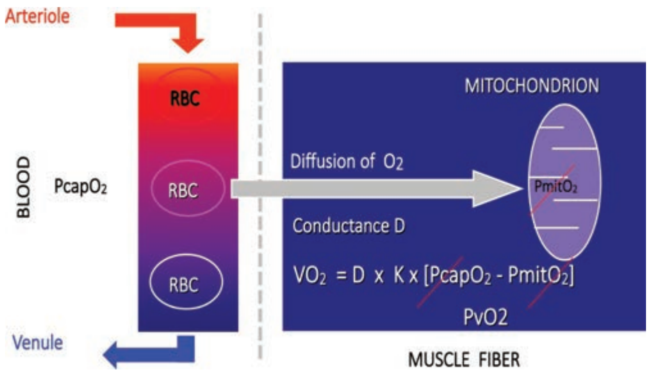

Figure 32-3 O_2 diffusion from red blood cell to mitochondria. Diffusion is an important determinant of O_2 uptake. According to Fick's law of diffusion, $\dot{V}O_2$ = D (oxygen diffusive capacity) × K (a constant, which represents the ratio of arterial to venous PO_2 [approximately 2]) × the capillary mitochondrial difference between PaO_2 and PvO_2 (assuming an intracellular partial pressure of O_2 near 0).

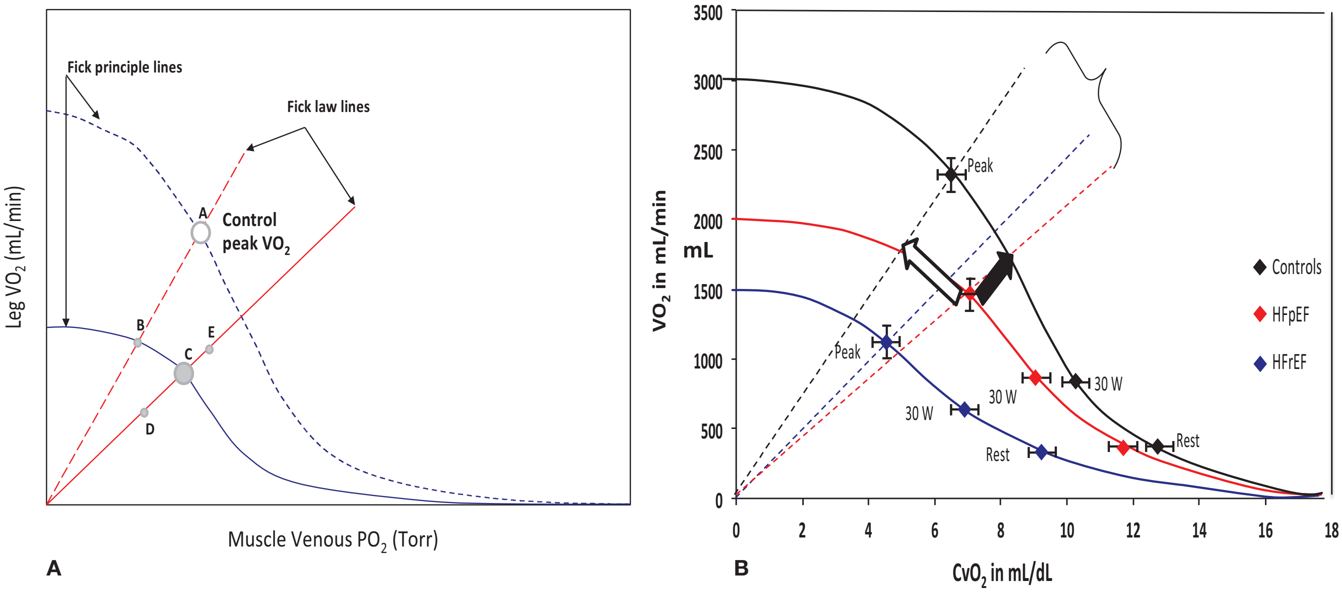

Figure 32-4 Relationships between O_2 diffusion and convection in HFrEF. **A.** Relative impairment of convection versus diffusion measured during two different exercise modalities: an incremental test to a maximum (*A, B*), and local isolated knee extension (*C,D,E*). **B.** $\dot{V}O_2$ and PvO_2 relationship in patients with HFrEF and HFpEF and controls, showing a limitation in either diffusion or convection. *(**A.** Reproduced with permission from Esposito F, Mathieu-Costello O, Shabetai R, et al. Limited maximal exercise capacity in patients with chronic heart failure: partitioning the contributors. J Am Coll Cardiol. 2010;55(18):1945–1954.)*

GAS EXCHANGE VARIABLES DEFINING ORGAN-SPECIFIC LIMITATIONS

A number of variables have been considered in the interpretation of results from CPET. Such variables are measured directly or are derived, and those used clinically have not changed to any large degree for more than two decades.[1,2] Nevertheless, appreciation of the utility of CPET measurements has evolved.[3] An overview of each, along with a highlight of its physiologic significance, is presented in Table 32-1. A basic premise in considering the aggregate measurements is that the best diagnostic potential comes from the measurements' *integrated* use and interpretation using 9-plot analysis, as originally proposed by Wasserman and coworkers.[5]

■ $\dot{V}O_2$, $\dot{V}O_{2max}$, and peak $\dot{V}O_2$

$\dot{V}O_2$ is the principal parameter examined during CPET, as it represents the patient's functional capacity and embodies all the complex interactions of organ systems involved in O_2 transport. The highest $\dot{V}O_2$ achieved during an incremental work-rate test is $\dot{V}O_{2max}$, defined as the $\dot{V}O_2$ at the plateau achieved during incremental exercise, as measured in healthy individuals, including athletes. In clinical practice, the plateau is usually preceded by occurrence of exercise-limiting symptoms. The gold standard measurement for cardiorespiratory fitness is $\dot{V}O_{2max}$.

Peak $\dot{V}O_2$ is defined as the maximal $\dot{V}O_2$ attained at maximal effort, averaged over a 20- to 30-s period. It is a useful measure of the functional capacity of deconditioned subjects and patients with cardiopulmonary disorders. Peak $\dot{V}O_2$, expressed as percent predicted and normalized for age, sex, and weight, describes the subject's overall functional capacity.

■ $\dot{V}O_2$ versus Work Rate

Under physiologic conditions, $\dot{V}O_2$ rises linearly with increases in power output. Therefore, if $\dot{V}O_2$ is plotted versus external work rate (WR), the slope of the relationship ($\Delta\dot{V}O_2/\Delta WR$) indicates the efficiency of metabolic conversion of chemical potential energy to mechanical work, as well as the efficiency of the musculoskeletal system in producing mechanical work. In healthy individuals, $\Delta\dot{V}O_2/\Delta WR$ is about 8.5–11 mL/min/watt and is independent of sex, age, height, type of work, and rate of workload increase.

$\Delta\dot{V}O_2/\Delta WR$ provides important information on the coupling of external to internal (cellular) respiration, reflecting a subject's overall ability to generate aerobically produced ATP and any pathologic derangements that affect O_2 delivery (e.g., cardiac, pulmonary, or circulatory disorders) or the metabolic efficiency of muscles (e.g., mitochondrial myopathy); each leads to a reduction in $\Delta\dot{V}O_2/\Delta WR$. The slope is altered in the presence of deconditioning and may be flattened in cardiac failure.[17]

■ Ventilatory Measures

Ventilatory measures are a key component of CPET and include: total minute ventilation ($\dot{V}_E$), tidal volume (V_T), respiratory rate (RR), and breathing reserve (BR). BR is the difference between the maximal voluntary ventilation (MVV) and the maximum ventilation achieved during exercise.

The demand for increased V_E during exercise is driven by the rate of CO_2 production; hence, the rise in V_E with increasing VCO_2 reflects the efficiency of ventilation and is reported as the slope of V_E versus VCO_2. By convention, the relationship is measured at the anaerobic threshold (see below). A value <30 for the slope of V_E versus VCO_2 is considered normal; it increases slightly with aging.[18]

During progressive exercise, three domains for $\dot{V}_E$ kinetics can be discerned: (1) a linear increase from rest to the point of so-called isocapnic buffering; (2) a steeper region as the isocapnic buffering period begins, reflecting increased ventilatory drive due to CO_2 generation via buffering of increasing lactate levels; and (3) an upward shift after the so-called respiratory compensatory point (RCP), which is further sustained by an increase in ventilatory drive due to respiratory compensation for metabolic acidosis.

Analysis of the pattern of increases in $\dot{V}_E$ during progressive increases in exercise workload enables detection of clinically relevant fluctuations in the ventilation signal, for example, "exercise oscillatory ventilation" (EOV), defined as an oscillatory ventilatory

TABLE 32-1 Commonly Measured Variables During Clinical Cardiopulmonary Exercise Testing

Variable, Unit of Measurement	Description and Technical Considerations	Physiologic Significance	Normal Value/Response	Clinical Relevance
Peak $\dot{V}O_2$, mL $O_2 \cdot kg^{-1} \cdot min^{-1}$ or % of appropriately selected predicted value	Highest O_2 uptake during exercise	Reflection of the patient's functional capacity, derived from the integrated function and interaction of pulmonary, cardiac, and skeletal muscle systems	Wide range, depending on age, sex, exercise habits, and genetic predisposition	Expression of aerobic exercise capacity
	When derived from breath-by-breath data reported as 10- to 60-s average, depending on protocol (i.e., shorter averaging interval for protocols with shorter stages and vice-versa)	In health, response is representative of the interaction between the functional components of the O_2 transport chain (i.e., delivery and extraction)	Normal range is wide: from $\sim$80 to $\sim$15 mL $O_2 \cdot kg^{-1} \cdot min^{-1}$ in an elite athlete and healthy 80-year-old woman, respectively	Measure of cardiovascular fitness in healthy persons
				Correlates with disease severity in a great variety of patient populations, including HF, HCM, PAH, secondary PH, COPD, ILD Broad prognostic marker
$\dot{V}O_2$ at Anaerobic Threshold, mL $O_2 \cdot kg^{-1} \cdot min^{-1}$ or % of the predicted peak $\dot{V}O_2$	$\dot{V}O_2$ above which $\dot{V}_E$ and $\dot{V}CO_2$ equally accelerate	Defines the upper limit of exercise workloads that can be sustained for a prolonged time	$\sim$50%–65% of maximal/peak $\dot{V}O_2$	Responsive to aerobic training; is a measure of fitness
	Point of exercise $\dot{V}O_2$ above which aerobic energy ATP production is supplemented by anaerobic mechanisms	Starting point of the isocapnic buffering period	Higher with advanced age and endurance training	Useful to set a tailored training intensity for exercise prescription
Peak RER	$\dot{V}CO_2/\dot{V}O_2$ ratio at maximal exercise	With exercise progression, excessive CO_2 generation due to bicarbonate buffering compared to $\dot{V}O_2$, makes RER rise	Peak RER $\geq$1.10 commonly used as indication of excellent effort	Good indicator of subject effort
	When derived from breath-by-breath data reported as 10- to 60-s average, depending on protocol (i.e., shorter averaging interval for protocols with shorter stages and vice-versa)	Depends on baseline respiratory quotient, rate of lactate accumulation, hyperventilation, and extent of exercise above AT		Best noninvasive estimate of maximal exercise test
Breathing reserve (BR), %	Difference between the maximal voluntary ventilation (MVV) and the maximum exercise ventilation	Erosion of BR is typical of COPD; low BR also occurs in athletes	Usually >20%, but variance is wide; values <15% identify ventilatory mechanical limitation	Index of mechanical ventilatory constraints
	MVV can be either directly measured or estimated as $FEV_1 \times 35–40$ with some drawbacks to be considered (see text for explanation)			
V_E/VCO_2 slope	Relationship between V_E, plotted on the y-axis, and VCO_2 plotted on the x-axis; both variables in $L \cdot min^{-1}$	Represents ventilation-perfusion matching within the pulmonary system	<30 considered normal; slightly increases with ageing	Index of ventilatory efficiency
	Nonlinear data at starting exercise and near-maximal exercise, usually excluded from measurement			Correlates with disease severity in a great variety of patient populations including HF, HCM, PAH, secondary PH, COPD, ILD Prognostic marker in certain chronic disease populations

TABLE 32-1 Commonly Measured Variables During Clinical Cardiopulmonary Exercise Testing *(Continued)*

Variable, Unit of Measurement	Description and Technical Considerations	Physiologic Significance	Normal Value/Response	Clinical Relevance
$PetCO_2$, mm Hg	Partial pressure of CO_2 at the end of a tidal breath exhalation	Represents ventilation–perfusion matching within the pulmonary system	Rest: 36–42 mm Hg	Correlates with disease severity in a great variety of patient populations including HF, HCM, PAH, secondary PH, COPD, ILD
		Low values can also reflect acute or chronic hyperventilation (consider confirmation by arterial blood gas analysis)	Increases 3–8 mm Hg by AT; decreases from AT to maximal exercise	
$\dot{V}_E/\dot{V}O_2$ at peak exercise	When derived from breath-by-breath data reported as 10- to 60-s average, depending on protocol (i.e., shorter averaging interval for protocols with shorter stages and vice-versa)	Represents ventilatory cost of O_2 uptake at peak exercise testing	$\leq$40 (50 is considered the upper limit of normal)	Has diagnostic utility in patients with suspected mitochondrial myopathy
EOV	No universal definition: most commonly defined as an oscillatory pattern at rest that persists for $\geq$60% of the exercise test at an amplitude of $\geq$15% of the average resting value Recommend using 10 s averaged V_E data for plotting	Oscillatory ventilation during exercise reflects impaired CO reserve	The presence of EOV pattern is always pathologic	Prognostic marker in advanced HF
Oxygen pulse, mL $O_2 \cdot beat^{-1}$	Ratio between $\dot{V}O_2$ (mL $O_2 \cdot min^{-1}$) and HR (bpm)	Represents the amount of O_2 extracted per heartbeat	Curvilinear increase throughout exercise, with possible plateau near maximal effort	O_2 pulse profile provides valuable information on cardiorespiratory performance
		At a near maximal work rate, it is a surrogate of stroke volume	A premature plateau or down-sloping with increasing work rate suggest low or falling stroke volume (e.g., myocardial ischemia)	Prognostic marker in certain chronic disease populations
$\Delta\dot{V}O_2/\Delta WR$, mL $\cdot$ $min^{-1} \cdot W^{-1}$	Relationship between $\dot{V}O_2$, plotted on the y-axis in mL $\cdot$ min^{-1}, and workload, plotted on the x-axis in watts	Provides important information on the coupling of external to internal (cellular) respiration	Slope is linear with a normal value between 8.5 and 11 mL $\cdot$ $min^{-1} \cdot W^{-1}$ (on average 10 mL $\cdot$ $min^{-1} \cdot W^{-1}$) Deconditioning and initial cardiac limitation make this relationship shallow Flattening or down-sloping have been described in advanced heart failure	$\Delta\dot{V}O_2/\Delta WR$ profile provides valuable information on cardiocirculatory performance
Heart rate (bpm) vs. $\dot{V}O_2$ relationship	HR increase along incremental workload	Reflects chronotropic competence and cardiac response to exercise	Increase ~10 beats per 3.5 mL $O_2 \cdot kg^{-1} \cdot min^{-1}$ increase in $\dot{V}o_2$, achieve at least 85% of age-predicted maximal HR with good effort	Index of cardiac response to exercise
				Peak HR should not be used to define effort level nor maximal exercise test
Heart rate reserve, %	Difference between the age-predicted maximal HR (calculated as 220 – age) and the maximal HR achieved during exercise	Reflects chronotropic competence and cardiac performance	>70%	Index of chronotropic incompetence (CI) CI predicts the cardiovascular risk in apparently healthy subjects CI is a prognostic marker in certain chronic pathologic conditions

(continued)

TABLE 32-1 Commonly Measured Variables During Clinical Cardiopulmonary Exercise Testing *(Continued)*

Variable, Unit of Measurement	Description and Technical Considerations	Physiologic Significance	Normal Value/Response	Clinical Relevance
Heart rate recovery, beats	Difference between maximal exercise HR and HR 1 min into recovery	Mirrors the speed of parasympathetic reactivation	$>$12 beats	Prognostic marker in subjects without cardiovascular diseases Prognostic marker in certain chronic disease populations
Exercise BP, mm Hg	BP increase along incremental workload	Reflects cardiovascular response to exercise and left ventricular afterload	SBP increase ~10 mm Hg per 3.5 mL $O_2 \cdot kg^{-1} \cdot min^{-1}$ increase in $\dot{V}O_2$ Upper range of normal maximal SBP is ~210 mm Hg for males and ~190 mm Hg for females DBP remains the same or slightly decreases	Index of cardiac response to exercise and left ventricular afterload
SpO_2, %	Noninvasive measurement of the percent of saturated hemoglobin in the capillary bed by pulse oximetry	Exercise hypoxemia is common in many lung diseases and right-to-left shunt	$\geq$95% at rest and throughout exercise	Desaturation is common in patients with COPD, ILD, PAH/secondary PH as disease severity advances
	Accuracy may vary according to device, perfusion, motion, and ambient light		Decrease by $>$5% suggests abnormal oxygenation	May have diagnostic utility in characterizing unexplained exertional dyspnea
FEV_1 ($L \cdot min^{-1}$) pre- and post-CPET	Forced expiratory volume in 1 s	Component of pulmonary function	$<$15% reduction from pre- to post-exercise test	May have diagnostic utility in characterizing unexplained exertional dyspnea (e.g., exercise-induced bronchospasm)

AT, anaerobic threshold; ATP, adenosine triphosphate; BP, blood pressure; bpm, beats per minute; BR, breathing reserve; CI, chronotropic incompetence; COPD, chronic obstructive pulmonary disease; CPET, cardiopulmonary exercise testing; DBP, diastolic blood pressure; EOV, exercise oscillatory ventilation; FEV_1, forced expiratory volume in 1 s; HCM, hypertrophic cardiomyopathy; HF, heart failure; HR, heart rate; ILD, interstitial lung disease; MVV, maximal voluntary ventilation; O_2, oxygen; PAH, pulmonary arterial hypertension; $PetCO_2$, partial pressure of end-tidal carbon dioxide; PH, pulmonary hypertension; RER, respiratory exchange ratio; SBP, systolic blood pressure; SpO_2, saturation of peripheral oxygen; VCO_2, carbon dioxide production; V_E, minute ventilation; $\dot{V}O_2$, oxygen consumption; W, watt; WR, work rate.

Data from Guazzi M, Adams V, Conraads V, et al. Clinical recommendations for cardiopulmonary exercise testing data assessment in specific patient populations. Circulation. 2012;126(18):2261–2274 and Arena R, Sietsema KE. Cardiopulmonary exercise testing in the clinical evaluation of patients with heart and lung disease. Circulation. 2011;123(6):668–680.

pattern at rest that persists for ≥60% of the exercise test at an amplitude of ≥15% of the average resting value.[3] Notably, EOV is seen in 20% to 30% of cases of HF (Fig. 32-5).

During low levels of exercise, an increase in V_T is the first physiologic step in augmenting V_E. Thereafter, both V_T and RR increase through 70% to 80% of peak exercise; in the last phase of achieving maximal exercise, the contribution of RR predominates. V_T usually increases 3- to 5-fold in younger subjects, while older adults demonstrate a 2- to 4-fold increase. RR typically increases up to 3-fold. In most healthy subjects, peak exercise ventilation approaches 70% of MVV (BR is typically greater than 15% of the MVV); it varies according to fitness level and age. MVV can be measured directly, or it can be estimated as $FEV_1 \times 35–40$.[19–21] In daily practice, ventilatory capacity is assessed by measuring MVV. A ventilatory mechanical limitation is identified if peak V_E is <15% of MVV. This approach is practical but likely flawed due to the lack of reproducibility of breathing rate and tidal volume when MVV curves are superimposed on flow–volume loops near peak exercise. Indeed, MVV is performed at high respiratory rates, during which end-expiratory lung volume is increased. Conversely, during exercise, end-expiratory lung volume is reduced, resulting in more advantageous positioning of the pressure-volume relationship and a lower work of breathing (Fig. 32-6).

At a moderate level of work, the partial pressure of end-tidal carbon dioxide ($PetCO_2$) increases, while the partial pressure of end-tidal oxygen ($PetO_2$) decreases; the changes occur in parallel with changes in $\dot{V}_E/\dot{V}O_2$. $PetO_2$ and $\dot{V}_E/\dot{V}O_2$ reach their nadirs near the anaerobic threshold (see below), prior to increasing as exercise effort becomes more intense. Meanwhile, $PetCO_2$ initially slightly increases, and then stabilizes, until the subsequent increase in $\dot{V}_E/\dot{V}CO_2$ (close to RCP), when $PetCO_2$ falls in tandem with a continuous increase in $PetO_2$.

CPET measurements allow an estimate of ventilation-to-perfusion ($\dot{V}/\dot{Q}$) matching during exercise, reflected in the V_D/V_T ratio, as well as ventilatory efficiency, indicated by V_E/VCO_2. When $\dot{V}/\dot{Q}$ is uniform, V_D/V_T is low. Indeed, V_D/V_T represents the fraction of

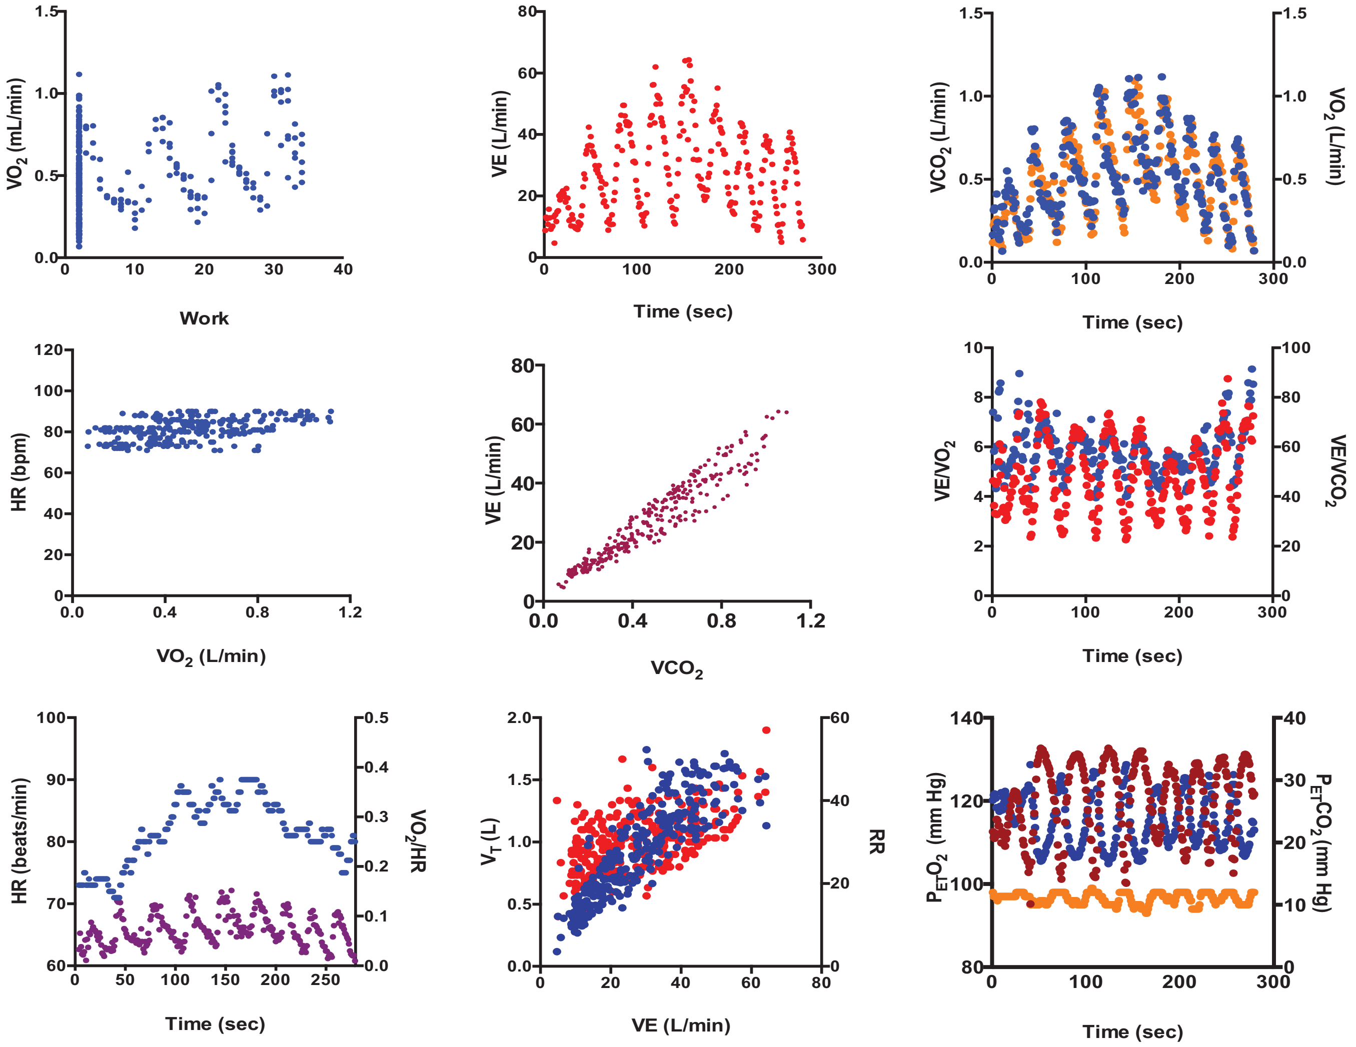

Figure 32-5 Nine-plot analysis demonstrating a typical EOV pattern. *(Reproduced with permission from Guazzi M, Bandera F, Ozemek C, et al. Cardiopulmonary Exercise Testing: What Is its Value? J Am Coll Cardiol. 2017;70(13):1618–1636.)*

each breath that is “wasted” in ventilating anatomic and physiologic dead space (i.e., nonperfused alveoli). Under physiologic conditions, V_D is approximately one-third of V_T and, during exercise, it drops to one-fifth. Accurate measurement of V_D/V_T requires arterial blood sampling. In fact, use of $PetCO_2$ to noninvasively estimate $PaCO_2$ can be misleading and may result in overestimation of V_D/V_T in normal subjects, or underestimation in patients with lung disease.

Another important parameter useful in assessing gas exchange during exercise is the alveolar–arterial oxygen gradient, $P(A–a)O_2$. Normally, $P(A–a)O_2$ is <10 mm Hg at rest; it may normally increase up to 20–30 mm Hg during exercise. However, values greater than 35 mm Hg likely indicate a gas exchange abnormality. The value for $P(A–a)O_2$ is dependent on $\dot{V}/\dot{Q}$ mismatching, right-to-left shunt, O_2 diffusion limitations, mixed venous O_2 content, and the time available for diffusion equilibrium of O_2 between alveoli and red blood cells.

■ CO_2 Output

The rate of CO_2 production ($\dot{V}CO_2$) correlates strongly with the level of ventilation (V_E). Moreover, control of CO_2 levels is important in blood pH homeostasis. When anaerobic metabolism prevails following attainment of the anaerobic threshold (see below), bicarbonate buffering of the increased lactic acid produced generates additional CO_2 that, in turn, increases ventilatory drive. Following attainment of the anaerobic threshold, the relationship between $\dot{V}CO_2$ and WR becomes steeper. $\dot{V}CO_2$ is used in calculating a number of derived variables, including the respiratory exchange ratio (RER), that is, $VCO_2/\dot{V}O_2$, and the respiratory quotient (RQ).

■ Respiratory Exchange Ratio

The respiratory exchange ratio (RER) is the ratio of $\dot{V}CO_2$ to $\dot{V}O_2$. Under steady state conditions, RER is equal to the respiratory quotient (RQ). The value for RQ depends on the fuels used for metabolism and energy production. An RQ of 1.0 indicates metabolism of primarily carbohydrates, whereas an RQ of 0.7 to 0.8 indicates metabolism of a mixture of carbohydrates and fat or protein. During CPET, a measured RER >1.0 suggests lactic acidosis or hyperventilation. RER is the best non-invasive indicator of exercise effort; when RER ≥ 1.10, exercise effort is usually considered maximal.[22]

■ Anaerobic Threshold

The anaerobic threshold (AT), or lactic acid threshold, represents the $\dot{V}O_2$ during progressive exercise above which aerobic energy used to produce ATP is supplemented by anaerobic mechanisms, resulting in increases in muscle and plasma lactate levels. Due to effective hydrogen ion buffering by the bicarbonate system, initially, blood pH remains constant. Subsequently, with progression of exercise effort, the net increase in lactic acid accumulation overcomes the buffering

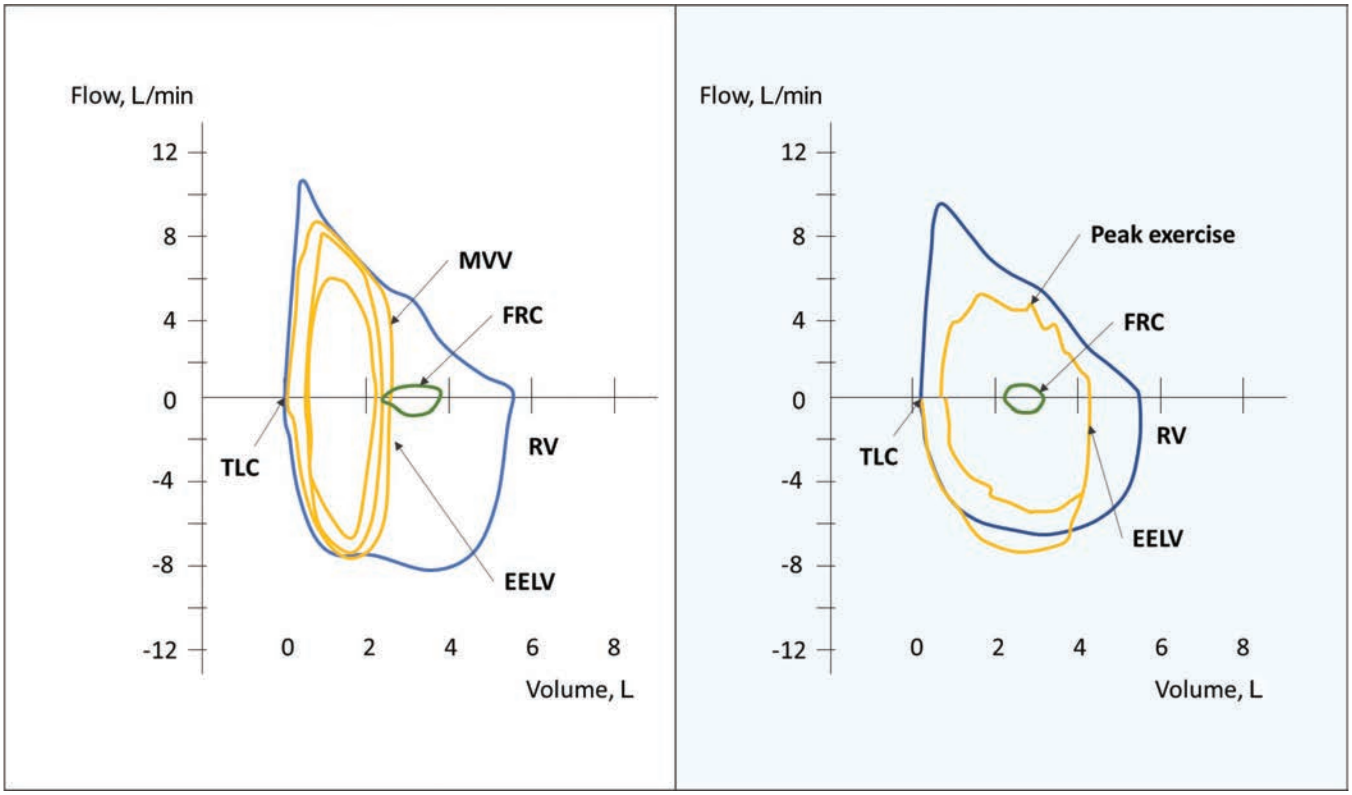

Figure 32-6 Comparison of the flow–volume loops obtained during a maximal voluntary ventilation (MVV) maneuver ***(left)*** and near maximal incremental exercise ***(right)***, in the same healthy subject. The MVV is performed at high lung volumes, as EELV is increased, thus producing a high elastic load and requiring large expiratory pleural pressures to obtain high flows in early expiration; the work of breathing is increased. In contrast, during exercise, EELV is reduced, resulting in tidal breathing at a more advantageous position of the pressure–volume relationship of the lungs and chest wall; consequently, work of breathing is reduced. Blue line, maximal flow–volume loop; yellow line, MVV maneuver (left, white panel) and incremental exercise (right, light blue panel); green line, rest tidal breathing; EELV, end-expiratory lung volume; FRC, functional residual capacity; MVV, maximal voluntary ventilation; RV, residual volume.

capacity and pH gradually decreases. This development identifies the "respiratory compensation point" (RCP). The exercise interval between the AT and RCP is called the *isocapnic buffering period*. During isocapnic buffering, the excess CO_2 generated is buffered by bicarbonate; exercise beyond the RCP triggers increased ventilation as compensation for the developing metabolic acidosis.

The main determinants of the increase in $\dot{V}O_2$ during the isocapnic buffering period are the rate of lactic acid production; the availability of bicarbonate for hydrogen ion buffering; and the partial pressure of CO_2 in arterial blood ($PaCO_2$), which is regulated by the chemoreceptors.[23] In healthy subjects, the AT occurs at 50% to 65% of peak $\dot{V}O_2$ and is influenced by age and the level of aerobic training.[3] AT can be determined invasively (through measurement of lactic acid and bicarbonate concentrations) or noninvasively (through V-slope analysis and measurement of "ventilatory equivalents") (Table 32-2). The noninvasive methods are more useful in clinical practice.

■ Heart Rate versus $\dot{V}O_2$ Relationship

During normal exercise, tissue perfusion increases as the metabolic requirements increase. The relationship of CO to increasing $\dot{V}O_2$ is nearly linear, with an approximate 6-mL/min increase in CO for every 1-mL/min increase in $\dot{V}O_2$.[24]

The increase in CO is initially achieved by increases in stroke volume (SV) and heart rate (HR). At moderate- to high-intensity exercise, a physiologic plateau to increases in SV is noted, and HR becomes the main variable contributing to further increases in CO. The increases in HR are primarily mediated by reduced vagal tone and, secondarily, by increased sympathetic activity. The difference between the age-predicted maximal HR (calculated as 220 − age, in years) and resting HR is referred to as the "HR reserve" (HRR). A useful index is calculation of HRR as a percentage of age-predicted maximal HR:

$$\frac{\text{peak exercise HR-rest HR}}{\text{peak exercise HR-age predicted maximal HR}}$$

HRR <80% of age-predicted maximal HR defines "chronotropic incompetence" and may signal that the impairment in exercise performance is due to deconditioning.[25] CI is an important contributor to exercise intolerance and an independent predictor of worse outcome in subjects with and without previous cardiovascular events.[25]

■ O_2 Pulse

O_2 pulse is defined as the ratio of $\dot{V}O_2$ to HR; it reflects the amount of O_2 consumed per heart beat. Since $\dot{V}O_2/HR = SV \times (CaO_2 - CvO_2)$, the increase in O_2 pulse during exercise depends on stroke volume and the arterial-venous O_2 content difference. At near maximal work rate, $(CaO_2 - CvO_2)$ is assumed to be maximized and constant; therefore, a change in O_2 pulse directly reflects a change in SV under these conditions. Evaluation of the O_2 pulse profile may provide valuable information on cardiopulmonary performance. Under normal conditions, O_2 pulse increases curvilinearly with progressive exercise, as there are well-known limits to increases in SV at peak exercise.

TABLE 32-2 Invasive and Noninvasive Methods for AT Determination

	Variable	AT Definition	Observations and Pitfalls	Graphical Example and Explanation
Invasive determination	Arterial lactate	$\dot{V}O_2$ at which the blood lactate level increases	• Multiple blood sampling is required • The precise definition remains controversial	*There are several mathematical models for the AT determination.*
	Arterial standard bicarbonate	$\dot{V}O_2$ at which the arterial standard bicarbonate decreases	• Multiple blood sampling is required • The precise definition remains controversial • It represents an acceptable alternative if lactate cannot be measured	
Noninvasive determination	Ventilatory equivalents method: simultaneous analysis of $\dot{V}_E$/$\dot{V}O_2$, $\dot{V}_E$/$\dot{V}CO_2$, $PetO_2$, and $PetCO_2$	$\dot{V}O_2$ at which $\dot{V}_E$/$\dot{V}O_2$ and $PetO_2$ reach a minimum and thereafter start to rise, coinciding with an unchanged $\dot{V}_E$/$\dot{V}CO_2$ and $PetCO_2$ slope	• Many factors can prevent proper identification of AT: irregular breathing, an inappropriate rate of increase in work rate, suboptimal plotting scales, or a poor patient ventilatory response; • a dual method approach (combined assessment of ventilatory equivalents and V-slope method) is recommended to minimize errors		V-slope method	$\dot{V}O_2$ at which the slope of $\dot{V}CO_2$ to $\dot{V}O_2$ relationship changes		
Diamonds: $\dot{V}_E$ and $\dot{V}CO_2$ initially accelerate equally above the AT. Therefore, $\dot{V}_E$/$\dot{V}O_2$ and $PetO_2$ increase, whereas $\dot{V}_E$/$\dot{V}CO_2$ and $PetCO_2$ remain constant (isocapnic buffering period). As the work rate further increases, decreasing pH acts as a strong stimulus for ventilatory drive augmentation. Consequently, V_E/VCO_2 increases, and $PaCO_2$ and $PetCO_2$ decrease, while there is a further increase in $\dot{V}_E$/$\dot{V}O_2$ and $PetO_2$. This point corresponds to the RCP.

Circles: At the beginning of exercise, $\dot{V}CO_2$ increases linearly with increases in $\dot{V}O_2$. Since the relation between O_2 consumption and CO_2 production is almost equimolar, the early slope of the relationship (S1) is slightly less than 1.0. Thereafter, the slope increases sharply (S2) due to excessive CO_2 generation from bicarbonate buffering of the increased lactic acid produced. The intercept of S1 and S2 identifies the anerobic threshold (AT).

■ Blood Pressure Response

During exercise, a reflex increase in sympathetic tone causes vasoconstriction in nonworking muscles, while release of local mediators is responsible for intense vasodilation in working muscles (a phenomenon necessary for balancing oxygen supply and demand). The net result is a fall in systemic vascular resistance. Although systolic blood pressure typically rises progressively as work rate increases, diastolic blood pressure usually remains constant or declines slightly.

■ Flow–Volume Loop Analysis

Complementary information on the source and degree of ventilatory limitation to exercise may be derived by analysis of the flow-volume loop (FVL). Indeed, examination of the FVL may explain expiratory airflow limitation and changes in lung volumes during increased physical effort.[26] "Ventilatory demand" versus "ventilatory capacity" measures can be obtained by plotting exercise tidal flow–volume loops (extFVLs) along with the maximal flow–volume loop (MFVL). Accurate alignment of the loops is crucial for reproducible, accurate analysis. Precise knowledge of any changes in end-expiratory lung volume during exercise, relative to rest, is required and may be inferred from changes in inspiratory capacity, periodically measured during the exercise test.

By plotting extFVLs and MFVL, valuable information on the ventilatory response and any ventilatory constraints can be derived. During spontaneous breathing, encroachment of V_T on the expiratory limb of the flow–volume envelope of the MFVL identifies the amount of expiratory flow limitation. In addition, an increase in end-expiratory lung volume relative to resting volume identifies development of dynamic hyperinflation. Finally, encroachment of tidal inspiratory flow rates on the inspiratory limb of the MFVL indicates that that the ability of the inspiratory muscles to generate pressure and flow is approaching a maximum.

Flow limitation and dynamic hyperinflation have been extensively studied in patients with COPD.[27] However, the significance of, and influence on, exercise performance of flow limitation and lung volume changes remain to be elucidated in other populations, including patients with heart failure, athletes, and the elderly.[1]

CLINICAL APPLICATION OF CPET IN CARDIOPULMONARY DISORDERS

CPET is used in the clinical evaluation of a wide variety of respiratory and cardiac disorders, including investigation of patients with unexplained dyspnea, possible exercise-induced bronchospasm, obstructive lung disease, a wide variety of interstitial lung diseases, and underlying pulmonary vascular disorders. CPET is also employed in assessing patients for general surgery risk; in anticipation of lung resection, volume reduction surgery, or heart or lung transplantation; and in functional evaluation of patients with heart failure.

■ Unexplained Dyspnea

Two main categories of patients with dyspnea can be distinguished: (1) those with new onset of breathing discomfort, and (2) those experiencing worsening breathlessness due to a known cardiovascular, respiratory, or neuromuscular disease. In the former group, clinical evaluation is directed toward establishing a diagnosis; in the latter, the goal is discriminating between the underlying disease and superimposition of a new, pathologic condition.[28]

Initial evaluation, including a meticulous medical history, physical examination, and basic screening tests, such as spirometry, chest radiograph, electrocardiogram, selected blood tests, and, usually, an echocardiogram, may uncover the root cause of the patient's exertional dyspnea. When this first level of evaluation is inconclusive or nondiagnostic, CPET, by providing breath-by-breath analysis of ventilation, pulmonary gas exchange, and cardiac function at rest and during incremental exercise, may help in identification of a specific diagnosis (e.g., exercise-induced arrhythmias, chronotropic incompetence, myocardial ischemia, hyperventilation syndromes, exercise-induced bronchoconstriction, or HFpEF).[29–34]

A useful alternative approach to simplification of the differential diagnosis of dyspnea is categorization of abnormalities as cardiovascular (reduced O_2 delivery), ventilatory, or peripheral/muscular (reduced O_2 utilization) in nature. The patient population undergoing CPET for evaluation of unexplained dyspnea on exertion is highly heterogeneous and includes subjects with neuromuscular, hormonal, myopathic, metabolic, and psychogenic conditions.[1] CPET may be useful in defining the degree of exercise intolerance and assessing pathophysiologic contributions to the patient's dyspnea.[1,3,5] For example, CPET may help discriminate pulmonary mechanical and pulmonary vascular limitations to exercise effort and distinguish disorders due primarily to central cardiovascular dysfunction versus those due to impaired O_2 extraction in the periphery.[35,36]

■ Evaluation of Patients with Respiratory Disease

CPET is commonly utilized in evaluating patients with a wide variety of pulmonary disorders, including obstructive airway disease, interstitial lung disease, and pulmonary vascular disorders.

Chronic Obstructive Pulmonary Disease (COPD)

Dyspnea and fatigue are hallmarks of the exercise limitation noted in patients with COPD (i.e., emphysema and chronic bronchitis).[37] The major elements contributing to the dyspnea include a decreased ventilatory capacity and an increased ventilatory requirement. The limited ventilatory capacity is caused by increased airway resistance, variably combined with reduced lung elastic recoil. The increased ventilatory requirement is principally due to ventilation-perfusion mismatching.

In emphysema, lung compliance is increased, and respiratory system relaxation volume (i.e., the point of balance between the inwardly directed elastic recoil pressure of the lung and the outwardly directed recoil pressure of chest wall) elevated. This pathophysiologic condition is known as "static lung hyperinflation." In patients with airflow limitation, the increased ventilatory demand of exercise, along with insufficient expiratory time, contribute to air trapping. As a result, end-expiratory lung volume (EELV) fails to decline to normal, leading to dynamic hyperinflation (Fig. 32-7). The magnitude of hyperinflation varies with the degree of resting lung hyperinflation, the severity of expiratory flow limitation, and the breathing pattern. Dynamic hyperinflation causes a critical reduction in inspiratory reserve volume (IRV) (i.e., the ability to augment V_T is impaired), inspiratory muscle weakness, and increased work of breathing. A substantial disparity arises between respiratory muscle effort and the resultant V_T response ("neuromechanical uncoupling"), and cardiac hemodynamics are potentially adversely affected.[38] Even in nonhyperinflated patients with moderate-to-severe COPD, progressive constraining of increases in V_T as IRV is reduced influences development of dyspnea and contributes to exercise limitation.[39]

Hence, exercise intolerance in patients with moderate or severe COPD is characterized by erosion of the ventilatory reserve ($\dot{V}_E$/MVV), which may approach or exceed 100%. Breathing adaptations consist of an increase in respiratory rate and reduction in tidal volume, resulting in a reduction in alveolar ventilation. As a result, inadequate alveolar ventilation may result in CO_2 accumulation, evident as increases in $PetCO_2$ and $PaCO_2$. Dynamic hyperinflation, resultant reduction in inspiratory capacity, and increased work of breathing further contribute to a ventilatory limitation to exercise, which may be observed prematurely, even before the AT is reached. $P(A–a)O_2$ is usually elevated, especially when P_aO_2 decreases due to underventilation of perfused alveolar units A higher nadir of the plot of V_E versus VCO_2, and a steeper plot of V_E versus VCO_2 compared to normal, reflect the increase in V_D.[40]

Another parameter related to V_E and VCO_2 appears to better depict the magnitude of the increase in V_D: the V_E intercept (V_{Eint}).[41] V_{Eint} represents the ventilatory requirement when pulmonary gas exchange is absent (i.e., $VCO_2 = 0$). Higher values of V_{Eint} characterize the ventilatory performance of patients with COPD compared to patients with heart failure who have a similar maximal exercise capacity.[42,43] Higher values of V_E*int* also directly mirror the progression of functional impairment from mild to end-stage COPD.[44]

Interestingly, exercise-related desaturation occurs more frequently in patients with predominant emphysema than in those with predominant chronic bronchitis.

Finally, a role for CPET in the prognostic evaluation of patients with COPD[45] and in monitoring treatment aimed at improving breathing strategy or reducing dynamic hyperinflation has been demonstrated.[46]

Interstitial Lung Disease (ILD)

Interstitial lung diseases are characterized by deranged lung mechanics, reduced functional pulmonary capillary bed, and reduction in the total number of functioning lung units. Dyspnea with exercise is common in patients with ILD. Multiple mechanisms contribute to the increased ventilatory demand in these patients: (1) exaggerated dead space ventilation (i.e., increased V_D/V_T), (2) ventilatory inefficiency (i.e., increased V_E/VCO_2), (3) hypoxemia, (4) early onset of metabolic acidosis, (5) possible concomitant pulmonary

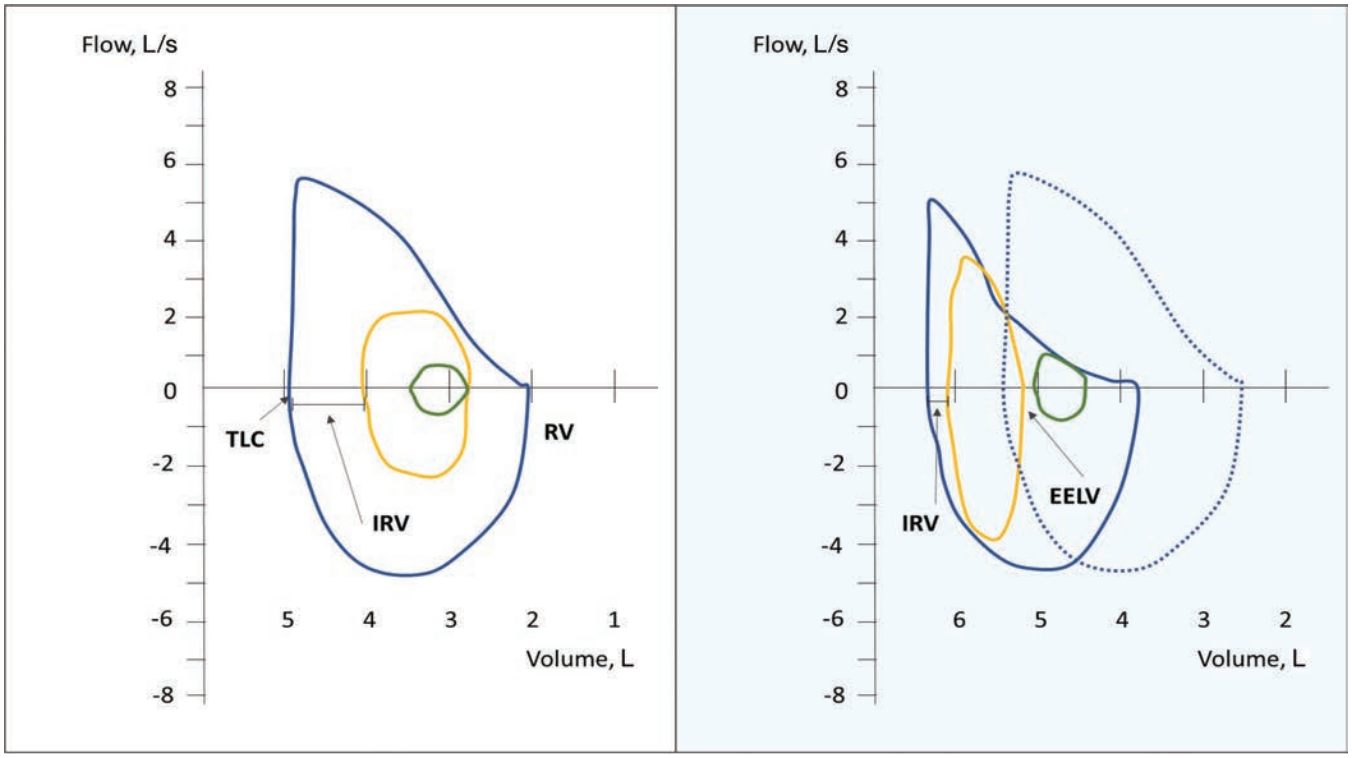

Figure 32-7 Comparison of tidal flow–volume loops at rest and during exercise in a healthy subject ***(left)*** and a typical patient with COPD ***(right)***. Shown are maximal flow–volume loops (MFVL). Notable observations regarding ventilatory demand versus ventilatory capacity in the patient with COPD include: (1) Expiratory flow limitation (encroachment of V_T during spontaneous breathing on the expiratory limb of the flow–volume envelope of the MFVL) identifies the magnitude of expiratory flow limitation at rest and during exercise. (2) Dynamic hyperinflation occurs during exercise (identified by the increase in end-expiratory lung volume relative to resting volume). (3) Progressive erosion of inspiratory reserve volume leads to critical constraints on tidal volume expansion (as reflected in the closeness of tidal inspiratory flow rates and the inspiratory limb of the MFVL). Blue line, maximal flow–volume loop; yellow line, incremental exercise; green line, rest tidal breathing; dot blue-line, predicted flow-volume loop; COPD, chronic obstructive pulmonary disease; EELV, end-expiratory lung volume; IRV, inspiratory reserve volume; RV, residual volume; TLC, total lung capacity. *(Reproduced with permission from O'Donnell DE, Banzett RB, Carrieri-Kohlman V, et al. Pathophysiology of dyspnea in chronic obstructive pulmonary disease: a roundtable. Proc Am Thorac Soc. 2007;4(2):145–168.)*

hypertension, (6) derangement of lung mechanoreceptor responses, and (7) increased central respiratory drive. Because of a mechanical limitation for increasing tidal volume, $\dot{V}_E$ increases primarily due to an augmentation in respiratory rate, except for very early exercise. A reduced ventilatory reserve also is frequently present.

During physical effort, most patients with ILD experience an abnormal widening in $P(A–a)O_2$ and arterial desaturation, likely the result of $\dot{V}/\dot{Q}$ mismatching, thickening of the alveolar capillary membrane, destruction of the pulmonary capillary bed, and hypoxic pulmonary vasoconstriction.[47,48] Cardiovascular limitations may play a concomitant role, particularly when pulmonary vascular disease and right ventricular dysfunction are present.

With some limitations, it may be possible to identify CPET responses specific for different types of ILD.[49] Patients with interstitial pulmonary fibrosis (IPF) usually experience arterial desaturation and abnormal pulmonary gas exchange with widening of the alveolar–arterial oxygen tension gradient that is greater than that seen in those with sarcoidosis or cryptogenic fibrosing alveolitis–scleroderma type. In addition, concomitant pulmonary hypertension is much more common in IPF. Patients with sarcoidosis may have a higher incidence of cardiovascular abnormalities due to myocardial involvement.

CPET is a sensitive test for unmasking subtle pulmonary gas exchange abnormalities not revealed by routine testing. Peak $\dot{V}O_2$, reduced ventilatory efficiency (i.e., increased V_E/VCO_2), and exercise-induced hypoxemia have each been reported to have prognostic value in ILD,[48] although a systematic review failed to draw definite conclusions on the utility of CPET in patients with ILD in everyday clinical practice.[50]

Pulmonary Vascular Disease

Patients with pulmonary vascular disease (e.g., pulmonary arterial hypertension [PAH], pulmonary embolism, chronic thromboembolic pulmonary hypertension [CTEPH], and pulmonary vasculitis) have abnormally high pulmonary vascular resistance (PVR). During exercise, the elevated PVR prevents physiological recruitment of the pulmonary vascular bed and an appropriate increase in pulmonary blood flow, leading to hypoperfusion of ventilated alveoli (i.e., $\dot{V}/\dot{Q}$ mismatch). Because of the increase in alveolar dead space ventilation (i.e., overventilation of the hypoperfused alveoli), minute ventilation is increased and $PetCO_2$ reduced. Exercise limitation is, therefore, characterized by an increase in the slope of the V_E/VCO_2 relationship (i.e., inefficient ventilation), an increase in V_D/V_T and in pulmonary artery pressures, and arterial hypoxemia, evident as an increase in $P(A\text{-}a)O_2$. Additionally, a reduction in AT and flattening of the O_2 pulse may be seen due to superimposed right ventricular dysfunction secondary to pressure overload and an inability to maintain adequate CO. The typical breathing pattern is reduced V_T and increased RR (presumably due to mechanical stimulation of "J-receptors," along with hyperactivation of the sympathetic nervous system, chemoreceptor hypersensitivity, and stimulation of chemoreceptors by hypoxemia). Nearly 20% of patients with significant pulmonary vascular disease experience arterial desaturation from right-to-left shunting across a patent foramen ovale.

A large body of evidence emphasizes the utility of variables measured during CPET in assessing disease severity and in predicting survival and time to clinical worsening in patients with PAH and CTEPH. In particular, peak $\dot{V}O_2$, V_E/VCO_2, and arterial oxygen saturation have been demonstrated to better predict prognosis than resting hemodynamics and lung function measurements.[51,52]

Evaluation of General Surgery Risk

CPET has a role in predicting perioperative risk in noncardiopulmonary surgical procedures. Furthermore, current literature suggests that variables measured during performance of CPET outperform alternative methods of preoperative risk stratification; they can be used as complementary tools to refine predictions of perioperative risk[53] and postoperative complications.[54] The parameters most often examined are peak $\dot{V}O_2$, AT, and V_E/VCO_2 at AT. However, the selection of variables and threshold values considered differ according to the surgical procedure planned and the patient's underlying medical conditions.[53]

In addition to its value in preoperative risk profiling, CPET measurements may guide optimization of comorbidities and preoperative exercise training, help direct the choice of procedure to be utilized, and inform aspects of postoperative care.[55] Further studies are needed to optimize use of CPET in this setting and to heighten awareness of the value of the physiologic data provided—data that have been clinically underutilized to date (e.g., chronotropic incompetence is predictive of postoperative outcome, but is still rarely reported).[56] In addition, CPET can be used in development of multiparametric risk prediction models, which include putative risk factors, biomarkers, noninvasive imaging, and objective measures of functional capacity.[57]

Evaluation for Lung Resection and Lung Volume Reduction Surgery

Lung cancer is common among patients with COPD. Although surgical resection is currently the most effective therapeutic approach for localized non–small-cell lung cancer, it carries a significant perioperative risk in patients with underlying lung disease. Along with spirometry and measurement of diffusion capacity of the lung for carbon monoxide (D_LCO), CPET has emerged as a powerful tool for risk stratification of patients with moderate or high perioperative risk.[58]

Major clinical guidelines (e.g., those of the ERS/European Society of Thoracic Surgeons, American College of Chest Physicians, and British Thoracic Society) recommend performing CPET in the preoperative evaluation of patients with lung cancer prior to lung resection. In this context, peak $\dot{V}O_2$ is the most useful prognostic parameter. A peak $\dot{V}O_2$ <15 mL/kg/min or a peak $\dot{V}O_2$% <50%–60% predicted are independent markers of increased morbidity, including postoperative complications, and mortality.[45]

Lung volume reduction surgery (LVRS) for patients with severe emphysema has been associated with improvement in survival, quality of life, and exercise capacity.[59] In patients with predominantly upper-lobe emphysema, CPET can be used to delineate the subgroup of patients who benefit more from LVRS compared with standard medical treatment alone. Indeed, a preoperative peak WR <25 W for females and <40 W for males is associated with the most favorable cost-effective outcome at 3 years.[60]

Evaluation for Heart or Lung Transplantation

A number of landmark clinical trials have addressed the role of CPET in the prognostic evaluation of patients with heart failure and in prioritization of patients for heart transplantation.[61–63] Current guidelines recommend using CPET to guide transplant listing.[64] Patients with a peak $\dot{V}O_2$ ≤14 mL/kg/min during a maximal CPET (or a peak $\dot{V}O_2$ ≤12 mL/kg/min if on beta-blocker therapy) and young females who achieve <50% predicted peak $\dot{V}O_2$ should be referred for cardiac transplant evaluation. In the case of submaximal CPET results (i.e., RER <1.05), a V_E/VCO_2 of >35 may be used as a criterion for listing. The best predictive power would likely derive from a multiparametric model incorporating $\dot{V}O_2$, V_E/VCO_2, AT, and oscillatory breathing.[65,66]

Despite the excellent prognostic power of CPET variables in assessing chronic lung diseases,[67–69] they have not been routinely used in selecting candidates for lung transplantation; nor are they currently recommended in international guidelines.[70] A consideration for the future is that CPET play a role in the setting of lung transplant evaluation, along with, or as a replacement for, the 6-minute walk test (6MWT) as a measure of exercise capacity.[71]

Exercise-Induced Bronchospasm

Exercise-induced bronchospasm (EIB) is defined as a fall in post-exercise FEV_1; it should be suspected in any patient who presents with dyspnea, wheezing, cough, or chest tightness during or shortly after exercise. A "challenge" test is useful in establishing a diagnosis of EIB and in validating use of inhaled bronchodilators in management of EIB. Comparative studies of chemical challenge, for example, using histamine or methacholine, versus exercise have demonstrated a lower sensitivity and higher specificity for exercise challenge.[29] EIB can usually be detected with incremental exercise testing, but it may be more evident using near-maximal, constant load exertion.[72] Importantly, a reduction in FEV_1 following a standardized exercise protocol may also be considered a specific index of asthma severity. Addition of cold air inhalation during the test increases the sensitivity.[73]

■ Evaluation of Patients with Cardiac Disease

Just as cardiac stress testing has a well-accepted role in evaluating patients with suspected coronary artery disease, CPET has proved very useful in clinical assessment of patients with heart failure.

Heart Failure

CPET has become the standard for functional assessment of the pathophysiologic basis of exercise intolerance in patients with heart failure, conveying impactful clinical and prognostic information.[7] Even though application of CPET has been well established in patients with advanced heart failure with reduced ejection fraction (HFrEF), in the last decade, data on patients with heart failure with preserved ejection fraction (HFpEF) have been reported. Each phenotype may demonstrate a similar extent of exercise intolerance, despite differing underlying pathophysiologic mechanisms and precipitating factors.[74]

Although results from CPET may be a strong predictor of future development of heart failure, caution is advised in its use as a primary diagnostic tool. Indeed, manifestations of heart failure are common in other chronic conditions (e.g., PAH, congenital heart defects, and interstitial lung diseases) which are characterized by a low peak$\dot{V}O_2$.[3] Accordingly, a consensus algorithm for the diagnosis of HFpEF incorporates use of CPET simply as an exclusionary initial test.[75] CPET would appear to be used most appropriately for investigating the underlying pathophysiologic consequences of heart failure, irrespective of etiology, for optimizing clinical decision-making, and for establishing a prognosis.

Pioneering studies in heart failure by Weber et al.[6] and Mancini et al.[62] introduced use of CPET into daily practice. Measurement of peak $\dot{V}O_2$ quickly became the standard for staging the severity of disease, unmasking the underlying pathophysiology, and addressing optimal timing for performing heart transplantation. The Weber classification,[62] based on four categories of peak $\dot{V}O_2$ and levels of cardiac index, facilitated establishment of many important advancements in the field.[76]

In the late 1990s, evidence for the role of abnormalities in V_E in patients with heart failure led to another useful observation: V_E/VCO_2 is a stronger predictor of adverse events than is peak $\dot{V}O_2$.[77] The advantages of V_E/VCO_2 over peak $\dot{V}O_2$ were confirmed by the effort-independent nature of the physiologic information provided,[3] as well as its prognostic utility, even in patients with a near normal peak $\dot{V}O_2$ (~18 mL/min/kg).[78]

In 2007, a ventilatory classification (VC) scheme was proposed.[4] Four classes were designated, based on V_E/VCO_2, as an integrative way of optimizing CPET-derived risk stratification in heart failure ventilatory class. VC I is defined as $V_E/VCO_2 \leq 29$; VC II as V_E/VCO_2 of 30.0–35.9; VC III as V_E/VCO_2 of 36.0–44.9; and VC IV as $V_E/VCO_2 \geq 45.0$. The higher the VC class, the greater the risk for major cardiac events (e.g., increased mortality or need for cardiac transplantation or left ventricular assist device implantation).

Currently, either VC classification or peak $\dot{V}O_2$ may be used in a multiparametric combination, along with other derived variables embedded in the score's format, for prognostic purposes[79] and as a reference endpoint in pharmacologic[80,81] or interventional trials.[82,83] These multiparametric approaches apply primarily to patients with HFrEF. However, a study combining CPET with echocardiographic evaluation (i.e., CPET imaging; see below) tested the validity of the Weber and VC classifications in a population of patients with different forms of heart failure, including those with HFrEF, HFpEF, and patients with midrange ejection fractions (mrEF). Both classifications demonstrated prognostic utility, especially when peak $\dot{V}O_2$ and V_E/VCO_2 strata were combined (Fig. 32-8).[84]

In addition to the clinical value of assessing inefficiency of V_E in heart failure, recent attention has been directed to the observation that an abnormal "exercise oscillatory ventilation" (EOV) pattern indicates an adverse prognosis. EOV is the pathophysiologic manifestation of two main processes: hemodynamic instability sustained by circulatory delay and pulmonary congestion, and impaired chemosensitivity.[85]

Assessment of exercise ventilatory patterns is particularly attractive in identifying the various phenotypes related to pulmonary hypertension secondary to left-sided heart disease. Identification of "left-sided" pulmonary hypertension is particularly important, given its prognostic role and high prevalence in both HFrEF and HFpEF.[86,87]

In a study incorporating CPET and measurement of pulmonary artery pressures, a V_E/VCO_2 cutoff of 36 was found to be the strongest predictor of a pulmonary artery pressure (PAP) ≥40 mm Hg, followed by peak exercise $PetCO_2$ of 36 mm Hg and the presence of EOV in patients with HFrEF. More compelling was the greater predictive utility when all measures were considered together.[88] Multiple trials have demonstrated that in HFpEF, a high V_E/VCO_2 is typical of patients with documented increased pulmonary vascular resistances[88,89] and right ventricle-to-pulmonary circulation uncoupling. Finally, measurements of pulmonary and systemic hemodynamics that incorporate use of echocardiography and "invasive CPET" (see below) have emerged as fundamental additions to CPET in evaluating mechanisms of exercise limitation in patients with heart failure.

CPET IMAGING

CPET imaging (CPET IM) has been recently proposed as a valuable testing modality to expand knowledge of organ system limitations to exercise performance. The technique combines physiologic data obtained from exercise testing with noninvasive measures (e.g., echocardiography) of cardiac function and geometry, valvular status, and systolic and diastolic function, including assessment of left atrial function.[7,90] Assessment of cardiac "functional reserve" using CPET IM is greatly augmented by study of the pathophysiologic response of the pulmonary circulation to exercise.

Multiple applications of CPET IM in assessing cardiopulmonary disorders have been described. For example, good discrimination between a circulatory disorder and deconditioning is signaled by a subject's inability to reach an exercise stroke volume of >50 mL/m^2.[91] Additionally, the importance of measuring CO reserve, in parallel with LV compliance and filling pressures, is well established,[90] and estimation of O_2 extraction in peripheral tissues using CPET IM and an echocardiographic-derived analysis of the determinants of the Fick equation provides useful information.[92,93]

In COPD, combined CPET and stress echocardiographic testing can be helpful in determining individual contributions to exercise intolerance. In addition to airflow limitation and hyperinflation, exercise impairment may be precipitated by hemodynamic factors. For example, in a group of patients with COPD, CPET IM reveals significant adverse effects on LV volume, right ventricular area, tricuspid regurgitation grade, heart rate, stroke volume, and $\dot{V}O_2$. The major mechanisms resulting in reduced exercise tolerance include bowing of the septum to the left, abnormal increases in the LV filling pressure, as estimated by the ratio of early mitral flow wave (E) to

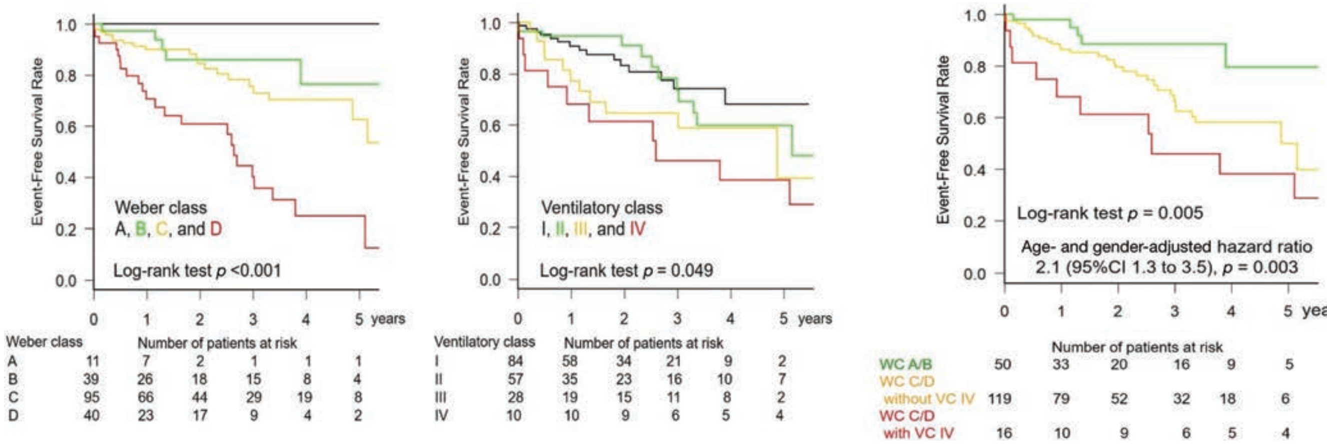

Figure 32-8 Kaplan-Meier stratification according to Weber (WC) (*A*) and ventilatory (VC) classifications (*B*) and their combined survival rates. *(Reproduced with permission from Guazzi M, Borlaug B, Metra M, et al. Revisiting and Implementing the Weber and Ventilatory Functional Classifications in Heart Failure by Cardiopulmonary Imaging Phenotyping. J Am Heart Assoc. 2021;10(5):e018822.)*

early tissue Doppler (e′), an abnormal stroke volume, and chronotropic incompetence in approximately 60% of cases.[92]

In cardiac patients, assessment of functional mitral regurgitation (MR) is relevant as a marker of disease severity and adverse outcome, that, in early stages, may be detectable only during exercise.[93] "Dynamic pulmonary hypertension" is another pathophysiologic mechanism closely related to MR and associated with specific ventilatory phenotypes of gas exchange, such as EOV.[93] In advanced HFrEF, assessment of exercise-induced RV contractile reserve may be investigated using CPET, providing important insights into potential RV functional recovery.[94]

Recently, findings suggest that an impaired left atrial (LA) dynamic during maximal exercise and during the recovery phase plays a central role in triggering RV-to-PC uncoupling and ventilatory inefficiency, especially when LV systolic function is reduced.[95,96] LA dynamic can be assessed in a feasible and reproducible way by strain analysis. Strain measures the extent of myocardial deformation and can be derived by specific echocardiographic and cardiac magnetic resonance techniques.[95,96]

The body of literature on CPET IM in patients with HFpEF is expanding, and it now elucidates how the test may be used to uncover unexplained dyspnea in patients with suspected HFpEF. CPET IM may be helpful in confirming a diagnosis of HFpEF in cases with uncertain diagnostic criteria at rest, and it may be used to predict cardiovascular risk.

The American Society of Echocardiography (ASE)/European Association of Cardiovascular Imaging (EACVI) recommendations on diastolic function evaluation advocate the use of exercise E/e′ ratio to detect diastolic dysfunction,[97] and for several years, changes in E/e′ have been taken as a reference in interpreting unexplained dyspnea in patients with suspected HFpEF.[98] In a study of 87 patients with unexplained dyspnea and hypertension during exercise, combined measurements of gas exchange and Doppler analysis led to a diagnosis of HFpEF in the minority of patients presenting with a combination of E/e′ > 15 at peak exercise and an elevated V_E/VCO_2.[99]

Additional observations have focused on how exercise E/e′ may add to the clinical follow-up of patients with established HFpEF, especially when coupled with examination of the associated changes in pulmonary pressure during effort.[100] Interestingly, CPET IM, including immediate post-exercise echocardiographic assessment, has documented that in about one of three patients with HFpEF, exercise-induced elevation of left ventricular filling pressure (i.e., E/e′EXE >13) may be absent, despite its association with reduced contractile reserve and ventricular-arterial coupling and a mild degree of functional impairment.[101] On the other hand, a similar approach has showed that peak E/e′ >15 occurred in 9% of hypertensive patients with exertional dyspnea and normal resting left ventricular function and was associated with lower peak $\dot{V}O_2$ and significantly impaired ventilatory efficiency (increased V_E/VCO_2) compared with patients with normal exercise E/e′.[99]

The rationale for using CPET IM in valvular disease is based on extensive investigation. However, systematic data are not yet available, and future investigation is desirable for assessment of surgical risk, especially in complex conditions, such as paradoxical, low-flow gradient, severe aortic stenosis.[102]

INVASIVE CPET (iCPET)

Invasive CPET (iCPET) is the gold standard for in-depth characterization of the hemodynamic basis for exercise limitation; it provides precise delineation of central and peripheral hemodynamic mechanisms. The approach has been reassessed in recent years and has been established as a routine approach in several laboratories.[103]

Measurement of pulmonary hemodynamics, left ventricular filling pressures, cardiac output (via the Fick equation), and $CaO_2 - CvO_2$ is extremely helpful in cases of unexplained exercise-induced dyspnea,[103] in the presence of severe limitation of cardiac output, and in evaluation of exercise-induced pulmonary hypertension, either idiopathic or secondary in origin.[103] A recent analysis documented that iCPET allows considerable shortening of the diagnostic interval from time of onset of exertional dyspnea to establishment of an organ-specific diagnosis. Conditions that can be diagnosed using iCPET include HFpEF, mitochondrial myopathy, preload failure, and deconditioning.[34]

Additionally, pulmonary hemodynamic measurements during exercise, especially of PAP and pulmonary arterial wedge pressure (PAWP), demonstrate increased prognostic value compared with measurements at rest.[104]

Studies have demonstrated an opportunity to diagnose HFpEF in symptomatic, euvolemic patients with normal levels of B-type natriuretic peptide, and without clear signs and symptoms of heart failure at rest.[105] In one-half of cases in whom examination of PAWP and end-diastolic LV pressure were performed, an observed increase in PAWP during exercise was diagnostic for HFpEF.

These findings have been reproduced and indicate that in patients with normal biventricular function, an increase in mean PAWP to >20 mm Hg at peak exercise, in the absence of an elevation in pulmonary vascular resistance, indicates exercise-induced HFpEF.[105] Patients with early stages of PAH and normal cardiopulmonary hemodynamics at rest demonstrate an increase in mean PAP to >30 mm Hg and in pulmonary vascular resistance to >80 to 120 $dyn \cdot s \cdot cm^5$ on iCPET with no increase in PAWP.[104]

A distinctive pulmonary hemodynamic pattern useful in defining exercise-induced dyspnea due to HFpEF is an increase in PAWP/CO.[106] A high slope for PAWP/CO (>2.0 mm Hg/L/min), combined with abnormal gas exchange measurements, for example, lower peak $\dot{V}O_2$ and V_E/VCO_2, predicts heart failure outcomes.

Exertional intolerance may be associated with preload-dependent limitations to stroke volume and CO increase. In the affected patient population, failure to augment right atrial pressure on exercise is observed with a concomitant reduction in CO.[34] Finally, impaired systemic O_2 extraction indicates left-to-right shunting or a mitochondrial myopathy. An algorithm for diagnosing these conditions has been proposed.[34]

Evaluation of the pulmonary artery pressure-flow relationship during exercise, reflected in a plot of mean PAP versus CO, provides a strong indication of any abnormality in RV-pulmonary circulation coupling.[103] A mean PAP/CO relationship >3 mm Hg/L/min is reflective of a pulmonary hypertension response, which may be seen with a typical pattern of ventilatory inefficiency during exercise, as suggested by an elevated V_E/VCO_2. Interestingly, the development of RV-pulmonary circulation uncoupling becomes the main hemodynamic substrate responsible for a delayed $\dot{V}O_2$ kinetics during early exercise.[107]

The most relevant limitations to this approach are its invasive nature and technical inaccuracies in obtaining reliable pulmonary hemodynamic tracings during high respiratory frequencies, despite the averaging of repeated measures.

CHAPTER **33**

Diagnostic Bronchoscopy, Transthoracic Needle Biopsy, and Related Procedures

David M. DiBardino
Daniel H. Sterman
Anil Vachani

INTRODUCTION

Gustav Killian reported his experience with the first bronchoscopy in 1898. Technological advances during the next century facilitated development of bronchoscopy as a pivotal diagnostic and therapeutic tool in pulmonary medicine. Although a number of bronchoesophagologists contributed to refinement of the technique based upon use of a rigid instrument, the advent of flexible fiberoptic bronchoscopy, pioneered by Ikeda in 1967, opened new horizons to clinicians. Subsequently, transthoracic needle biopsy was added to the pulmonologist's diagnostic armamentarium, although it is now most frequently performed by radiologists under CT guidance.

This chapter comprises an overview of bronchoscopy, transthoracic needle biopsy, and related techniques. Following a general discussion of bronchoscopy and associated general instrumentation, indications for the technique and patient preparation are considered. Specific applications of diagnostic bronchoscopy are discussed. Subsequently, safety factors related to bronchoscopy and complications of the technique are reviewed. Finally, transthoracic needle biopsy is described.

GENERAL INSTRUMENTATION

The original bronchoscope, developed by Killian in Europe, and further perfected by Chevalier Jackson in the United States, was a rigid metal tube that permitted either spontaneous or assisted ventilation. With development of fiberoptic and advanced electronic technology, the flexible bronchoscope has, to a large extent, replaced the rigid bronchoscope for most diagnostic and some therapeutic indications. Therapeutic bronchoscopy is discussed in Chapter 34.

■ Flexible Fiberoptic and Videobronchoscopy

Although the optical resolution of early fiberoptic bronchoscopes was inferior to that of rigid devices, their flexibility, ease of manipulation, and simplicity of use, which permit rapid examination with local anesthesia and conscious sedation, have made flexible bronchoscopy the primary endoscopic procedure in pulmonary diseases.

Unlike the larger-bore rigid bronchoscope, the flexible bronchoscope varies from ultra-thin (allowing for greater access to the lung periphery in adults and for neonatal endoscopy) to larger, adult-size therapeutic devices. The diameter of the working channel permits aspiration of secretions or introduction of accessories required for diagnostic purposes (see below). With flexible bronchoscopy, the patient's ventilation is assured by airflow around the bronchoscope, between the external wall of the device and the tracheobronchial tree. Thus, the appropriate selection of bronchoscope size is crucial.

Fiberoptic systems have largely been replaced by videobronchoscopes, which utilize a miniaturized camera at the tip of the scope that provides electronic transmission of images to a television monitor. Flexible bronchoscopes are more fragile and more prone to damage than are rigid metal instruments. Appropriate care and adherence to safety techniques during procedures, as well as during routine cleaning and maintenance of the instruments, help assure extended instrument life and reduce repair costs.

Recently, the advent of a flexible single-use disposable fiberoptic bronchoscope attempts to address rising concerns over the efficacy of endoscope cleaning practices, the burden of repair costs, the size of a modern endoscopy tower, and the challenge of prompt bedside availability.[1] Improving image quality and improved maneuverability will undoubtedly be the focus of innovation for this device, although it has proved useful in certain scenarios such as airway emergencies, bedside bronchoscopy, and percutaneous tracheostomy.[2]

■ Ultrathin Bronchoscopes

Ultrathin bronchoscopes—flexible scopes with external diameters ≤3 mm—were initially developed for pediatric applications; however, these have now incorporated larger working channels, allowing for their use in the diagnosis of peripheral pulmonary lesions in adults.[3,4] Ultrathin bronchoscopes can be advanced to more peripheral bronchi than conventional bronchoscopes under direct observation, allowing for examination of sixth- to eighth-generation bronchi. Ultrathin scopes may be particularly useful when combined with additional diagnostic tools, such as navigational bronchoscopy and radial ultrasound probes (see below).

■ Robotic Bronchoscopy Systems

Most recently, technologic advancements in bronchoscopy involve optimizing the mechanical design of the endoscope itself with the goal of improving articulation, stability, and biopsy instrument guidance within the distal lung.[5,6] These systems integrate novel endoscopic designs with unique navigation platforms (see below). As with ultrathin bronchoscopes, the combination of these modalities may improve diagnostic yield for small, peripherally located lesions. Potentially greater accuracy in lesion access coupled with improved stability may also enable certain therapeutic applications.

■ Diagnostic Bronchoscopy Accessories

The working channel of the fiberoptic or videobronchoscope, although of relatively small diameter, allows the insertion of various diagnostic and therapeutic accessories. Often these instruments are used serially during the same procedure in the hopes that different forms of tissue acquisition will optimize sampling.

■ Biopsy Forceps

The cutting jaws of biopsy forceps may be round or elliptical and may have smooth or jagged edges. The use of nonserrated edges, however, seems to reduce tissue trauma and the concomitant risk of bleeding. The biopsy procedure is simple and generally associated with only minimal complications in the case of a visible lesion. Even peripheral lesions, which are not visible through the bronchoscope, may be biopsied. With diffuse parenchymal or interstitial lung disease, the use of fluoroscopic guidance has not resulted in higher diagnostic yield or safety. However, the use of fluoroscopy improves

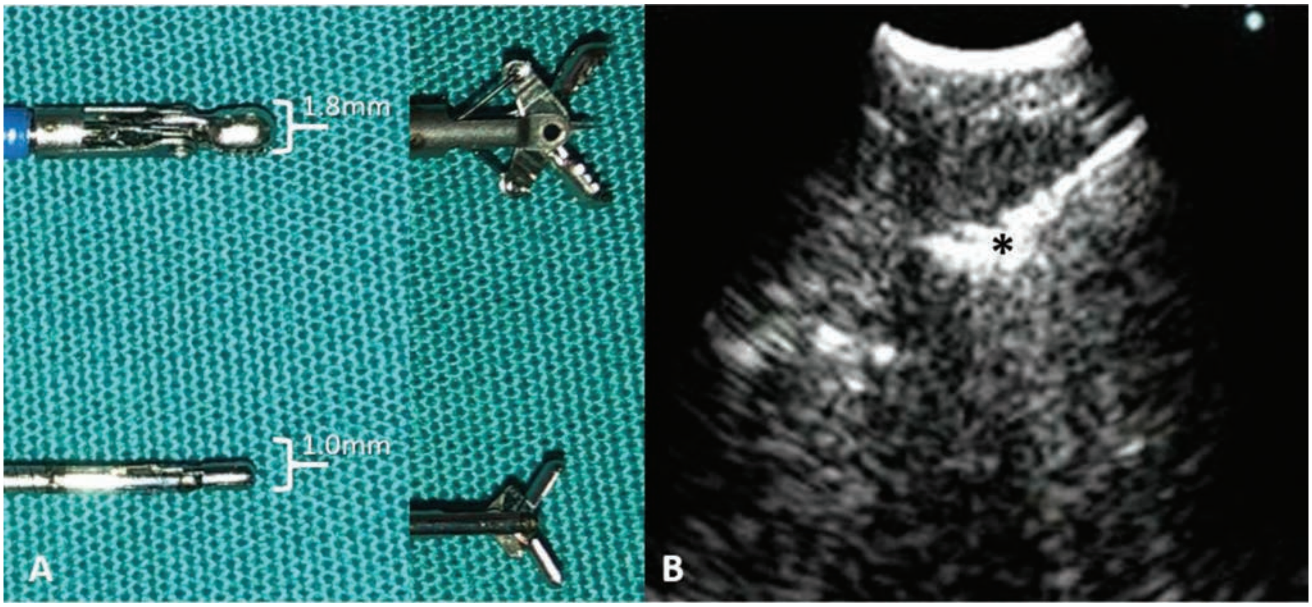

Figure 33-1 Intranodal forceps biopsy tools. **A.** Transbronchial biopsy forceps (Top, Radial Jaw 4), Intranodal biopsy forceps (Bottom, CoreDx). **B.** EBUS image of intranodal biopsy forceps open within lymph node *(asterisk)*. *(Image provided courtesy of Boston Scientific. © 2022 Boston Scientific Corporation or its affiliates. All rights reserved.)*

the diagnostic yield of biopsies for focal lesions. The development of new electromagnetic and remote guidance systems suggests that further improvement in the diagnostic yield of bronchoscopic biopsies can be expected.

More recently, miniaturized forceps have been used to obtain biopsies of mediastinal lymph nodes under real-time endobronchial ultrasound guidance (Fig. 33-1). These forceps range from 1.0 to 1.8 mm in diameter and can be passed via a previously created needle puncture or electrocautery incision.[7–9] Ideally samples obtained this way can optimize diagnostic yield for certain conditions, such as lymphoma, where fine-needle aspiration may not provide an adequate sample.

■ Bronchial Brushes

A bronchial brush consists of a rigid central wire surrounded by bristles of various sizes and shapes. To-and-fro movement of the brush against the adjacent tissue produces minor trauma but enables collection of ample specimens for cytologic or microbiologic analysis.

In some clinical circumstances, there is a need to obtain an uncontaminated specimen from the lower respiratory tract for microbiologic studies. A brush protected by an additional sheath and tip may be passed through the working channel of the bronchoscope (protected brush specimen, as discussed below). In these cases, special attention is needed not to use an excessive amount of local anesthetic or saline lavage, since these solutions contain bacteriostatic material that may inhibit microbial growth. The diagnostic yield depends on use of proper technique, appropriate choice of brush, and careful collection and preservation of the specimen.

■ Needles for Aspiration and Biopsy

The first performance of a transbronchoscopic needle aspiration (TBNA) through a rigid bronchoscope was reported by Schieppati in 1958. Wang then developed a flexible needle technique using a fiberoptic bronchoscope in 1978.[10] Initially, several models of needles were designed to obtain cytologic material; subsequently, histologic specimens from peribronchial mediastinal and hilar lymph nodes were obtained with larger-bore needles. These biopsy needles have subsequently been adapted to work under direct ultrasound guidance from within the airway (see below), although current ultrasound techniques do not yet allow for real-time guidance during biopsy of a peripheral lesion. These needles employ a sheath to protect the bronchoscope working channel and are widely available in a variety of sizes, ranging from 18 to 25 gauge. The addition of TBNA to forceps and brushes for the sampling of a peripheral lesion improves the diagnostic yield of a bronchoscopy.[11]

TBNA is generally safe, although pneumothorax and hemomediastinum may occur; rare cases of air embolism also have been reported.[12] Clinically significant bleeding is extremely rare, particularly when a 22-gauge needle is used, even if a major vessel is inadvertently punctured or if the patient suffers from superior vena cava syndrome.

■ Cryoprobe

Since 1994 flexible cryoprobes have been available for use through a bronchoscope's working channel. This instrument utilizes the Joule-Thomson effect by bringing liquefied gas from a compressed reservoir into a small orifice at the tip of the probe where it rapidly expands into gas. This conversion is associated with a rapid drop in temperature. The orifice is positioned beyond the end of the bronchoscope working channel where the cryoprobe tip freezes upon activation using a foot pedal. An endobronchial and transbronchial biopsy technique is possible through the principle of cryoadhesion, where the frozen probe tip adheres to tissue before being abruptly pulled proximally during the rapid freezing phase. Frozen tissue is removed en-bloc with the instrument and bronchoscope. The sample is then thawed in saline and collected from the probe tip before the device can be removed from the working channel, allowing for larger and better-preserved biopsy samples compared to forceps.[13]

■ Bronchoscopic Transparenchymal Nodule Access (BTPNA)

One common necessity for sampling a parenchymal lung lesion is an adequate airway to lead the biopsy tool to the abnormality. To combat this limitation, the technique of BTPNA has been developed to sample lesions with no clear connection to an airway.[14] With this method, an airway puncture site is chosen using software that maps the lesion relative to the surrounding vasculature. The airway entry point is created by expanding a needle puncture site that allows a tunneling sheath to be pushed through the lung parenchyma. Maneuvering of the tunneling sheath is guided by augmented fluoroscopy (see below). Although promising, limited data are available to adequately assess the full spectrum and frequency of potential risks or the added benefit of this approach for the sampling of peripheral lesions.

ENDOBRONCHIAL ULTRASOUND

Among the new diagnostic modalities available to chest physicians, endobronchial ultrasound (EBUS) has unquestionably had the most profound impact.[15] Two major barriers to EBUS development existed: ultrasound probe size and sound wave transmission in air-filled structures. Ultrasound engineering advances allowed the former barrier to be overcome, while the latter was surmounted by the development of an integrated, fluid-filled balloon surrounding the EBUS probe, thereby allowing for a sound wave–transducing medium interface to exist between the ultrasound probe and airway wall (i.e., ultrasonographic coupling).

Lower ultrasound frequencies provide better penetration depth with less resolution; higher frequencies provide better spatial resolution but less penetration depth. For EBUS applications, the frequencies range from 7.5 to 30 MHz. Currently, there are two EBUS probes utilized for diagnostic applications: ultra-miniature radial probes (20 and 30 MHz) and convex probe or curvilinear EBUS (CP-EBUS). Each of these is discussed in greater detail below.

■ Ultra-Miniature Radial Probes

Ultra-miniature EBUS (UM-EBUS) was developed to allow for improved assessment and sampling of peripheral pulmonary lesions (Fig. 33-2A). There are two ultra-miniature radial probes currently available, with diameters of 1.4 mm and 2.0 mm, allowing insertion into bronchoscopes with working channels of 2.0 mm and 2.6 mm, respectively (Olympus Corporation, Tokyo, Japan). When a lesion is reached with the probe, the usual normal lung "snowstorm" appearance is replaced by a focal ultrasound alteration that can be marked by fluoroscopy, a guide sheath (GS), or both fluoroscopy and GS (Fig. 33-2B and Video 33-1). Traditionally, after the lesion is localized, the GS can be left in place, allowing for guided biopsies of the lung using forceps, brush, or needle biopsy. Future developments will include more sophisticated guide sheaths and smaller radial probes that would allow real-time ultrasound guided TBNA in the peripheral lung.[16]

■ Convex-Probe EBUS

The convex-probe EBUS (CP-EBUS) bronchoscopes available have a built-in curvilinear ultrasound transducer with a larger distal diameter (6.7–6.9 mm) compared with a standard bronchoscope. White light video bronchoscopy occurs at an oblique angle with EBUS at 90° from the longitudinal axis. Dedicated biopsy needles (19-, 21-, 22-, or 25-gauge with a variety of tip styles) are inserted through the 2-mm working channel to perform aspirations of the target lesion (Fig. 33-3A). Real-time EBUS imaging displays needle penetration through the tracheobronchial wall into the target during the biopsy maneuver (Fig. 33-3B). If there is difficulty in achieving adequate EBUS images because of poor ultrasonographic coupling, a saline-filled balloon surrounding the transducer can be used to improve image quality. In addition, Doppler capabilities allow vascular structure differentiation, which minimizes the risk of unintended vascular puncture.

NAVIGATIONAL BRONCHOSCOPY

There has been continued emphasis on improving the ability to access and sample peripheral pulmonary lesions through technologic advances in electromagnetic navigational bronchoscopy (EMB), augmented fluoroscopy, and virtual bronchoscopy (VB)[17–20] (Fig. 33-4A–C). Furthermore, these guided bronchoscopy techniques can be combined with each other, UM-EBUS, guide sheaths, ultrathin bronchoscopes, and, most recently, robotic bronchoscopy platforms (Fig. 33-4D and 33-4E). The role of navigational bronchoscopy in the evaluation of peripheral pulmonary nodules is discussed below.

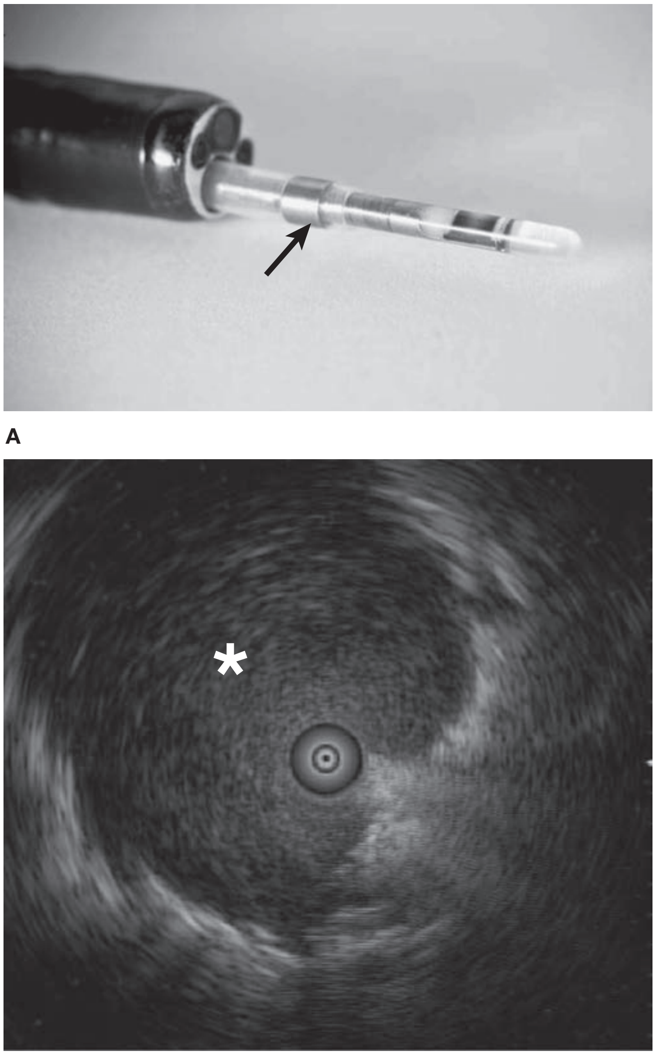

Figure 33-2 **A.** The ultra-miniature (UM)-EBUS probe contains a circulating ultrasound crystal that provides a 360° view of the surrounding structures when full airway ultrasonographic coupling occurs. The probe is inserted through a guide sheath (*arrow*; Olympus Corporation, Tokyo, Japan), which can remain in the airway upon UM-EBUS probe removal to allow for instrument guidance for biopsy. **B.** This UM-EBUS image demonstrates a focal lung lesion *(asterisk)* surrounding the probe.

Video 33-1 The ultra-miniature (UM)-EBUS probe is used via the working channel of a fiberoptic bronchoscope to identify a focal lung lesion. When the lesion is reached with the probe, there is an alteration in the ultrasound image, with replacement of the usual normal lung "snowstorm" appearance by the presence of a denser focal lesion that surrounds the centrally located probe. *Video available on AccessMedicine.com.*

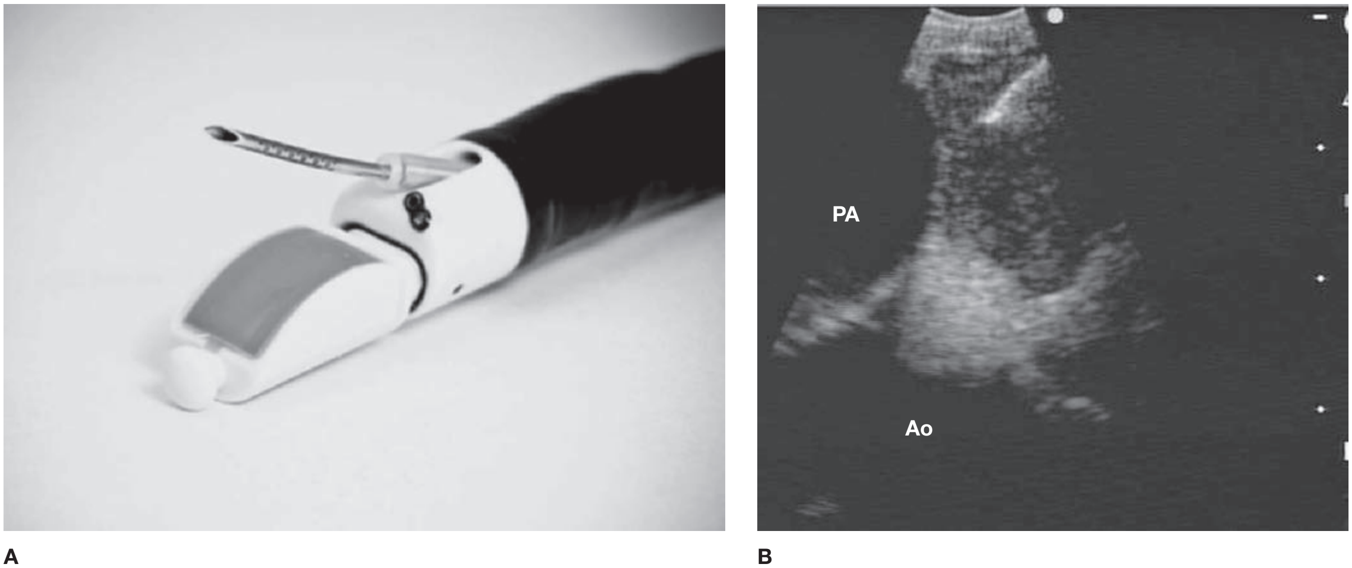

Figure 33-3 **A.** The convex probe (CP)-EBUS TBNA (Olympus Corporation, Tokyo, Japan) videobronchoscope has an integrated ultrasound probe that scans 90° perpendicular from the longitudinal axis, a 35° forward oblique video view, and a 2.0-mm working channel through which a dedicated biopsy needle can be passed. Distal tip dimples on the needle provide an echogenic surface to reflect ultrasound waves to allow needle visualization. **B.** This CP-EBUS image demonstrates a left paratracheal lymph node with the ascending aorta (Ao), the pulmonary artery (PA), and the needle present in the lymph node.

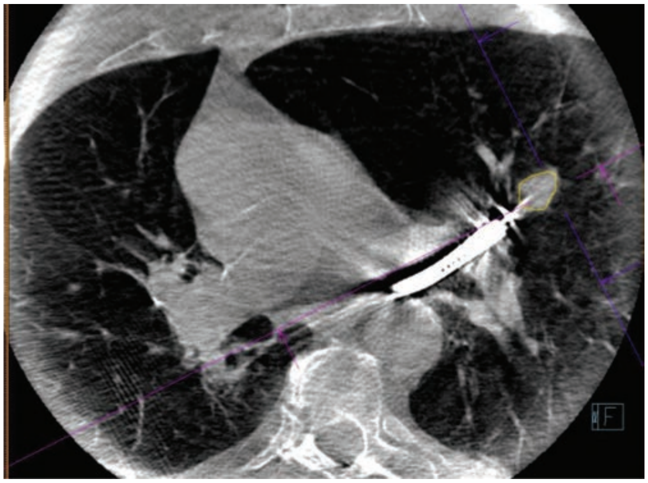

Figure 33-5 Intraprocedural cone beam–CT confirming placement of transbronchial needle within lung nodule.

EMB utilizes an electromagnetic board to generate a magnetic field around the patient, a sensor probe, an extended working channel, and three-dimensional integration of CT scan reconstruction and bronchoscopy position. In essence, this system works on the same triangulation principle as a global positioning system and allows the bronchoscopist to direct the FB through the airways to the target. There are slight variations on how the magnetic field is generated and how the sensor probe interfaces with the biopsy procedure, depending on the specific EMB equipment used. Innovation has focused on development of biopsy instruments that act as magnetic sensor probes (i.e., “tip-tracked”), approaches to account for lung movement during the respiratory cycle, and combining EMB with other technology.[21]

Augmented fluoroscopy is a technology designed to fuse previously obtained radiographic images with live fluoroscopy during a procedure (Fig. 33-5). This technique has long been utilized to aid surgical procedures involving bony structures. In the lung, this approach has evolved to the use of CT images to create a target lesion, and superimposing an artificially highlighted target to live fluoroscopy images generated during bronchoscopy.[22] Variation in patient positioning and lung volumes can be minimized between CT scan and intraprocedural fluoroscopy by using cone beam CT scan or multiple focused fluoroscopy images obtained during the procedure itself.[23] Augmented fluoroscopy can be combined with any other localization techniques such as VB and EMB.

VB based approaches utilize virtual navigation by creating a CT scan based “road map” that can be overlaid onto real-time endoscopic images. Pre-procedure CT images are assessed using a software system, a target location is selected, and a proposed airway path is suggested for an attempt at bronchoscopic sampling. Recent improvements have focused on expanding this technology to map not only the airways, but also the pulmonary vasculature. The combination of “vessel mapping” with augmented fluoroscopy allows for BTPNA.

In addition to diagnostic indications, navigational bronchoscopy can be used for fiducial placement and presents a promising tool that may be useful if future therapies for malignant nodules include focal tumor ablation or injection.[24–27]

■ Patient Preparation and Monitoring During Bronchoscopy

Success of bronchoscopy, whether diagnostic or therapeutic, depends, in large part, on proper preparation of the patient, including relief of anxiety, muscle relaxation, cough suppression, and adequate anesthesia. Time spent in achieving these goals will be well worth it in reducing the risks of complications and in increasing the ease of performance of the procedure. As with any other procedure, analysis of the risk-benefit ratio helps reduce the complication rate. During and shortly after the procedure, appropriate monitoring of hemodynamic parameters (heart rate, rhythm, and blood pressure), oxygenation, and ventilation contributes to the safety of bronchoscopy.

Most flexible bronchoscopies are performed after patient premedication with sedative agents and the use of bronchoscopically instilled lidocaine for local anesthesia of the upper airway, larynx, and tracheobronchial tree. Most frequently, moderate sedation is achieved using a combination of a short-acting benzodiazepine (e.g., midazolam) and a narcotic agent (e.g., fentanyl). Intravenous propofol also may be used to provide moderate sedation and appears to provide similar results in terms of patient satisfaction and degree of hypoxia, with the advantage of a faster recovery time.[28] Because the use of propofol can lead to deep sedation, it is important that these patients receive careful monitoring. Deep sedation (i.e., a deeper state of depressed consciousness with potential for compromised airway function and spontaneous respiration) and general anesthesia are increasingly being employed, given the shift of diagnostic and therapeutic bronchoscopy toward more complex and lengthier diagnostic procedures.

Anticholinergic medication (e.g., atropine or glycopyrrolate) has been advocated by some to reduce the risk of vasovagal reactions and to minimize airway secretions, thereby allowing for better examinations of the tracheobronchial tree. In a randomized trial comparing these two drugs with placebo, glycopyrrolate, but not atropine, led to a reduction in airway secretions.[29] There was no significant reduction in cough, patient discomfort, oxygen desaturation, or procedure time with either drug. Current recommendations discourage the use of these agents during bronchoscopy.[28]

BRONCHOSCOPY TECHNIQUE

Core elements of bronchoscopy include assessment of airway anatomy and function, evaluation of peribronchial structures, performance of biopsies, and sampling of airway and alveolar constituents. Each is discussed below.

■ Assessment of Airway Anatomy and Function

Thorough bronchoscopic evaluation begins with examination of the upper airways. Special attention should be paid to the integrity of air passages and the function of the nasopharynx and larynx. The vocal cords should be examined for the presence of polyps and tumors and for evidence of cord paralysis.

Once upper-airway inspection is completed, a systematic evaluation of the lower respiratory tract should be performed. Critically important is the distinction among normal anatomy, anatomic variations without clinical significance, and frankly pathologic conditions. These considerations have important implications regarding potential diagnostic and therapeutic approaches. For example, finding abnormal branching of a bronchus may be of no clinical significance. On the other hand, such an abnormality could explain symptoms of frequent infections due to impaired ventilation and drainage of the affected area. Special skills and observational experience are required for bronchoscopic examination after surgery, especially following bronchoplastic procedures or lung transplantation.

Assessment of airway integrity, with special attention to dynamic changes in airway caliber during either relaxed breathing or forced expiration, may be crucial in diagnosing tracheobronchomalacia (TBM) and determining appropriate therapeutic maneuvers. Airway assessment is best performed with a thin flexible bronchoscope performed with the patient spontaneously breathing.

Video 33-2 Dynamic airway examination performed to assess tracheobronchomalacia. Demonstrated is excessive dynamic airway collapse (EDAC) during exhalation, as well as anterior tracheal malacia with wide splaying of the cartilaginous rings. *Video available on AccessMedicine.com.*

Relaxation and prolapse of the membranous portion of the trachea and main bronchi secondary to destruction of elastic connective tissue may account for exacerbations of expiratory airflow obstruction. This is often referred to specifically as "excessive dynamic airway collapse" (EDAC), although distinguishing or grouping this entity with TBM becomes a matter of semantics. On the other hand, finding localized, anterior chondromalacia causing crescent-shaped TBM can have very different therapeutic implications (Video 33-2). On the basis of these bronchoscopic determinations, the choice of performing an open surgical approach or bronchoscopic therapeutic intervention may be made.

Bronchoscopic examination generally permits evaluation and localization of congenital or postsurgical pathologic changes in bronchial integrity, such as tracheoesophageal or bronchopleural fistulas. Bronchoscopic observation and early diagnosis of bronchial rupture after chest trauma also greatly influence further therapy and prognosis. The same is true for evaluation of anastomoses following reconstructive surgery or lung transplantation.

Evaluation of Tracheobronchial Mucosa

Careful examination of the mucosal surface is crucial in the formulation of differential diagnosis. Rapid development of granulation tissue is frequently associated with reaction to a foreign body. Inflammatory mucosal reactions, although not very characteristic, should raise the possibility of mycobacterial infection, nonspecific viral and nonviral infections, and other granulomatous diseases, such as sarcoidosis.

The distinction between normal, pale-pink mucosa and hypervascular areas in the tracheobronchial tree may provide important diagnostic clues. Most frequently, changes in mucosal coloration are associated with an inflammatory reaction due to bronchitis. These findings are, however, very distinct from small hemangiomas or vascular distentions due to compression by enlarged, neoplastic lymph nodes. Similarly, a network of small mucosal lymphatics may be visible, with lymphatic interruption due to surgery, radiation therapy, fibrosis, or malignancy. This is most frequently associated with local edema, which contributes to airflow obstruction. In addition, distinct and characteristic mucosal discoloration can be observed in Kaposi's sarcoma or in airway metastases from melanoma.[30–32]

Ulcerations of the mucosa are more characteristic of polyangiitis (formerly known as Wegener's granulomatosis) or malignancy. Loss of the usual mucosal luster and presence of a roughened surface may alert the expert bronchoscopist to an early infiltrative or neoplastic process. Previously sustained injuries are characterized by the formation of mucosal and submucosal fibrosis, resulting in airway retraction or distortion.

Autofluorescence bronchoscopy (AFB) permits observation and analysis of tracheobronchial mucosal surfaces using the discriminant characteristic of tissue autofluorescence (Video 33-3). With the use of a monochromatic light source, computer-controlled image analysis, and a sophisticated camera attached to a fiberoptic bronchoscope, the airways can be examined for varying degrees of autofluorescence as an indicator of early-stage malignant changes. The acquisition of images is obtained in real time and helps in the detection of minute areas of change in normal tracheobronchial mucosal fluorescence. Biopsies from areas of abnormal fluorescence increase the rate of detection of small, premalignant (dysplasia) or early malignant (carcinoma in situ) lesions in the tracheobronchial tree.

Video 33-3 White light and autofluorescence bronchoscopy (AFB) demonstrating a focal airway lesion at the carina between the lingua and superior branch of the left upper lobe superior. The lesion demonstrates abnormal autofluorescence, manifested by a brownish color on AFB. The remainder of the airway examination demonstrates normal green fluorescence. *Video available on AccessMedicine.com.*

Although AFB may provide the ability to localize these early lesions with greater sensitivity than white light bronchoscopy (WLB),[33–36] longitudinal studies demonstrate that only 0% to 9% of moderate dysplastic foci and 0% to 32% of severe dysplastic foci progress to CIS or invasive cancer;[37–39] 60% to 65% of moderate or severe dysplastic lesions regress or resolve spontaneously.[37] The uncertainty of the natural history of central airway dysplastic lesions and the increasing incidence of peripheral adenocarcinomas not accessible to bronchoscopic visualization have likely contributed to the lack of benefit observed when evaluating AFB as a screening tool, even in high-risk populations.[40]

Narrow-band imaging (NBI) uses a unique filter to select light wavelengths that preferentially are absorbed by hemoglobin, thereby permitting superior microvasculature detection. Because angiogenesis occurs preferentially in dysplastic and neoplastic lesions, NBI may identify early dysplastic lesions better than WLB or AFB. Early studies with NBI in high-risk patients demonstrated its ability to detect lesions that could not be visualized by WLB, with a similar sensitivity to AFB.[41,42] A comparison of WLB, AFB, and NBI in the same patients who presented for airway surveillance revealed similar sensitivity for AFB and NBI, but improved specificity with NBI for detecting abnormal lesions.[41] Although current clinical applications for AFB and NBI are limited, they may play a role in future risk stratification, prognostication, or chemoprevention trials in high-risk patients.

Another promising technique, optical coherence tomography (OCT), is analogous to ultrasound imaging except that infrared light waves, rather than acoustic waves, are used.[43–49] By using light instead of sound waves, OCT overcomes the major limitations of ultrasound in the lung: the inability to image through air and poor spatial resolution. At present, OCT can resolve structures as small as 3 μm, rendering this imaging technique superior to conventional CT or magnetic resonance imaging for detecting microscopic airway abnormalities (Fig. 33-6). The ability to acquire such precise views in real time may aid in the diagnosis of malignancy and interstitial lung disease in the near future.[50–52] A similar modality, confocal laser endomicroscopy (CLE), is based on confocal microscopy which allows thin section imaging via use of a fiberoptic miniprobe that can be introduced through a flexible bronchoscope. This technology does not rely on light reflectance as in OCT, but rather cellular and tissue autofluorescence upon laser excitation. This technique may offer the possibility of an "optical biopsy" of peripheral lung lesions or lymph nodes at the cellular level, with a resolution up to 3.5 μm, with a 240-μm maximum depth and 600-μm field of view (Video 33-4).[53]

Evaluation of Peribronchial Structures

The trachea and bronchi are surrounded by mediastinal and parenchymal structures. Developmental or pathologic changes in these organs may be noted during bronchoscopic evaluation. An enlarged goiter or thymus may compress upper airways, resulting in airflow obstruction. Lymphadenopathy may produce structural changes, including widening of the carina due to subcarinal involvement and compression of other bronchi—as, for example, in the right-middle-lobe syndrome. Calcification of peribronchial lymph nodes

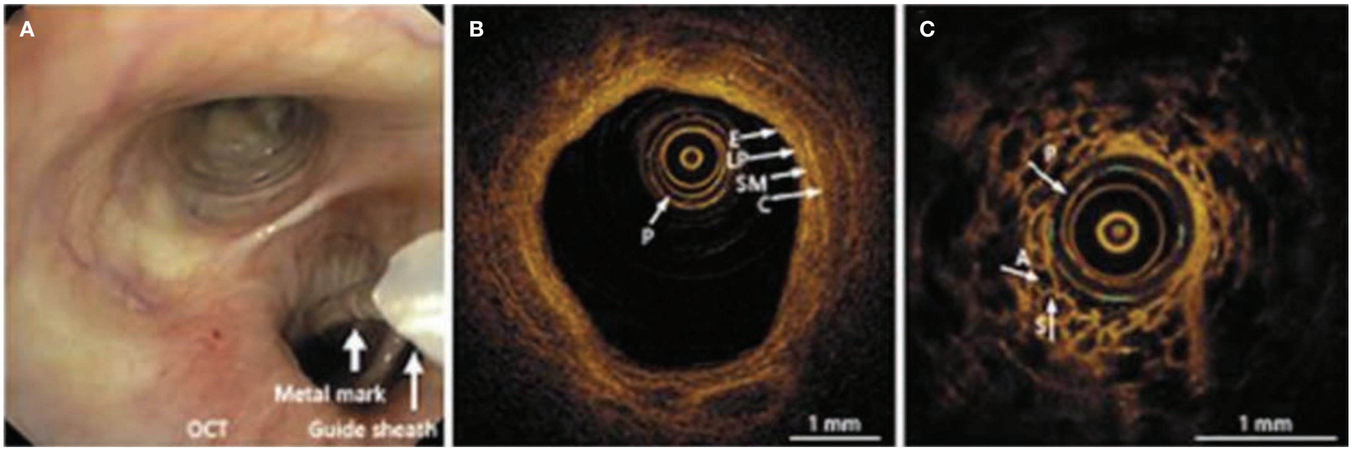

Figure 33-6 OCT imaging procedures of the airway wall and alveolar compartment. **A.** Bronchoscopic view of an OCT imaging procedure showing the guide sheath and the OCT catheter positioned in the right lower lobe. The metal mark guides the distance of 5.4 cm to the distal tip of the OCT catheter. **B.** OCT image of a normal segmental airway wall showing the airway wall layer identification. **C.** OCT image of the alveolar compartment showing normal alveoli and septae. *(Reproduced with permission from Goorsenberg A, Kalverda KA, Annema J, et al. Advances in optical coherence tomography and confocal laser endomicroscopy in pulmonary diseases. Respiration. 2020;99(3):190–205.)*

may result in erosion of the bronchial wall and formation of a broncholith. These lesions are potential sources of obstruction, infection, hemoptysis, or lithoptysis.

Development of the techniques of standard TBNA and EBUS-TBNA provide diagnostic options for the evaluation of peribronchial structures that pose much less risk and a lower complication rate than mediastinoscopy; in addition, they are less costly.[54]

Performance of Bronchial and Parenchymal Biopsies

Improvements in bronchoscopic instrumentation since the days of Chevalier Jackson have permitted performance of endobronchial biopsies, as well as biopsy of peripheral lung lesions. Knowledge of the underlying disease process has a significant influence on the choice of specific diagnostic procedures and risk of complications. In the case of diffuse lung diseases, such as sarcoidosis, use of fluoroscopy has not been demonstrated to improve the diagnostic yield of transbronchial biopsies. Fluoroscopy is useful, however, in providing information regarding the proximity of the forceps to the pleura and in more rapidly establishing the diagnosis of complications (e.g., pneumothorax).

Bronchoscopically visible lesions are generally biopsied with minimal risk; if bleeding occurs, it can usually be controlled easily (Fig. 33-6). The diagnostic yield of bronchoscopy for focal peripheral lesions depends on several factors, including lesion size, its location in the lung, and the relationship between the lesion and bronchus. The presence of a bronchus sign on chest CT predicts a much higher yield of bronchoscopy for peripheral lung lesions. In these cases, fluoroscopy is beneficial to assure proper positioning of the cytology brush, biopsy forceps, or needle. A promising approach with a number of recent innovations is the combination of radial EBUS, augmented fluoroscopy, and navigational bronchoscopy in evaluation of peripheral pulmonary nodules.

Video 33-4 This video demonstrates the findings on "alveoloscopy" using a confocal microscopy probe (Cellvizio, Mauna Kea Technologies, Paris, France). This thin probe is advanced into the distal lung parenchyma through the working channel of a flexible bronchoscope and can image auto-fluorescence of structures of the lung. In particularly, elastin in the alveolar wall is readily detected, and therefore allows for visualization of the architecture of the alveolus, including areas of breakdown in the alveolar wall as may be seen in emphysema. In addition, intra-alveolar macrophages emit significant auto-fluorescence and are therefore readily visualized with the Cellvizio probe. These are the cells seen to be mobile within the elastin-containing alveolar walls on the video. Type I and type II pneumocytes are not readily visualized with this technology. *Video available on AccessMedicine.com.*

The diagnosis of various infectious diseases can be established using a variety of transbronchoscopic sampling techniques. The role of bronchoscopic biopsy has been reaffirmed in immunocompromised hosts, in whom documentation of the precise pathogen is crucial for appropriate therapy. For example, while the presence of cytomegalovirus in bronchoalveolar lavage fluid may not be diagnostic, documentation of intracellular inclusion bodies on a transbronchoscopic biopsy specimen is practically pathognomonic.

Sampling of Airway and Alveolar Constituents

Bronchoscopy provides easy and relatively safe access to material in the tracheobronchial tree and distal alveolar spaces. A variety of studies are routinely performed on specimens obtained from the airways and alveolar spaces using several techniques. For example, aspirated secretions can be sent for microscopy and culture to determine the offending organism in cases of infection or suspected infection. Cytologic analysis of bronchoscopically obtained materials can provide proof of malignancy. Following lung transplantation bronchoscopy plays an important role in the early diagnosis of rejection or infection in these immunocompromised subjects. The most commonly employed bronchoscopic techniques for sampling the airways and alveolar spaces include bronchial wash, bronchial brush (see above), transbronchial forceps biopsy, and bronchoalveolar lavage.

Bronchoalveolar Lavage

Bronchoalveolar lavage (BAL) is commonly performed during bronchoscopy, allowing for the collection of the alveolar milieu for further analysis of its composition.[55,56] BAL is safe, even in critically ill patients, when biopsy or brushings may be contraindicated because of the risk of complications such as pneumothorax or bleeding. Normal saline solution, devoid of any bacteriostatic material, is instilled into distal airspaces through the "wedged" bronchoscope and then aspirated through the instrument's suction channel (Fig. 33-7). The fluid collected in this manner is analyzed for gross appearance to detect

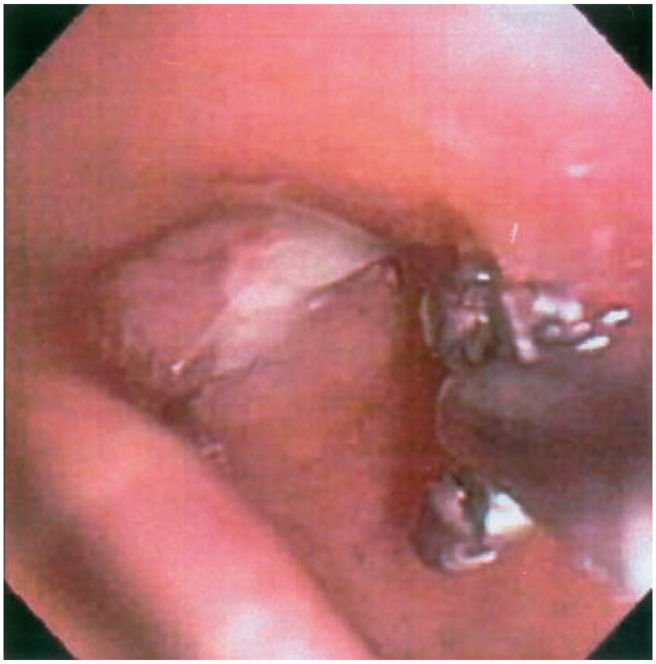

Figure 33-7 "Hot" forceps biopsy of a vascular endobronchial lesion. Use of the electrocautery forceps allows for safe, hemostatic biopsy of friable or vascularized endobronchial lesions (such as bronchial carcinoid), while obtaining pathologically interpretable tissue biopsy specimens.

possible alveolar hemorrhage. The fluid may also be subjected to a variety of tests, depending on the clinical circumstances: microbiologic testing, specific cytologic analysis and cell count, immunologic parameters, presence of various biochemical mediators related to pathologic processes, tissue markers, polymerase chain reaction, electron microscopy, flow cytometry, and DNA probes. Overall, the diagnostic yield of BAL is very much dependent on specific patient characteristics, underlying pathologic process, and many technical factors.

INDICATIONS FOR DIAGNOSTIC BRONCHOSCOPY

Although there are several indications for diagnostic bronchoscopy (Table 33-1), evaluation of a lung nodule or mass and mediastinal staging of a lung cancer are the most common. Sampling a suspected lung cancer now includes the goal of obtaining enough tissue to perform several laboratory assays aimed at immunohistochemical characterization, driver-mutation analysis, and assessment of the immune microenvironment. There are many other potential indications, some of which are discussed below.[57]

Bronchogenic Carcinoma

Bronchoscopy plays a central role in the evaluation of lung masses and nodules, including those suspicious for bronchogenic carcinoma. Centrally located lesions generally may be approached using flexible bronchoscopy with minimal risk. Bronchogenic carcinoma of the central airways may manifest as exophytic mass lesions with partial or total bronchial lumen occlusion, as peribronchial tumors with extrinsic compression of the airway, with submucosal tumor infiltration, or with some combination of these entities. The mucosal abnormalities seen with peribronchial tumors or with submucosal infiltration often are subtle—the airways should be examined closely for characteristic changes such as erythema, loss of bronchial markings, and nodularity of the mucosal surface.

TABLE 33-1 Indications for Diagnostic Flexible Bronchoscopy

Signs and symptoms
Hemoptysis
Stridor
Unilateral wheezing
Hoarseness
Unexplained chronic cough
Infections
Pneumonia in immunocompromised host
Nonresolving pneumonia
Cavitary lesion
Diffuse lung disease
Interstitial lung disease
Diffuse alveolar damage and hemorrhage
Drug-induced lung disease
Malignancy
Lung nodule or mass
Endobronchial tumor
Suspected airway invasion by adjacent malignancies (e.g., esophagus, thyroid)
Early detection (positive sputum cytology/negative CT scan)
Mediastinal or hilar lymphadenopathy or mass
Mediastinal staging or restaging
Other airway disorders
Mucus plugging
Foreign body aspiration
Benign airway stricture (e.g., idiopathic, granulomatosis with polyangiitis [formerly known as Wegener's granulomatosis], sarcoidosis, tuberculosis)
Intensive care
Bronchoscopy-guided intubation (difficult airway)
Endotracheal tube position
Miscellaneous
Lung transplant
Bronchopleural fistula
Aerodigestive fistula
Chest trauma
Chemical/thermal injury of airways
Preoperative and postoperative for lung resection surgery

Reproduced with permission from Casal RF, Ost DE, Eapen GA. Flexible bronchoscopy. Clin Chest Med. 2013;34(3):341–352.

Central lesions are usually sampled using a combination of bronchial washes, bronchial brushings, and endobronchial biopsies. The yield of bronchoscopy is highest for endoscopically visible lesions, with a diagnostic yield of approximately 90%.[58] Yield can be optimized further by utilizing the cryoprobe to perform endobronchial biopsies, albeit with an increased risk of bleeding.[59] Attempts should be made to obtain biopsy specimens from areas of the lesion that seem viable. Endobronchial needle aspiration (EBNA) to obtain a "core" biopsy from centrally located tumors can be considered, particularly if the lesion appears necrotic (Video 33-5). For submucosal lesions or peribronchial disease causing extrinsic compression, EBUS-TBNA can be performed with real-time ultrasound

Video 33-5 Demonstrated in this video is the utilization of a standard 22-gauge Wang transbronchial needle aspiration needle (MW-122, ConMed, Utica, NY) for sampling of a partially necrotic endobronchial lesion in the right main stem bronchus. The advantages of bronchoscopic needle aspiration of endobronchial lesions include decreased bleeding risk compared to endobronchial biopsy or brushing; facilitation of sampling of material from the center of the lesion avoiding necrotic surface; and the ability to obtain real-time feedback through rapid on-site evaluation (ROSE) of aspirates by cytopathology. *Video available on AccessMedicine.com.*

guidance. For these indications, EBNA and EBUS-TBNA have been shown to increase the diagnostic yield over conventional sampling methods.

■ Evaluation of Peripheral Lesions and Pulmonary Nodules

The evaluation of peripheral lesions or nodules remains a common dilemma for chest physicians. A balance between pretest probability of a specific diagnosis and the complication risk associated with a biopsy method must be assessed.[60] Surgical biopsy offers a superior yield at the cost of increased morbidity. Transthoracic needle biopsy has a high yield, but it carries a 15% to 25% risk of pneumothorax.[61–63] Although bronchoscopy has the advantage of a low complication risk, it has been hampered by a significantly lower diagnostic yield than these other modalities.

The yield of flexible bronchoscopy for peripheral pulmonary lesions, defined as lesions that are not visible beyond the segmental bronchi, is significantly lower than for central lesions. Historically, in patients with high probability of malignancy, the sensitivity of standard bronchoscopy for peripheral lung malignancies has been reported to range from 35% to 88% based on studies that used a combination of transbronchial biopsy, cytology brush, BAL, and TBNA.[64–80] Recent evidence suggests that the diagnostic yield of standard bronchoscopy (without the use of navigational techniques) for peripheral lesions is under 50% overall, and only 14% in patients with screen-detected nodules.[81] Given this poor performance, conventional bronchoscopy should not be performed in the evaluation of small, peripheral pulmonary nodules.[61,76]

Much effort has been dedicated to further refining our understanding of the diagnostic performance of bronchoscopy for smaller peripheral lesions as technology has advanced. Success depends on several factors, including lesion size, location, prevalence of malignancy in the population being studied, distance from the proximal airways, and the presence of a bronchus sign. The bronchus sign on CT may reflect the relationship of a tumor with the airway and has been categorized into four patterns by Tsuboi:[82] (1) type I, in which the bronchial lumen is patent up to the tumor; (2) type II, in which the bronchus is contained in the tumor mass; (3) type III, in which the bronchus is compressed, narrowed, and displaced by the tumor, but the bronchial mucosa is intact; and (4) type IV, in which the proximal bronchus is narrowed by the submucosal and peribronchial spread of tumor or by enlarged lymph nodes (Fig. 33-8). Transbronchial biopsy has the lowest diagnostic yield for lesions with a type III or IV tumor–bronchus pattern. In these cases, the use of peripheral TBNA may improve the overall diagnostic yield of bronchoscopy.

The use of guided bronchoscopic approaches (e.g., navigational bronchoscopy, robotic bronchoscopy, UM-EBUS, or ultrathin bronchoscopy) has allowed pulmonologists to attempt sampling of much more challenging nodules and significantly improved the diagnostic yield of small, peripheral pulmonary lesions. In a randomized comparison of traditional, fluoroscopically guided transbronchial biopsies (TBB) versus UM-EBUS–guided TBB, no statistical difference was found in establishing a diagnosis for lesions greater than 3 cm; however, for lesions smaller than 3 cm, and for lesions smaller than 2 cm, the sensitivity of EBUS-guided TBB remained at 75% and 71%, whereas that of standard TBB fell dramatically to 31% and 23%, respectively.[83] Similar improvements also have been reported repeatedly with the use of EMB- or VB-based systems for peripheral pulmonary lesions in single-arm, descriptive studies. The early experience with robotic bronchoscopy and augmented fluoroscopy systems also results in similar yields.[5,84]

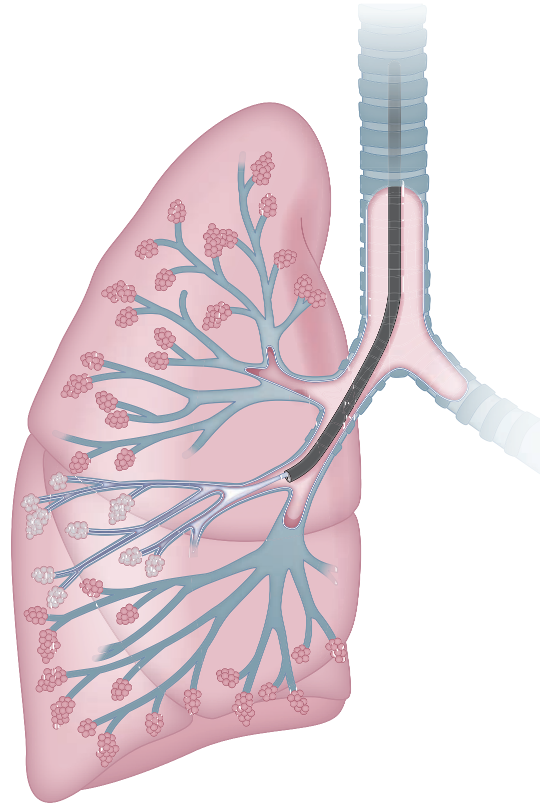

Figure 33-8 Bronchoalveolar lavage is performed by wedging the tip of bronchoscope in the segmental bronchus of interest. Normal saline is instilled into the distal airspaces, and then collected by suctioning back into a sterile container.

A recent meta-analysis of 30 studies with >3000 nodules reported a combined diagnostic yield of 70% for all available guided bronchoscopic techniques.[85] The diagnostic yield was influenced by the size of the primary lesion, with a yield of 61% for lesions <2 cm and 82% for lesions >2 cm.[85] Several other factors also impact the likelihood of obtaining diagnostic tissue using guided bronchoscopy: ability to place UM-EBUS probe completely within a lesion (as opposed to adjacent to it), presence of a bronchus sign on CT scan, location in the middle lobe or lingula, and distance from the visceral pleura.[86–89] The use of TBNA in addition to conventional diagnostic procedures (TBB and BAL) in UM-EBUS-localized lesions also significantly improves diagnostic yield.[11,90]

The evidence on guided bronchoscopy is largely composed of observational studies that provided limited guidance due to bias regarding both modality choice and determination of overall diagnostic yield. Although it is now clear that guided approaches overall are better than conventional bronchoscopy for smaller lesions, only a few comparative studies have been performed that provide evidence on the selection of a particular modality. In one randomized study of EMB alone, UM-EBUS alone, or EMB followed by confirmatory UM-EBUS, there was a significantly higher yield with the combined approach (combination, 88%; UM-EBUS, 69%; EMN, 59%),[91] suggesting that the highest yield

Video 33-6 This video demonstrates use of a 22-guage EBUS-TBNA aspiration needle (Olympus, Center Valley, PA) to sample a left hilar node. The convex probe-EBUS scope is used to identify the left hilar node, allowing visualization of the TBNA needle entering the node in real time. *Video available on AccessMedicine.com.*

may come from combining complementary diagnostic modalities. Similarly, a randomized study combining fluoroscopy, UM-EBUS, and VB with either a thin bronchoscope or ultrathin bronchoscope found benefit in using the ultrathin bronchoscope (70.1% vs. 58.7%).[92] However, a recent randomized study comparing ultrathin bronchoscopy with and without VB did not demonstrate any significant difference in the overall diagnostic yield (67% vs. 60%).[93] Furthermore, another recent randomized trial comparing standard bronchoscopy with fluoroscopy alone to the combination of a thin bronchoscope with fluoroscopy and UM-EBUS also failed to demonstrate a significant difference in diagnostic yield (37% vs. 49%).[94] Further studies are needed to define the utility and specific indications for combination approaches for the sampling of peripheral lung lesions aimed at minimizing bias and maximizing generalizability.[95]

Staging

Bronchoscopy is an important modality for establishing cancer stage. In patients with potentially resectable tumors, a thorough airway examination helps confirm the absence of a concomitant, radiographically occult lesion. For lesions that involve the central airways, it is important to document the extent of disease and the degree of involvement of the mainstem bronchi and main carina.

The use of CP-EBUS allows for real-time visualization and TBNA of hilar and mediastinal lymph nodes or tumors adjacent to the central airway (Video 33-6). Sampling of lymph nodes with EBUS-TBNA is now commonly performed for staging purposes in patients with lung cancer. This technique frequently allows the establishment of both diagnosis and nodal stage, obviating the need for, and avoiding the risks associated with, sampling of the primary parenchymal lesion. TBNA has proved particularly useful with the employment of rapid on-site evaluation (ROSE), in which a cytopathologist present in or near the bronchoscopy suite can evaluate specimens in real-time. Such precise sampling of tumor-draining lymph nodes, or a primary tumor, has led to the exploration of CP-EBUS to facilitate local delivery of cancer therapy.[96]

In general, patients with lung cancer may be separated into four categories with respect to intrathoracic radiographic characteristics, as suggested by the published guidelines on lung cancer staging (Fig. 33-9).[97] In radiographic pattern A, mediastinal infiltration is extensive, with encircling of vessels and airways. In this case, the risk of malignant involvement can be assumed, and biopsy to establish diagnosis should be performed by the safest method available for that particular case. In pattern B, there is discrete lymph node enlargement that can be measured by CT, which may also be FDG-avid. In this case, sampling is recommended, as the likelihood of mediastinal involvement is high and requires confirmation. In radiographic pattern C, the presence of a central tumor or suspected N1 disease makes the likelihood of mediastinal node involvement relatively high (20%–25%), necessitating invasive sampling. In the final group (i.e., those with a peripheral clinical stage I tumor), the chance of either distant metastases or mediastinal involvement is quite low (radiographic group D), especially if the mediastinum is also normal by PET scan.

Some patients with probable early-stage lung cancer may be poor surgical candidates due to inadequate pulmonary function or a high comorbidity burden. In this setting, local treatment approaches most commonly employ include stereotactic ablative radiotherapy (SABR) and radiofrequency ablation (RFA). For patients that will receive nonsurgical therapy, identification of occult lymph node metastases can lead to alterations in the treatment plan. The decision to pursue invasive mediastinal staging should be considered on an individual case basis. Clinical prediction tools may potentially inform the likelihood of mediastinal and hilar node involvement.[98]

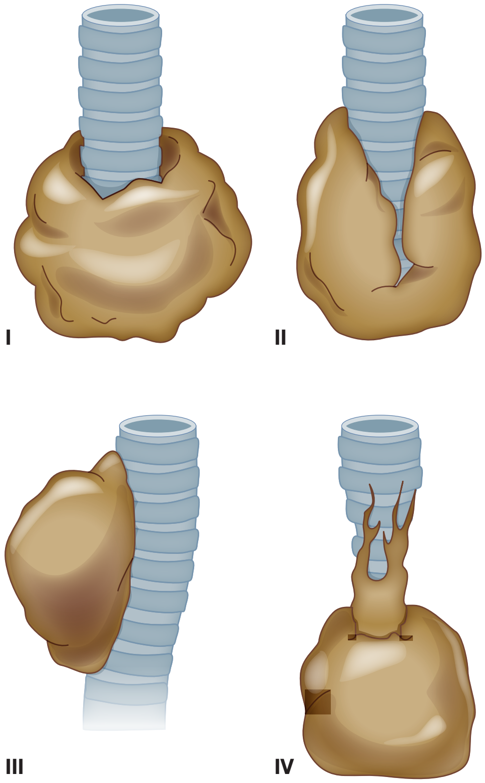

Figure 33-9 Tsuboi classification of tumor-bronchus relationship.

Several systematic reviews have confirmed that the sensitivity of EBUS-TBNA is equivalent to that of mediastinoscopy.[97,99–101] A recent randomized study of 241 patients with potentially resectable NSCLC compared mediastinoscopy alone to a combined approach of EBUS-TBNA and EUS-FNA, followed by surgical staging if the needle technique did not identify nodal metastases.[102] The needle approach followed by mediastinoscopy had significantly greater sensitivity (94%) compared with the other approaches and resulted in fewer unnecessary thoracotomies. One limitation to this approach has been the difficulty in many centers to operationalize a combined EBUS-TBNA and endoscopic (EUS)-FNA procedure. Interestingly, recent studies have shown that the EBUS-TBNA scope can be used through both the airway and the esophagus, resulting in similar results.[103,104] The aforementioned guidelines now recommend that a needle approach should be used first when performing mediastinal staging. Some authors have studied the routine use of EBUS-TBNA performed on radiographic group D patients showing the ability to detect occult metastases.[105] Interpreting a negative EBUS-TBNA should be done with caution as the negative predictive value does fluctuate tremendously based on the pre-test probability. Prediction models may aid decision-making when considering surgical staging methods.[98]

Evaluation of Hemoptysis

One of the most frequent indications for bronchoscopy is hemoptysis. Bronchoscopic evaluation may be of help in determining the precise location and source of bleeding. The choice of instrument (rigid vs. flexible scope) and timing of the procedure are dictated by clinical circumstances.[106] Studies have shown that active bleeding and its site are visualized more commonly with early bronchoscopy (within 48 hours) than with more delayed examination.[106–108] In the case of a normal chest radiograph and hemoptysis, trace signs of bleeding are commonly seen, but not the site of origin.[109] In these circumstances, examination using an ultrathin flexible instrument may be beneficial in identifying the source of bleeding in a peripheral airway once the more proximal airways have been cleared of blood by a therapeutic scope. In some instances, bronchoscopy is useful not only as a diagnostic method, but also to perform therapeutic maneuvers.

Pulmonary Infections

Bronchoscopy is a useful technique in the diagnosis of pulmonary infections, allowing for the collection of respiratory samples for evaluation with special stains and culture. Several common clinical areas in which bronchoscopy may play an important diagnostic role are described below.

Pneumonia

In general, bronchoscopy is not indicated for the diagnosis of community-acquired pneumonia, which is usually treated empirically with appropriate antibiotic therapy; however, bronchoscopy is likely to be useful and should be considered in cases of non-resolving pneumonia,[110,111] defined as a lack of improvement or worsening of symptoms despite a minimum of 10 days of antibiotic therapy or failure of radiographic abnormalities to resolve after 2 to 3 months. The causes of non-resolving pneumonia are myriad and include inadequate antibiotic therapy, resistant or highly virulent organisms, impaired host defenses, obstructing endobronchial lesions, or a noninfectious cause.

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is defined as a pneumonia occurring more than 48 h after intubation and initiation of mechanical ventilation.[112,113] VAP is usually suspected when an intubated, mechanically ventilated patient has signs of infection and an abnormal chest radiograph (Chapter 129). Intubated patients experience colonization of their upper and lower airways with nosocomial organisms; because of an abnormal mucociliary clearance mechanism, these patients are at greater risk for developing pulmonary infections. In addition, mechanically ventilated patients are often treated empirically with broad-spectrum antibiotics and, therefore, are at greater risk for infection with resistant organisms and unusual lower respiratory tract pathogens. Guidelines support the use of either a quantitative or semiquantitative strategy in the diagnosis of VAP.[112]

Quantitative sampling can be performed using endotracheal aspirates, or BAL or protected specimen brush (PSB) collected with or without a bronchoscope.[112,114] Quantitative BAL entails the performance of a standardized BAL, with infusion of at least 120 mL of saline for adequate sampling of a pulmonary subsegment. Quantitative culture of the aspirated material is performed to determine the number of colony-forming units (CFU) recovered. PSB uses a double-catheter system in which an outer cannula and distal, biodegradable plug protect the bronchoscopic brush within the inner cannula from contamination with secretions in the upper airway and suction channel of the bronchoscope. When the bronchoscope is positioned proximal to the segmental orifice of interest, the PSB inner cannula is advanced into a subsegment and the protective distal plug ejected. The brush is then advanced peripherally, rotated gently, and retracted into the inner cannula. The inner cannula is subsequently retracted into the outer cannula and the bronchoscope removed from the airway. The distal portion of the catheter is cleaned with 70% alcohol and the brush clipped into saline solution under sterile conditions. The PSB is then submitted for quantitative bacterial culture within 15 min of performance of the procedure.

The threshold for diagnosis of VAP using PSB is 10^3 CFU per milliliter. PSB has higher specificity than sensitivity for the presence of VAP—a positive result greatly increases the likelihood that pneumonia is present. For quantitative BAL, a threshold of 10^4 or 10^3 CFU/mL is used for diagnosis of VAP.[115] The detection of VAP by quantitative BAL culture has a sensitivity of 40% to 90% and a specificity of 45% to 100%.[115] Because a larger proportion of lung parenchyma is sampled with BAL, this technique may be a better method than PSB for VAP diagnosis. However, samples contaminated by upper airway secretions (based on a high percentage of squamous epithelial cells) should be interpreted with caution. There are likely several factors that affect the diagnostic yield of the bronchoscopic methods, such as a change in antibiotics prior to sampling, inadequate technique in sampling, and lack of a gold standard for comparison.

Infections in Immunocompromised Patients

Pulmonary infections in immunocompromised patients constitute the most common complication in this population and represent an important contributor to mortality. Such infections are increasingly common, reflecting the expanding use of aggressive chemotherapeutic regimens and the ever-increasing number of solid organ and hematopoietic stem cell transplantations. The differential diagnosis of pulmonary infiltrates is broad in scope; however, most cases are caused by infectious agents, including bacterial, fungal, viral, and mycobacterial pathogens.[116] Bronchoscopy is the most commonly used diagnostic procedure in these patients and should be performed as early as possible, because a delay in diagnosis of longer than 5 days has been shown to significantly increase mortality.

The sensitivity of bronchoscopy varies, depending on the immunocompromised population studied and the specific etiologic disorder. In non–human immunodeficiency virus (HIV)-infected patients, the yield of BAL for *Pneumocystis jirovecii* pneumonia (PJP) is approximately 80%, compared with a greater than 90% yield observed in HIV-seropositive patients.[117,118] This difference is due to the much lower organism load present in HIV-negative subjects. Although empirical therapy often is initiated in patients suspected of having PJP infection, bronchoscopy should be performed in most cases to confirm the diagnosis. Bronchoscopic lung biopsy and BAL galactomannan testing may increase the diagnostic yield of BAL for diagnosis of PJP infection, particularly in the non–HIV-infected population.[117] Several PCR assays have been tested on BAL fluid, induced sputum, and oral wash specimens; these generally have been more sensitive, but less specific, than traditional microbiologic methods.

Bronchoscopy also has a high diagnostic yield for cytomegalovirus (CMV); however, because CMV cultures from BAL are not specific, the diagnosis of CMV pneumonia should be limited to patients with pathologic evidence of CMV infection demonstrated by the presence of CMV inclusion bodies on BAL or biopsy. Although bronchoscopy is also useful for the diagnosis of aspergillosis—the sensitivity is approximately 50%—the disease often is peripheral and patchy and, thus, is not easily diagnosed by BAL or bronchoscopic biopsy. Recent clinical practice guidelines now suggest the use of *Aspergillus* PCR in BAL when evaluating severely immunocompromised patients at risk for fungal pneumonia to increase the sensitivity.[119] Overall, in immunocompromised patients with infiltrates, the diagnostic yield of bronchoscopy varies from 30% to 80% and is impacted by factors such as the prevalence of an infectious etiology, timing of bronchoscopy, and use of prophylactic antibiotics.[120–127]

Mycobacterial Infections

In cases in which pulmonary tuberculosis is suspected, the initial diagnostic evaluation should consist of serial examination of sputum for the presence of acid-fast bacilli (AFB) in stained smears. Ideally, induced sputum samples should be obtained. If sputum study results are negative, or if the patient is unable to produce sputum and tuberculosis is still suspected, bronchoscopy with BAL and biopsy should be performed. The use of bronchoscopy allows for the opportunity to establish a rapid diagnosis (by positive smear or histopathology), providing the potential for earlier intervention and treatment while awaiting culture results. Bronchoscopy should be performed with appropriate infection control precautions to minimize the risk of nosocomial transmission. A bronchoscopy may cause the patient to produce sputum for several days afterwards; these specimens also should be collected and analyzed, if possible.

The utility of bronchoscopy in establishing a rapid diagnosis varies widely in the literature, with reported diagnostic yields of 30% to 70%, although the overall yield of culture is considerably higher.[128] One study has shown an improvement in diagnostic yield from 58% to 81% with use of UM-EBUS-guided biopsy and washings.[129] The yield in patients with miliary tuberculosis, in whom sputum smears frequently are negative, is approximately 70%. Bronchoscopy is also useful in tuberculosis manifesting as an endobronchial lesion or with mediastinal and hilar adenopathy, in which case diagnostic tissue may be obtained with TBNA.

Recently, nucleic acid probes have become an important component of the diagnostic armamentarium for mycobacterial disease. DNA probes can be used to rapidly speciate mycobacterium that starts to grow on culture, as is the case for *M. avium* complex and *M. kansasii*. Similarly, nucleic acid amplification and sequencing-based assays can be used on BAL samples to rapidly distinguish tuberculosis from nontuberculous mycobacterium (especially in smear-positive patients), detect drug resistance, and predict culture positivity in smear-negative samples. None of these assays replaces mycobacterial culture, as drug resistance requires confirmation on cultured organisms, and 20% to 50% of positive cultures will not be proceeded by a positive molecular test.[130]

Human Immunodeficiency Virus Syndrome

The introduction of highly active antiretroviral therapy (HAART) has resulted in a sharp decline in the incidence of opportunistic infections in HIV-infected patients. Nevertheless, infectious complications remain one of the most common indications for bronchoscopy in this population. PJP remains the most frequent serious opportunistic infection in HIV-seropositive patients. Bronchoscopy with BAL remains the preferred diagnostic procedure for this disease, although in select centers, use of sputum induction has had a relatively high diagnostic yield and may mitigate the need for bronchoscopy. As previously mentioned, bronchoscopic lung biopsy may increase the diagnostic yield of BAL.[117] Empirical therapy often is initiated in patients with suspected *Pneumocystis* infection; such therapy can impair the diagnostic yield of BAL if the procedure is not performed within 24 h. In patients receiving pentamidine prophylaxis, the diagnostic yield is decreased unless the upper lobes are sampled.[131–133]

Bronchoscopy also plays an important diagnostic role in HIV-positive patients with infections caused by mycobacteria, including tuberculosis, atypical bacterial pneumonias, and various fungal infections. Kaposi sarcoma, caused by human herpesvirus type 8 (HHV8), may be manifest as violaceous endobronchial plaques that typically occur at airway bifurcations; pulmonary parenchymal involvement is characterized by lymphangitic infiltration of tumor, leading to the development of nodules and masses.

■ Diffuse Lung Diseases

A wide range of acute and chronic pulmonary disorders can cause a diffuse interstitial lung disease pattern of injury. These processes include infection, neoplasm, pulmonary edema, alveolar hemorrhage, alveolar proteinosis, occupational lung diseases, drug-induced disease, and various types of idiopathic or collagen vascular disease–associated interstitial lung disease. The pattern of lung injury should first be evaluated using high-resolution chest CT imaging, which helps to narrow the differential diagnosis and, in some cases, is virtually diagnostic of certain disorders. In many cases, it is still necessary to obtain samples for cytologic and histologic evaluation to confirm a specific diagnosis and to help exclude other possible disorders.

The most common bronchoscopic procedures used to help establish the diagnosis in diffuse lung disease are BAL and TBB. The findings on high-resolution CT (HRCT) can be used to determine the best location for BAL or TBB. In truly diffuse disease, the right middle lobe and the lingula are the best locations for BAL; with these sites, ease of access and good fluid retrieval are typical. BAL should be performed using a total of 100 to 200 mL of saline instilled in multiple aliquots. It is important to obtain a reasonable sampling of the alveolar spaces for the necessary cellular analysis.

The value of BAL is well documented in the diagnosis of diffuse parenchymal diseases, and findings may be diagnostic in eosinophilic pneumonia, eosinophilic granuloma, and pulmonary alveolar proteinosis.[57] For example, in acute eosinophilic pneumonia the identification of more than 25% eosinophils on BAL is diagnostic in the appropriate clinical context.[134] In most other diffuse disorders, BAL findings are mostly supportive of a suspected diagnosis (Table 33-2) and help to rule out potential infectious etiologies. In disorders such as sarcoidosis (see below), hypersensitivity pneumonitis, and organizing pneumonia, the combination of BAL and bronchoscopic lung biopsy can often establish the diagnosis and avoid the need for surgical lung biopsy.

In patients with suspected pulmonary sarcoidosis without significant lymphadenopathy, the diagnosis usually is established by a combination of BAL and biopsy findings. BAL can be used to exclude the presence of tuberculosis and fungal infections and may demonstrate the characteristic high CD4+/CD8+ ratio seen in sarcoidosis, whereas bronchoscopic biopsy specimens may demonstrate the classic finding of non-caseating granulomas. In general, TBB should be performed in several affected areas, and at least five or six specimens should be taken. The sensitivity of TBB alone for diagnosis of sarcoidosis is only approximately 60% to 70%.[135–137] Yields may be improved with the additional of endobronchial biopsies, particular in patients with evidence of bronchial mucosal involvement, and with the use of nodal sampling with EBUS-TBNA, as this can provide diagnostic evidence of non-caseating granulomas in 80% to 90% of cases.[138–143] A recent randomized study showed endosonographic needle approaches to have a greater diagnostic yield when compared with bronchoscopic lung biopsy.[144] At present, the data suggest that all patients with suspected sarcoidosis should undergo EBUS-TBNA for lymph node sampling, but it is unclear if bronchoscopic biopsy should be performed in all cases, given the added risk of pneumothorax and hemorrhage. The presence of mediastinal and hilar adenopathy, with or without parenchymal lung changes, also raises the possibility of lymphoma. In cases where lymphoma is suspected, nodal sampling should include histologic samples using mini-forceps (as noted above) or core needle biopsy, and TBNA samples should be performed for evidence of clonal proliferation by flow cytometry.

Bronchoscopy has an evolving role in the diagnosis of idiopathic interstitial pneumonias (IIP), especially idiopathic pulmonary fibrosis (IPF).[145] A nonspecific increase in levels of neutrophils, eosinophils, and, less commonly, lymphocytes has been documented in BAL fluid. Histologic evidence of IPF generally requires documentation of pathologic changes consistent with usual interstitial pneumonia. This is often difficult with bronchoscopic biopsies, which are frequently limited by the small size of the specimen obtained and lack of histologic preservation because of mechanical crushing of the tissue.

TABLE 33-2 BAL Findings in Diffuse Lung Disease

Diffuse Lung Disease	Typical BAL Cellular Pattern	T Lymphocyte CD4/CD8 Ratio	Other Relevant BAL Findings
Sarcoidosis	↑ Total cell count ↑ Lymphocytes	↑	—
Hypersensitivity Pneumonitis	↑ Total cell count ↑ Lymphocytes	↓	Neutrophils can be increased with recent exposure to antigen
Chronic beryllium disease	↑ Total cell count ↑ Lymphocytes	↑	BAL lymphocyte proliferation with beryllium salts
Asbestosis	↑ Neutrophils	↑	Ferruginous bodies
Idiopathic pulmonary fibrosis	↑ Neutrophils ↓ Lymphocytes	—	—
Cryptogenic organizing pneumonia	↑ Neutrophils ↑ Lymphocytes	↓	Foamy macrophages
Pulmonary alveolar proteinosis	Variable	—	Milky fluid and foamy macrophages with PAS-positive material
Drug-induced lung disease	Variable	↓	Foamy macrophages with amiodarone exposure
Pulmonary Langerhans cell histiocytosis	↑ Total cell count Variable differential	—	CD1+ Langerhans cells
Eosinophilic pneumonia	↑↑ Eosinophils	—	Eosinophil counts greater in acute than in chronic pneumonia

Cryobiopsy may improve the yield of bronchoscopy in IIP, including IPF, as it allows for larger biopsy specimens with increased amounts of alveolated lung parenchyma. Two recent studies reported conflicting results on the concordance between cryobiopsy and surgical lung biopsy in paired samples performed on the same patient, in the same lobe, during the same procedure, with agreement rates of 38% and 71%.[146,147] These studies had key differences in trial design and outcome measures, leaving this clinical question unanswered until further evidence becomes available. While controversy remains over the exact role of cryobiopsy in the evaluation of IIP, many experts, particularly in Europe, have adopted this technique.[148] If the diagnosis of IPF is probable or definite on the basis of clinical and HRCT criteria, bronchoscopy (and surgical lung biopsy) is not required, but in cases where the HRCT findings are not atypical for IPF, bronchoscopy can be performed to evaluate for the presence of other potential etiologic disorders. If a specific diagnosis is not established based on BAL and TBB findings, cryobiopsy or surgical lung biopsy should be considered.

COMPLICATIONS OF BRONCHOSCOPY

Bronchoscopy is a potentially hazardous procedure. Complications are generally due to inappropriate preparation of patients before bronchoscopy, effects of local or general anesthesia, and manipulation of various instruments. Appropriate training and experience of the bronchoscopist and supporting team are crucial in reducing the rate of complications.

Any diagnostic or therapeutic manipulation should be considered in relation to the underlying condition of the patient, localization of the area of investigation, and other surrounding structures in the thorax. It is essential to develop good communication between the bronchoscopist and other members of the team. While the bronchoscopist concentrates on the field of work—which, as seen through the bronchoscope, is two-dimensional—other team members are responsible for monitoring the patient (oxygen saturation, blood pressure, heart rhythm, etc.) and checking and maintaining the adequacy of ancillary equipment (suction, oxygenation, and accessories such as forceps, balloons, catheters, and laser light guides). Risks are decreased if, for example, special attention is paid to the control of accessories during their manipulation beyond the tip of the bronchoscope. Premature deployment of the needle biopsy device or inappropriate bending of the bronchoscope while an instrument is inside the flexible portion can result in perforation of the bronchoscope. Activation of the laser with a broken light guide inside the bronchoscope, or inadequate protrusion of the tip of the fiber beyond the bronchoscope, may result in airway fires or severe burns to the patient. Attention to details and proper maintenance of the equipment, including accessories, enhance safety for the patient and staff. Diagnostic yield and therapeutic results also are improved. Overall, when bronchoscopy is performed by an experienced endoscopist, backed up by a well-trained team and appropriate facilities, mortality and morbidity are very low.

■ Anesthesia and Related Blood Gas Abnormalities

Approximately half of the life-threatening complications of diagnostic bronchoscopy are associated with the risk of topical anesthesia and sedation. Risk is significantly increased in the elderly, and in those with serious concomitant illnesses. Predisposing factors include cardiovascular disease, chronic pulmonary disease, renal and hepatic dysfunction, seizures, and altered mental status. Mild sedation, anxiolysis, muscular relaxation, and anterograde amnesia increase patient cooperation and permit quicker and less traumatic procedures. Doses of benzodiazepines, opiates, propofol, and topical anesthetics must be adjusted if there is underlying organ dysfunction. In the event of severe respiratory depression from excess sedation, flumazenil and naloxone may be administered to reverse the effects of benzodiazepines and narcotics.

Inadequate topical anesthesia potentiates coughing, gagging, and patient discomfort and increases the risk of injury during bronchoscopy. However, topical anesthetics such as lidocaine, the most frequently used agent, are absorbed systemically through the respiratory mucosa, increasing the risk of cardiac or central nervous system toxicity. Although rare, these complications are more likely to occur in patients with underlying low cardiac output, hepatic dysfunction, and oropharyngeal candidiasis.

Another, less frequent complication of excessive lidocaine use is methemoglobinemia and resultant tissue hypoxia. This condition should be suspected when cyanosis occurs following the procedure, in combination with low oxygen saturation, but a higher-than-expected PaO_2 for the degree of cyanosis, and low oxygen saturation. Sampling of arterial blood reveals chocolate-brown blood. Methemoglobinemia occurs because lidocaine causes the rate of hemoglobin oxidation to exceed the reductive capacity of erythrocytes, leading to accumulation of methemoglobin. The diagnosis of this disorder may be made using co-oximetry. Methylene blue (1–2 mg/kg body weight) should be administered to symptomatic patients or when methemoglobin levels exceed 30%.

Introduction of the bronchoscope under general anesthesia or under conscious sedation with topical anesthesia frequently results in a decrease in oxygenation and in hypoventilation, with demonstrable increases in $PaCO_2$. The mechanisms responsible for hypoxemia include acute upper-airway obstruction, hypoventilation, and ventilation–perfusion mismatching. In patients with underlying chronic lung disease, severe hypoxemia may occur, triggering life-threatening cardiac arrhythmias. Skillful manipulation of rigid and flexible bronchoscopes reduces the risk of injury to the upper airways, which can result in life-threatening laryngospasm during or after completion of the procedure. Caution must be exercised in patients with underlying bronchospastic disorders, superior vena cava syndrome, or history of angioedema.

All patients undergoing bronchoscopic procedures should be monitored continuously (electrocardiogram, blood pressure, O_2 saturation, and, if indicated, expiratory CO_2 concentration). Use of supplemental oxygen during the procedure should be routine. Bronchoscopy probably should not be performed in patients who are unable to maintain adequate oxygenation on full ventilator support with high levels of supplemental oxygen.

Significant oxygen desaturation may occur during BAL. The degree of desaturation is directly related to the duration of the procedure and the volume of lavage fluid used. Return to the pre-bronchoscopy oxygen saturation may be prolonged after removal of the bronchoscope, and supplemental O_2 should be continued throughout the procedure and during the post-bronchoscopy observation period.

■ Fever and Infection

Appearance of transient fever after bronchoscopy, reported in 5% to 30% of procedures, generally does not require any therapy. The incidence of fever is increased in the elderly, in those with underlying chronic pulmonary disease or documented endobronchial obstruction, and in those with bronchoscopic interventions for malignancy. The incidence of fever and extension of pulmonary infiltrates increases with the volume of BAL fluid and the total number of pulmonary segments lavaged. In most cases, these complications resolve spontaneously within 24 h. However, persistent fever in the setting of progressive radiographic infiltrates suggests post-procedure pneumonia and necessitates antibiotic therapy. The incidence of post-bronchoscopic infections is higher in immunocompromised hosts and those with chronic suppurative lung disease (e.g., cystic fibrosis). There have also been reports of purulent pericarditis and mediastinitis following TBNA of mediastinal nodes or masses.[149,150]

In high-risk cardiac patients, including those with prosthetic valves, prior endocarditis, complicated cyanotic heart disease, or surgically constructed systemic-pulmonary shunts, American Heart Association guidelines indicate that prophylactic antibiotics are optional prior to flexible bronchoscopy.

■ Pneumothorax

Most of the serious complications related to diagnostic bronchoscopy have been reported in association with performance of transbronchial biopsies. Pneumothorax following transbronchial biopsy occurs in 4% to 5% of cases (Fig. 33-10), although a recent population-based study suggested pneumothorax rates of approximately 1%.[151–160] The impact of fluoroscopy on the incidence of pneumothorax remains controversial. Uncontrolled studies have not found a difference in the incidence of pneumothorax following transbronchial biopsy when performed with and without fluoroscopy.[161]

The risk of pneumothorax is not related to the size of the bronchoscopic biopsy forceps. The incidence of pneumothorax is increased, however, in immunocompromised hosts. This is likely due to the increased risk of pneumothorax associated with PJP. The risk is also elevated in mechanically ventilated patients, with peripheral lung biopsies, and in the presence of bullous lung disease. In rare cases, the development of pneumothorax can be delayed, with patients developing the complication after discharge. In case of a significant pneumothorax, a chest tube should be inserted immediately to avoid oxygen desaturation or tension physiology.

■ Hemorrhage

Clinically significant bleeding as a consequence of diagnostic bronchoscopy is reported to occur in 1% to 4% of cases, but it is more likely to occur after transbronchial biopsy and brushings.[159,160,162,163] This is especially important to consider before transbronchial cryobiopsy, where bleeding should be anticipated and adherence to safety guidelines is key to maximizing patient safety.[164,165] Although hemorrhage may also occur from inadvertent perforation of pulmonary vessels during TBNA, this is a very rare complication. Bleeding is more common in patients with immunosuppressed state, thrombocytopenia, uremia, liver disease, pulmonary hypertension, concurrent anticoagulation, and in those on positive pressure ventilation.

The incidence of post-bronchoscopy hemorrhage in uremic patients is reported as high as 45%. Consequently, a blood urea nitrogen (BUN) level above 30 mg/dL or a creatinine level above 3 mg/dL should be considered relative contraindications to bronchoscopy. Transbronchial biopsy or brushing should not be performed if the platelet count is below 50,000/mm^3. Thrombocytopenic patients may receive platelet transfusions if biopsy is necessary. Similarly, coagulopathic patients should receive vitamin K, fresh frozen plasma, or cryoprecipitate prior to the procedure and biopsy.

Increasingly, patients referred for bronchoscopy are receiving antiplatelet therapy for management of underlying cardiovascular disorders and post-coronary interventions. Importantly, aspirin use has not been shown to increase hemorrhage risk, and it generally does not require discontinuation prior to diagnostic bronchoscopy.[166] In contrast, the risk of bleeding from P2Y2 inhibitors (e.g., clopidogrel) is very high following transbronchial biopsy.[167] If transbronchial biopsies are necessary, P2Y2 inhibitors should be discontinued 5 to 7 days prior to the procedure. We also recommend discontinuation prior to TBNA, although the risk of major bleeding is lower, and successful TBNA may be performed without discontinuation. In cases where antiplatelet therapy cannot be discontinued (e.g., recent coronary artery stenting), careful assessment of the goals of bronchoscopy should be considered and the need for transbronchial biopsy should be clearly defined.

TRANSTHORACIC NEEDLE BIOPSY

Transthoracic needle biopsy (TTNB) has proved a valuable diagnostic procedure in patients with a range of thoracic radiographic abnormalities.

■ Indications and Contraindications

TTNB was first used for the diagnosis of pulmonary disease in 1883, when Leyden performed the procedure on three patients with

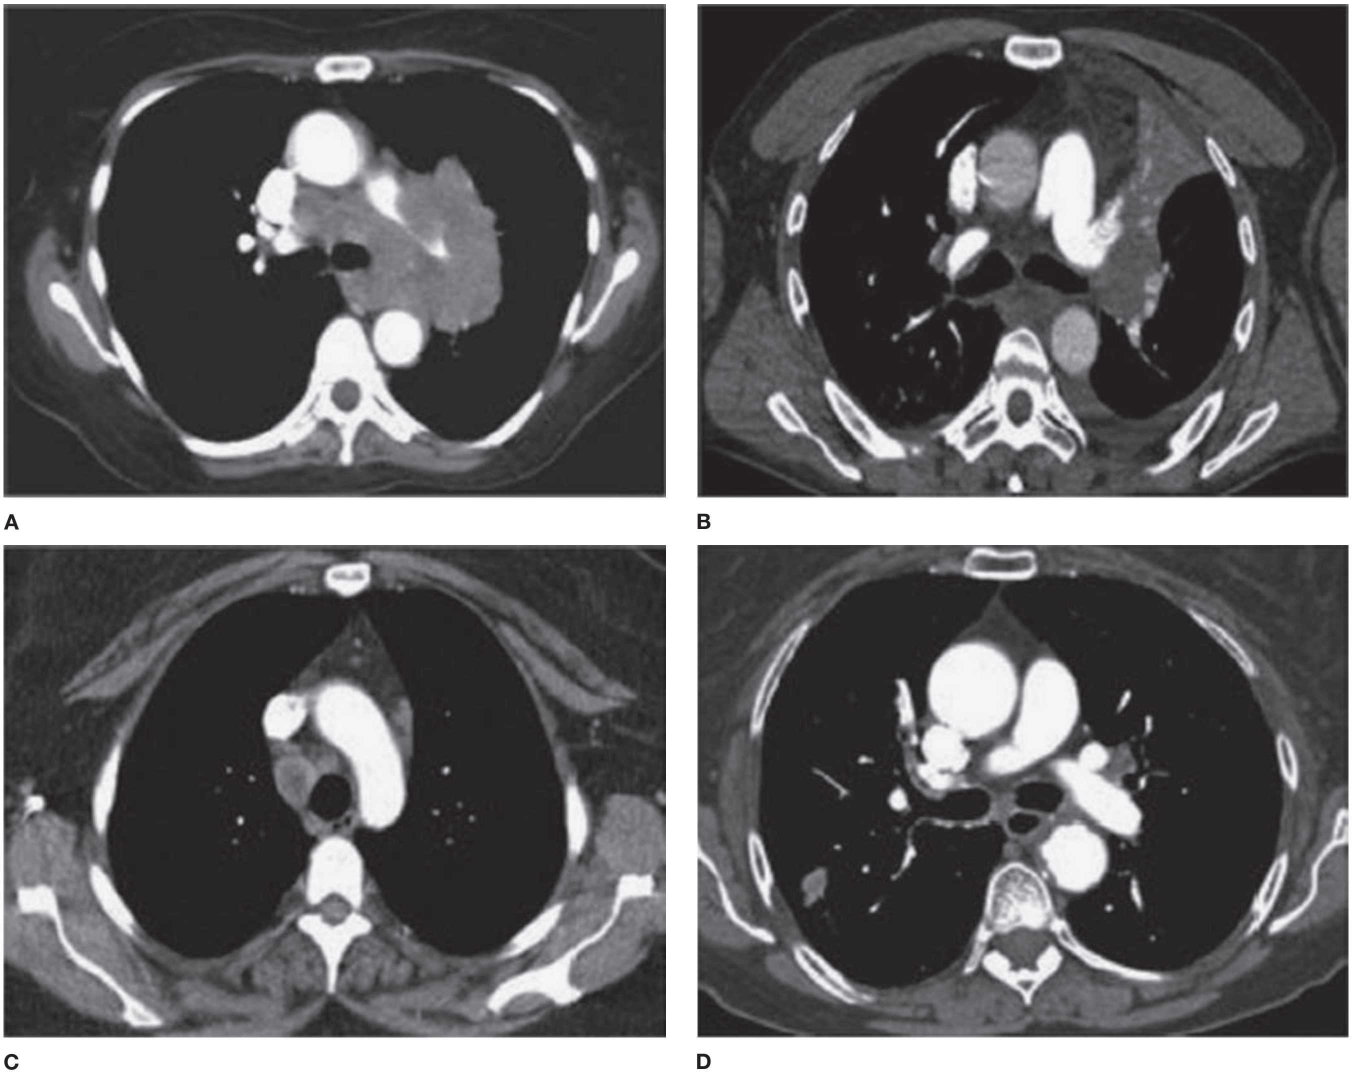

Figure 33-10 Intrathoracic radiographic (CT scan) categories of lung cancer from CHEST Guidelines. **A.** Mediastinal infiltration by tumor. **B.** Enlarged discrete N2,3 nodes. **C.** A central tumor or a tumor with enlarged N1 nodes, but a normal mediastinum. **D.** A peripheral small tumor (seen in lower left corner of image) with normal-sized lymph nodes.

pneumonia. Since that time, many published series have described the use of TTNB for the diagnosis of a variety of benign and malignant thoracic lesions.[168–177] The approach to biopsy may employ either an aspiration approach or an approach based on procuring histologic samples with use of cutting needles. The use of histologic samples provides improved diagnostic accuracy in lymphoma, both Hodgkin's and non-Hodgkin's varieties, in which anatomic structure is important in delineating the type of lymphoma and in distinguishing between clonal, neoplastic processes and inflammatory conglomerations of lymphocytes. Histologic specimens may also improve the yield in the diagnosis of pulmonary hamartomas, characterized by the presence of cartilage or adipose tissue.

The major indications for TTNB include evaluation of solitary lung nodules and masses (Fig. 33-11), mediastinal and hilar lesions, metastatic disease to the lung from a known extrathoracic malignancy, chest wall invasion by lung carcinoma, and pulmonary consolidation or infiltrates that are likely to be of infectious origin.

Few absolute contraindications to TTNB exist. These include an uncooperative patient or one with an intractable cough, as patients must be able to suspend respirations for 5 to 10 s while the needle crosses the pleura. In addition, TTNB is absolutely contraindicated in patients with a suspected pulmonary hydatid cyst because of the risk of capsule rupture and systemic dissemination. Relative contraindications include bullous emphysema, pulmonary arterial hypertension, and coagulation or platelet disorders. Patients with bullous emphysema are at increased risk of developing symptomatic or tension pneumothoraces after biopsy, although most induced pneumothoraces are small and can be treated conservatively. Those with pulmonary hypertension who undergo TTNB have a higher chance of developing pulmonary hemorrhage and significant hemoptysis.

■ Technique

Proper technique in performing TTNB is critical in obtaining adequate material for reliable interpretation. In addition to the mechanics of needle insertion and aspiration, the choice of needle type and careful specimen processing are important aspects of the procedure.

Choice of Needle

There are several different biopsy needles available for use, varying in length, gauge, and sampling mechanism. In general, needles can be divided into those used for aspiration, cutting needles for histologic evaluation, and automatic core biopsy needles. The choice of biopsy needle depends on various factors, including characteristics of the lesion, amount of tissue desired, and operator preference.[178,179]

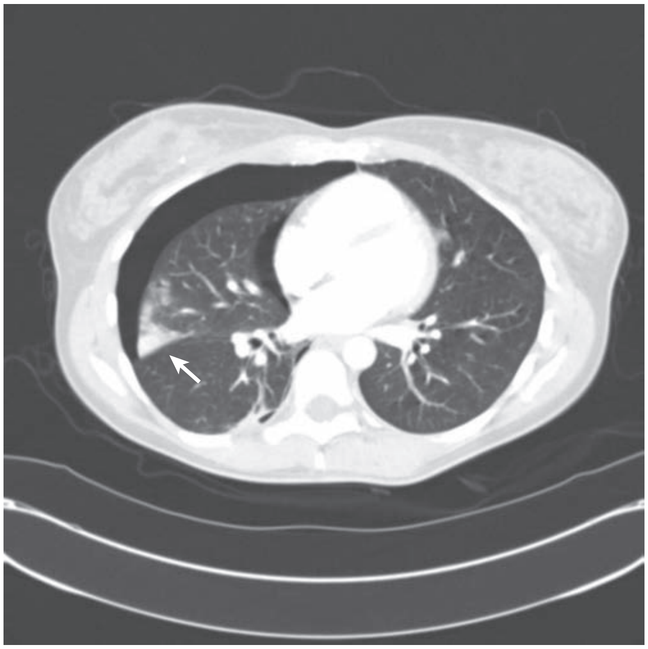

Figure 33-11 CT image demonstrating a pneumothorax of the right lung following transbronchial lung biopsy. An area of focal hemorrhage in the lateral right upper lobe *(white arrow)* as a result of biopsy can also be seen.

In the early 1960s, TTNA was performed using large-bore cutting needles; significant hemorrhagic complications were reported. More recently, thin-needle aspiration has become standard, with devices ranging in size from 18- to 22-gauge. Coaxial needle systems have been introduced for the purpose of obtaining multiple samples from a single pleural penetration. These systems are also useful for procuring specimens for histologic evaluation.

Radiographic Guidance and Biopsy Planning

Although TTNB can be performed under fluoroscopic or ultrasound guidance, CT is now the most commonly used image guidance approach for this procedure. CT can be used either intermittently during the procedure to guide needle placement, or with CT fluoroscopy (CTF) which allows for near real-time acquisition of images to guide needle adjustments. The diagnostic yield from either of these CT-based approaches appears to be similar.

Ultrasound-guided biopsies should be considered for peripheral lung lesions that extend to the pleural edge, or for the diagnosis of mediastinal masses. Ultrasound guidance also offers the advantage of real-time lesion imaging, easy portability, and absence of exposure to ionizing radiation for both the clinician and the patient.

Biopsy planning is an important step and should be performed prior the procedure. Considerations include choosing a needle path that avoids traversal of bullae, vessels, and bronchi. Crossing of interlobular fissures also should be avoided, as this increases the risk of pneumothorax.[180] In cases with more than one lesion, a more peripheral lesion is preferred to decrease the amount of lung traversed during needle insertion. In addition, upper lobe lesions are preferred over the lower lobe because of less respiratory motion in the upper lobes.

Needle Insertion

The lesion is localized using CT guidance, and the overlying skin is marked and anesthetized with 1% or 2% lidocaine. The needle is first inserted through the skin into the subcutaneous tissues. The needle is then advanced to the level of the pleura, followed by verification of the needle position and angle by CT. The needle is further advanced in one motion through the pleura to the prescribed length. The needle position can be confirmed prior to biopsy.

Ideal aspiration technique necessitates having the tip of the needle as close to the center of the lesion as possible. If an aspiration or cutting needle is used, the inner stylet should be removed. A syringe is attached to the needle hub. While suction is applied, the needle tip is advanced and withdrawn about 0.5 to 1 cm within the lesion. The needle is then removed from the chest, suction is released, and the aspirated material is flushed into a specimen container. Several samples should be obtained to increase the diagnostic yield. With a necrotic mass, aspiration should also be performed in peripheral locations of the lesion in order to obtain viable cells and to decrease the risk of false-negative results.

A coaxial technique may also be employed using a larger entry needle, which is advanced into the lesion, followed by a smaller biopsy needle that can be passed through the lumen of the larger needle into the lesion. This approach allows multiple passes into the lesion without repositioning of the needle with each pass.

■ Results

TTNB has an excellent success rate in the diagnosis of primary or metastatic pulmonary malignancies, with meta-analyses demonstrating pooled sensitivity of 90% (95% confidence interval, 88–91);[76] lower yields are seen for lesions smaller than 1.5 cm.[173,177,181] CT guidance yields better performance when compared with fluoroscopy (Fig. 33-12).[182] Aspiration biopsies have similar sensitivity to biopsies performed with cutting needles, but a poorer ability to determine a specific diagnosis from benign lesions. There is also concern that aspiration samples provide a lower likelihood of yielding sufficient tissue for molecular analysis, which is increasingly required in patients diagnosed with lung cancer.

Major causes of false-negative results in malignant disease are inadequate sampling of the lesion and aspiration in an area of necrosis or post-obstructive pneumonia. In addition, small, central malignant lesions may be difficult to diagnose accurately. Aspiration of vascular tumors, such as angiosarcoma, carcinoid, or metastatic renal cell carcinoma may yield a bloody aspirate with few, if any, malignant cells. False-positive results are extremely rare (1%–2%)

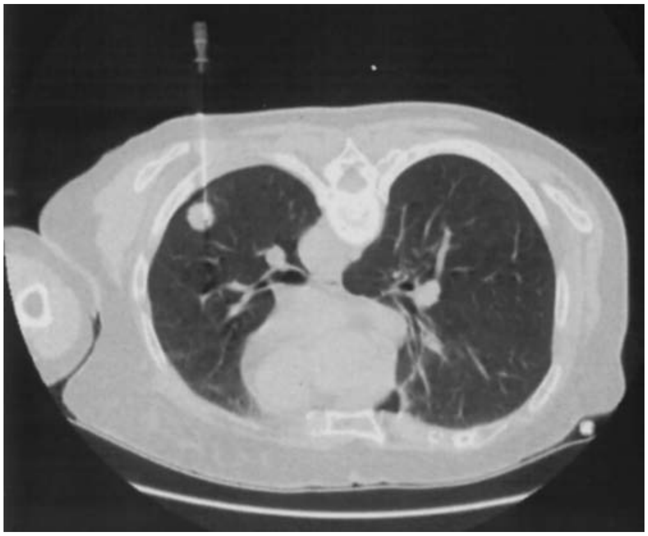

Figure 33-12 Transthoracic needle aspiration of pulmonary nodule. CT scan image of TTNA performed for a 2-cm right-lower-lobe nodule using a 22-gauge Westcott needle (Becton Dickinson & Co, Franklin Lakes, NJ). The needle can be seen entering the nodule. *(Reproduced with permission from Ana Kolansky, M.D.)*

and are typically reported in the setting of inflammatory processes, such as tuberculosis, radiation fibrosis, organizing pneumonia, and pulmonary infarction.

In the absence of a specific benign diagnosis, a lung biopsy that is negative for malignancy does not rule out the presence of neoplastic disease, especially if the biopsy was unsatisfactory. The degree of suspicion of malignancy in a particular clinical situation becomes extremely important in dictating the next step following a negative TTNB. For a smoker with a high risk of bronchogenic carcinoma, the proper course may lead to videothoracoscopic biopsy of the lesion, whereas in a young, otherwise healthy nonsmoker, close observation with serial CT scans may be the preferred option. This choice is influenced in part on the posttest probability of malignancy (after a nonmalignant result by TTNA), which depends on the pretest probability and the negative likelihood ratio (NLR). In an analysis conducted for the British Thoracic Society guidelines, the NLR was calculated at 0.10 allowing determination of posttest probability estimates.[183] As shown in Fig. 33-13, the posttest probability decreases significantly after a negative biopsy, but in patients with high pretest risk (e.g., 90%) there is still approximately a 50% chance of malignancy.

Complications

As mentioned previously, the most common complication of TTNB is pneumothorax; incidence rates reported in the literature vary from 8% to 61%. A recent population-based analysis reported a rate of pneumothorax of 15%, with 7% of all biopsies resulting in a pneumothorax requiring management with a chest tube.[62] Preexisting lung disease—in particular, bullous emphysema—is the most significant predisposing factor to development of pneumothorax after TTNB.[180,184–187] The vast majority of patients who develop clinically significant pneumothoraces after the procedure have an underlying diagnosis of chronic obstructive pulmonary disease. Other risk factors are smaller nodule size, crossing more than one pleural surface with the needle, needle size, and increased patient age.[180,184–187] Factors such as depth of lesion and increased number of transthoracic passes are controversial.[184,188]

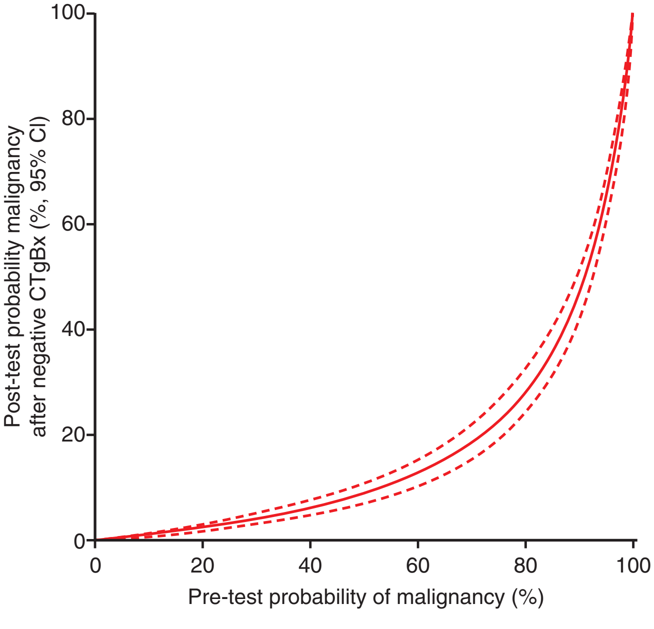

Figure 33-13 The effect of a negative CT-guided percutaneous biopsy on the post-test probability of malignancy. *(Reproduced with permission from Callister ME, Baldwin DR, Akram AR, et al. British Thoracic Society guidelines for the investigation and management of pulmonary nodules. Thorax. 2015;70:ii1–ii54.)*

Uncommon complications of TTNB include hemorrhage and hemoptysis, reported in approximately 1% of all biopsies. Although these are typically minor, one large study reported a transfusion requirement in 18% of cases with hemorrhage.[62] Cases of fatal hemorrhage from tracheobronchial obstruction from clot and subsequent asphyxia after use of large-bore (18-gauge) cutting needles have been reported.

Air embolism is a rare complication caused by creation of a communication between atmospheric air and a pulmonary vein. To minimize this risk, the needle should never be left open to air while in the chest, and the patient should be discouraged from deep breathing, straining, or coughing during the procedure. The procedure should be halted and the needle withdrawn if the patient is actively coughing. If an air embolism is suspected, 100% oxygen should be administered through a non-rebreather face mask and the patient placed in the left lateral decubitus position, with the head down; this position optimizes capture of air in the right heart. The patient should be transferred immediately to a hyperbaric chamber.

SUMMARY

Technologic advances in diagnostic bronchoscopy continue to improve our ability to perform minimally invasive, accurate evaluations of the tracheobronchial tree and to perform an ever-increasing array of diagnostic procedures. The continued development of imaging technologies and ancillary tools will certainly provide improvements in many of the modalities described above. Future improvements will include refinements in video and ultrasound imaging technology and the development of newer modalities, such as molecular imaging. This will be accompanied by further improvements in the ancillary tools, such as miniaturization of diagnostic accessories and further refinements in steerable probes that will allow improved access to peripheral regions of the lung. Improvements in image guided TTNA have also advanced the ability to safely and accurately sample lesions not accessible by bronchoscopy. These opportunities will need to be accompanied by well-designed studies to delineate the appropriate use of these techniques in clinical practice.

CHAPTER 34

Interventional Pulmonology

Daniel G. Dunlap
Andrew R. Haas
Daniel H. Sterman

INTRODUCTION

The first known bronchoscopy was performed by Gustav Killian in 1897 when he removed a pork bone from the right mainstem bronchus of a patient. For the subsequent 70 years, bronchoscopy was predominantly a therapeutic procedure performed for foreign body extraction. Two events shifted the landscape of bronchoscopy—the lung cancer epidemic and the development of flexible bronchoscopy by Shigeto Ikeda in 1967. Following an escalation in lung cancer incidence, malignant airway obstruction requiring therapeutic intervention became much more common than foreign body extraction. As a result, new tools were developed to address malignant airway obstruction based upon a minimally-invasive bronchoscopic approach. In addition, bronchoscopy-based technology has been developed to treat asthma, as well as select chronic obstructive pulmonary disease (COPD) phenotypes. This chapter presents an overview of interventional bronchoscopy and related modalities that can be utilized for benign and malignant airway obstruction, COPD, and asthma.

TABLE 34-1 Indications for Interventional Bronchoscopy

Hemoptysis
Atelectasis from inspissated secretions
Foreign body removal
Tracheobronchial tree neoplasms (primary or metastatic)
Direct bronchoscopic debulking
Laser therapy
Electrocautery/argon plasma coagulation
Cryotherapy
Brachytherapy
Photodynamic therapy
Stent placement
Airway strictures and stenoses
Rigid bronchoscopic dilation
Stricture/stenosis incision
Balloon tracheobronchoplasty dilation
Stent replacement
Lung lavage (pulmonary alveolar proteinosis)
Bronchoscopic drainage—lung abscess
Endotracheal tube and percutaneous tracheostomy placement
Treatment of persistent air leak
Evolving therapies for emphysema
Bronchial thermoplasty in severe asthma

INDICATIONS FOR INTERVENTIONAL BRONCHOSCOPY

Many potential indications for interventional bronchoscopy have been recognized, including malignant airway obstruction, benign airway obstruction, and foreign body extraction, among others (Table 34-1). The majority of therapeutic bronchoscopies performed today are undertaken for management of malignant airway obstruction, most commonly from lung cancer. It is estimated that up to 40% of patients with lung cancer develop symptomatic airway obstruction at some point during their disease process. Although lung cancer is the most common source of malignant airway obstruction, any primary thoracic malignancy or pulmonary metastases may result in symptomatic airway obstruction. Regaining airway patency to palliate symptomatic dyspnea and other respiratory symptoms can significantly improve the quality of life for patients with advanced malignancy.

Benign airway obstruction etiologies are listed in Table 34-2 and consist of a variety of localized inflammatory and systemic conditions. Although the etiologic airway process is benign and not malignant, the interventions and management of these complex processes are far from benign to the patient. Interventional bronchoscopy techniques can often improve the presenting symptoms; however, symptomatic stenosis often recurs, and patients may require repeat procedures to maintain airway patency. Selected patients may need to proceed with airway resection of the benign stenotic airway segment.[1]

Most patients with airway obstruction present with dyspnea or cough. Depending on the rapidity of airway obstruction, dyspnea may have a rapid onset or, more commonly, an insidious evolution that gradually limits patient activities. It is not uncommon for a family member to recognize this limitation more readily than the patient. As the airway obstruction worsens, the patient may develop orthopnea, which is a harbinger of an evolving critical

TABLE 34-2 Etiologies of Benign Tracheobronchial Stenosis

Endotracheal intubation
Tracheostomy tube
Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis)
Amyloidosis
Sarcoidosis
Tuberculosis
Inflammatory bowel disease
Idiopathic
Trauma
Lung transplantation
Post resection or airway repair
Trauma
Recurrent stenosis after prior stenosis resection
Sleeve resection
External beam radiotherapy or high-dose-rate brachytherapy (HDRB)
Photodynamic therapy
Thermal injury from fire exposure
Tracheobronchopathia osteochondroplastica
Postpneumonectomy syndrome
Fibrosing mediastinitis
Large vascular aneurysms

airway obstruction. Other symptoms, such as cough, inability to clear secretions, audible respirations, chest discomfort, or fever from post-obstructive pneumonia may develop. Early intervention is important to prevent worsening respiratory compromise or death.

SPECIAL CONSIDERATIONS FOR PATIENT PREPARATION, SEDATION, AND MONITORING

All patients undergoing bronchoscopy should undergo a complete pre-bronchoscopy evaluation, including a medical history, physical examination, and chest imaging. Although routine laboratory tests are not required, each evaluation should be individualized on the basis of patients' underlying conditions and the therapeutic procedures planned. CT imaging is important to assess the degree of airway involvement and to plan interventions.

Sedation and analgesia for patients undergoing interventional bronchoscopy must be considered carefully. Stable patients who can lay flat without distress can undergo bronchoscopy with moderate sedation. Should the patient have moderate or severe respiratory distress or be unable to lay flat, strong consideration should be given to additional monitoring or anesthesiology procedural assistance. Patients with high oxygen requirements may require endotracheal intubation to reduce the risk of developing hypoxemic respiratory failure during moderate sedation. Moreover, if patients are unable to lie flat, they may require an initial upright bronchoscopy with topical oropharyngeal anesthesia under minimal sedation to temporize luminal diameter before undergoing general anesthesia and more definitive interventional bronchoscopy.

Similar to diagnostic bronchoscopy, if a patient is stable for moderate sedation, topical analgesia of the oropharynx and airways should be achieved with lidocaine, followed by administration of a combination of a short-acting benzodiazepine (e.g., midazolam) and a narcotic (e.g., fentanyl).[2] Rigid bronchoscopy is most safely performed with a patient receiving general anesthesia and breathing spontaneously or paralyzed while being ventilated with a jet ventilator.[3] General anesthesia with inhaled anesthetics (e.g., sevoflurane) should be avoided in favor of total intravenous anesthesia in order to avoid exposure of the bronchoscopist to inhaled anesthetics when the ventilator circuit is open. With appropriate planning and monitoring, the vast majority of patients can undergo interventional bronchoscopy with low complication rates.

TYPES OF AIRWAY OBSTRUCTION

Figure 34-1 demonstrates the three main types of airway obstruction that may be encountered: purely intrinsic (A), purely extrinsic (B), or a combination of both intrinsic and extrinsic airway obstruction (C). Attention to preprocedural CT imaging allows fairly accurate assessment of these components and enables the therapeutic bronchoscopist to plan an approach. For lesions that are purely intrinsic, direct bronchoscopic debulking with rigid bronchoscopy, thermal ablation, cryotherapy, or snare extraction with or without stent placement is appropriate. For purely extrinsic lesions, no tumor is present to debulk, and modalities used in purely intrinsic disease cannot be employed due to the risk of airway perforation. Extrinsic lesions are most amenable to balloon bronchoplastic dilatation and endoluminal stent placement. For mixed intrinsic–extrinsic lesions, tumor debulking modalities, as well as dilatation and stent placement, are feasible.

■ Endoluminal Airway Obstruction

Endoluminal obstruction of the tracheobronchial tree may result from various benign and malignant processes. The most common cause of endobronchial obstruction is advanced lung carcinoma. In patients with inoperable central airway tumors, restoration of airway patency may provide palliation, improve quality of life, and can even prolong life, particularly in the case of impending respiratory failure or postobstructive pneumonia.

Signs and symptoms of malignant central airway obstruction vary but often include progressive dyspnea and functional limitation, wheezing, cough, stridor, hoarseness, hemoptysis, and chest pain. A careful pretreatment evaluation should be performed to distinguish symptoms attributable to focal tracheobronchial lesions from those related to underlying obstructive lung disease, parenchymal lung disease, or both. Although pulmonary function testing and thoracic imaging techniques, such as chest CT scan, may be useful in the evaluation of a patient with suspected malignant airway obstruction, bronchoscopy, either rigid or flexible, remains the diagnostic and therapeutic "gold standard." Increasingly, however, three-dimensional reconstruction CT imaging, so-called "virtual bronchoscopy," is being applied as a reliable noninvasive method of assessing the nature and extent of malignant airway obstruction, thereby allowing preprocedural intervention planning.

The bronchoscopic approach to management of malignant airway obstruction depends on the lesion location, presence or absence of associated extrinsic compression, and degree of clinical urgency. Rigid bronchoscopic debulking using adjunctive thermal ablation is recommended when airway recanalization must be performed on an emergency basis. If endobronchial obstruction is accompanied by marked extrinsic compression, stent placement may be beneficial.

The complexity of a lesion is equally important in determining the best approach to therapeutic bronchoscopy. Benign tracheal webs often are managed using laser or electrocautery-mediated resection alone, whereas complex fibrotic strictures may warrant the combination of rigid bronchoscopic or balloon dilatation, thermal incision, and stent placement. For focal tracheal stenosis in patients at low risk for complications, surgical resection with primary reanastomosis should remain the definitive treatment choice.

■ Extrinsic Airway Compression

Extrinsic airway compression usually results from malignant involvement of structures adjacent to the central airways, such as mediastinal lymph nodes or the esophagus, but it may be associated with a benign process, such as fibrosing mediastinitis, tuberculosis, aneurysmal dilatation of the aorta, or sarcoidosis. The clinical signs and symptoms of extrinsic airway compression often mimic those of endobronchial obstruction. The diagnosis is established on the basis of bronchoscopic detection of marked airway narrowing in the absence of an endoluminal mass.

Therapeutic options in the management of extrinsic airway compression are limited. Ablative endoscopic approaches, such as laser therapy, cryotherapy, PDT, and electrocautery are contraindicated because of the lack of demonstrable benefit and risk of airway perforation. Although some patients with malignant disease may benefit from endobronchial brachytherapy, tracheobronchial stent placement is the palliative treatment of choice for patients with symptomatic extrinsic airway compression.

TYPES OF THERAPEUTIC BRONCHOSCOPY INTERVENTIONS

A variety of bronchoscopic interventions are in common clinical use and are described below.

■ Rigid Bronchoscopy

The initial bronchoscope, developed by Killian, and further optimized by Chevalier Jackson, was a rigid metal tube that permitted either spontaneous or mechanical ventilation.[4] Over the decades, rigid bronchoscopes of various lengths and diameters have been developed that are adaptable for diverse applications in children and adults. Although the flexible bronchoscope has to a large extent replaced the rigid scope

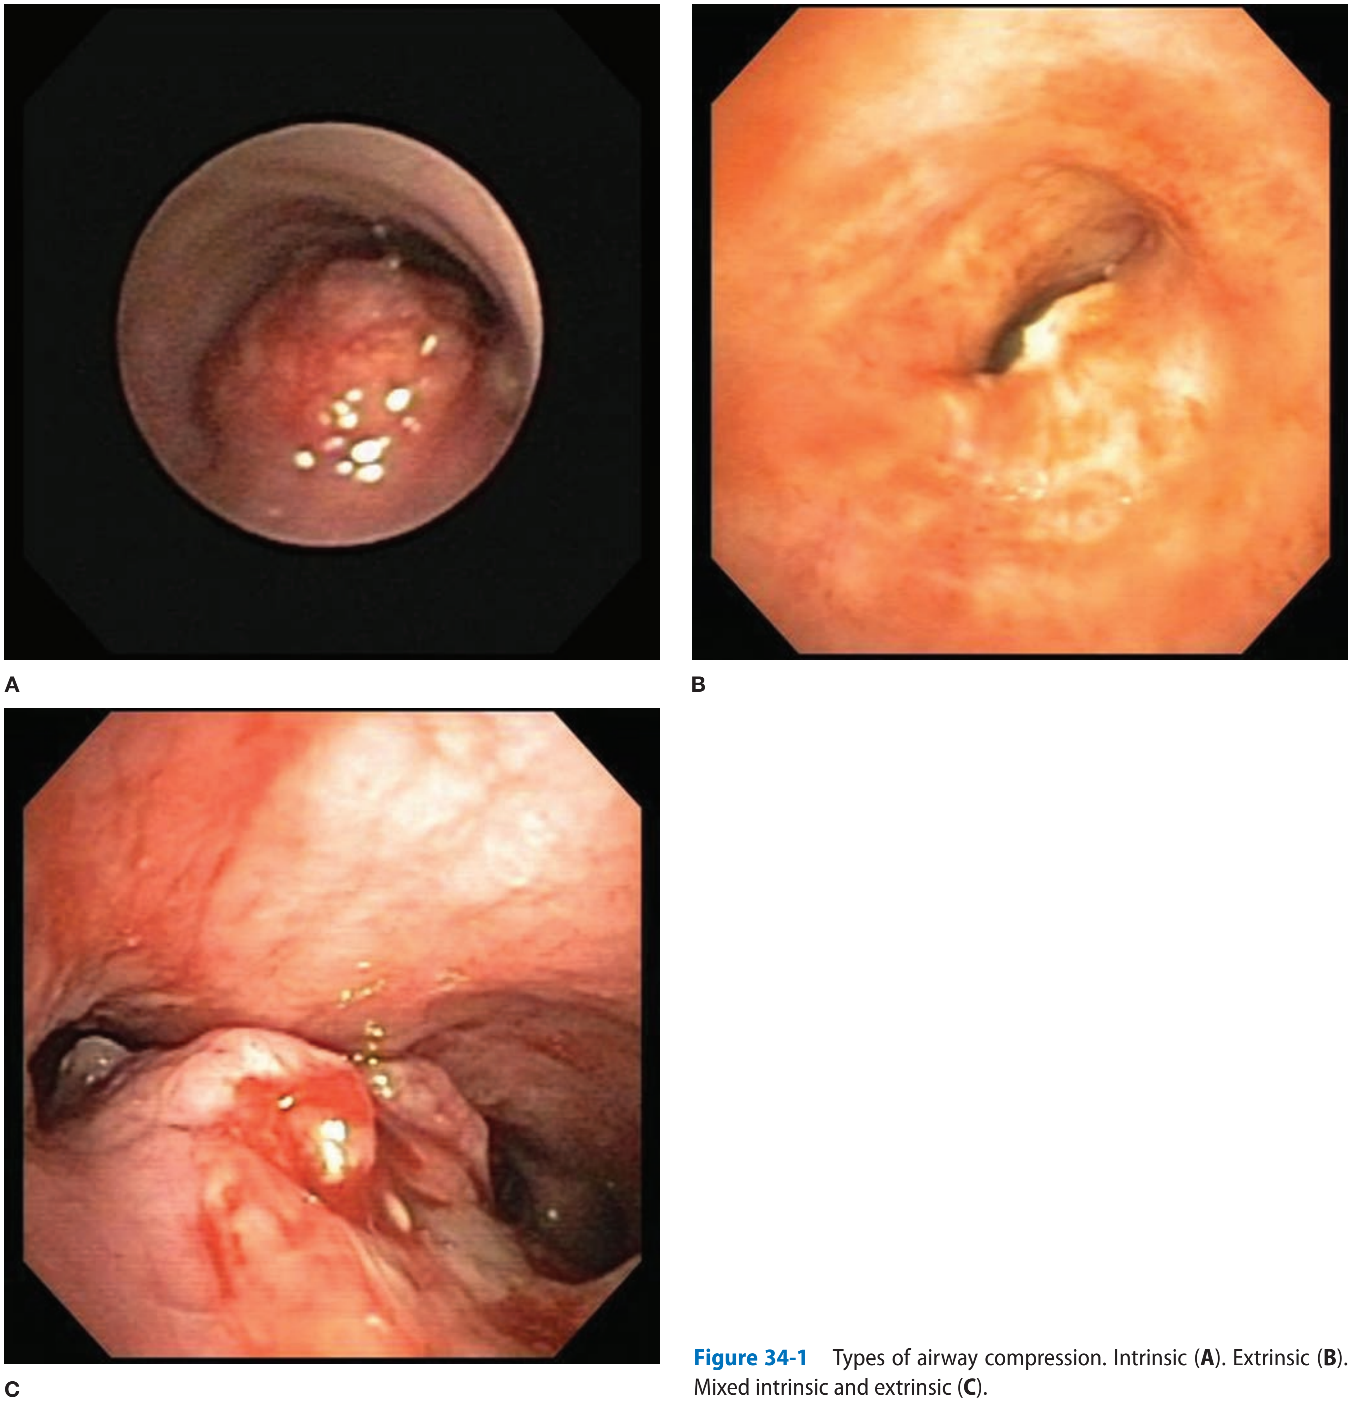

Figure 34-1 Types of airway compression. Intrinsic (**A**). Extrinsic (**B**). Mixed intrinsic and extrinsic (**C**).

for most diagnostic and some therapeutic indications, rigid bronchoscopy still has vital therapeutic applications.

Modern rigid bronchoscopy systems are equipped with optical capabilities to allow better direct, magnified, circumferential illumination and visualization. The main advantage of rigid bronchoscopy over flexible bronchoscopy is its luminal working diameter, which allows multiple therapeutic instruments to be utilized simultaneously while ventilating the patient. Rigid bronchoscopy allows a number of therapies, such as laser photocoagulation, placement of endobronchial stents, balloon dilatation, electrocautery, argon plasma coagulation, and cryotherapy to be performed safely and effectively. Perhaps most importantly, in the setting of malignant airway disease or obstruction, a rigid bronchoscope can be used to "core out" large bulky airway tumors more efficiently and effectively than any thermal modalities (Video 34-1). Initial rigid bronchoscopic debulking, followed by thermal modality ablation to cauterize remaining tumor, is common.[5] For benign, fibrotic airway stenosis, the rigid bronchoscope becomes a very effective modality to partially debulk stenotic tissue and to dilate the stenosis.[6] In experienced centers, rigid bronchoscopic airway recanalization remains the treatment of choice for serious or life-threatening tracheobronchial obstruction.

The video demonstrates effective and efficient use of rigid bronchoscopy to mechanically debride tumor. *Video available on AccessMedicine.com.*

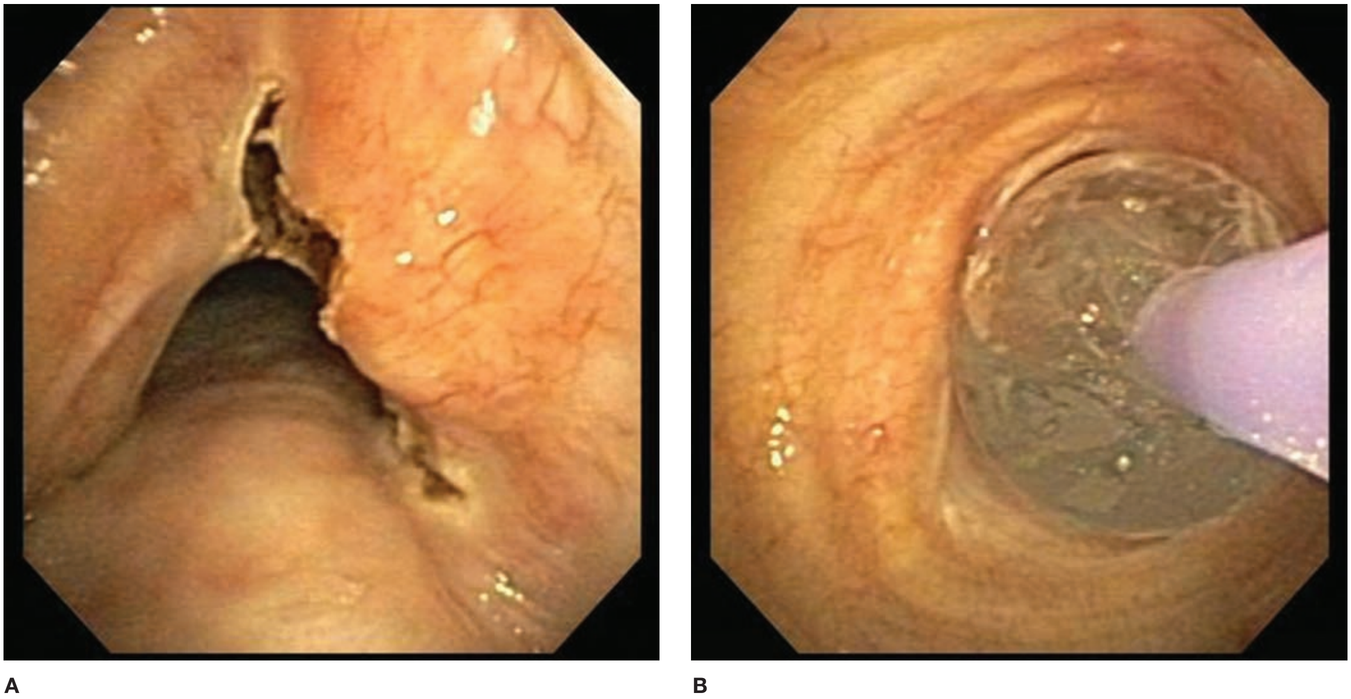

Figure 34-2 Electrocautery incisions were made into the benign stenotic lesion (**A**). Following incision, balloon bronchoplasty dilatation was performed (**B**).

The main complication from rigid bronchoscopy is dental injury from the scope fracturing teeth. Other complications, such as oropharyngeal laceration, arytenoid cartilage disarticulation, or vocal cord injury, are possible. Meticulous care upon rigid bronchoscope intubation is critical to avoid these potential complications. Intrathoracic complications, such as airway perforation, major bleeding from tumor debulking, and pneumothorax or pneumomediastinum also are possible but are infrequent in experienced hands.

■ Balloon Tracheobronchoplasty

Balloon dilatation has become an attractive alternative to rigid bronchoscopy for management of airway obstruction in benign and malignant airway obstruction, especially in anatomic locations where a rigid bronchoscope cannot enter or the luminal diameter is too narrow to allow safe rigid bronchoscope passage. High-pressure balloons of various lengths and diameters specifically designed for the tracheobronchial tree are readily available. These balloons are filled with saline or radio-opaque contrast media, advanced to the site of interest through the bronchoscope, and inflated until the desired diameter is attained.

In the setting of benign stenosis, an initial defect in the stenosis is often made with a thermal modality so as to control the stenotic release point (Fig. 34-2). This approach has been used successfully in benign stenoses from endobronchial tuberculosis, idiopathic subglottic stenosis, and posttransplant anastomotic strictures.[7] Balloon dilatation is less successful when used alone to treat airway compromise accompanied by extrinsic airway compression, as the initial bronchoscopic improvement often rapidly returns to its original position as the extrinsic process persists. Complications of balloon dilatation include bronchospasm, chest pain, mucosal laceration, airway perforation, bleeding, postprocedure airway edema, pneumothorax, and pneumomediastinum.

■ Bronchoscopic Laser Therapy

Perhaps the most widely known technique in therapeutic bronchoscopy is laser photocoagulation or photoablation. Table 34-3 compares characteristics of the laser modality compared with other modalities to be presented later. Lasers produce a beam of monochromatic, coherent light that induces tissue vaporization, coagulation, hemostasis, and necrosis. Although primarily useful in endoluminal malignant tumor ablation, bronchoscopic laser therapy also is beneficial in other tracheobronchial disorders, including inflammatory strictures, obstructive granulation tissue, amyloidosis, and benign tumors, such as hamartomas and lipomas.

Since the initial report of endobronchial laser ablation of an obstructive neoplasm by Laforet in 1976, several types of lasers have become available for management of tracheobronchial obstruction.[8] The carbon dioxide (CO_2) laser, used primarily by otolaryngologists, allows shallow tissue penetration (to a depth of 0.1–0.5 mm) with very precise cutting, but it has minimal hemostatic properties. With the development of other laser modalities, the CO_2 laser has minimal current application in endobronchial tumor ablation, and its role remains primarily in management of laryngeal lesions and subglottic stenosis.

For therapeutic bronchoscopy, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser ablation is most commonly used (Video 34-2). It provides tissue penetration to a depth of 3 to 5 mm, and superior coagulation with improved hemostasis, but at the cost of less cutting precision. Nd:YAG laser procedures may be performed through a rigid or flexible bronchoscope.

Use of Nd:YAG laser photoablation therapy as a single modality is associated with a recanalization rate >90% for central airway endobronchial obstruction.[9,10] Nd:YAG laser photocoagulation may be an important treatment tool for patients with airway obstruction caused by benign endoluminal tumors. The Nd:YAP (yttrium-aluminum-perovskite) laser, with a patented wavelength of 1.34 μm,

TABLE 34-3 Therapeutic Bronchoscopy Ablation Modalities

Therapy	Type of Lesion Therapy	Type of Bronchoscope	Rapidity of Positive Result	Repeatability
Mechanical debridement	Endoluminal or submucosal	Rigid or flexible (rigid preferable)	++++	+
Laser	Endoluminal	Rigid or flexible (rigid preferable)	++++	++++
Argon plasma	Endoluminal	Rigid or flexible	++++	++++
Brachytherapy	Endoluminal or submucosal	Flexible	+	+
Cryotherapy	Endoluminal	Rigid or flexible	++	+++
Balloon dilation	Endoluminal or submucosal with extraluminal compression	Rigid or flexible (rigid preferable)	++++	++++
Photodynamic therapy	Endoluminal	Flexible	++	+++
Electrocautery	Endoluminal	Rigid or flexible	+++	++++
Stent	Endoluminal with extraluminal compression	Rigid or flexible (Dumon stent requires rigid bronchoscope; Wall stents and Gianturco stents require fluoroscopy)	++++	+++

is purported to have better water absorption at that wavelength, thereby improving the power-to-effectiveness ratio compared with traditional Nd:YAG laser and carrying a lower complication risk.

Although endobronchial laser therapy generally is safe and well tolerated, it may be complicated by cardiac arrhythmias, airway perforation, pneumothorax, hemorrhage, hypoxemia, or endobronchial fire.[11,12] Endoluminal laser utilization requires careful consideration of the lesion, anatomic location, and configuration relative to vital intrathoracic structures. If the lesion is in close proximity to the esophagus or pulmonary artery, endobronchial laser therapy carries risk for fistula formation. Laser therapy in a patient with tracheobronchial narrowing caused by extrinsic compression may result in airway perforation. In rare cases, pulmonary edema or fatal pulmonary venous gas embolism have been reported.[13] Patients with standard silicone endotracheal tubes or silicone tracheobronchial stents, and those who require high concentrations of supplemental oxygen, are at increased risk for endobronchial fire. The bronchoscopist needs to ensure the inspired oxygen level is ideally <40%, especially if the patient is receiving mechanical ventilator support during the procedure. Fortunately, the overall risk of endobronchial fire is <0.1%.

■ Endobronchial Electrocautery, Argon Plasma, and Cryotherapy

Electrocautery, argon plasma coagulation (APC), and cryotherapy are cost-effective alternatives to laser therapy for the management of tracheobronchial lesions and obstruction, as equipment expenses are substantially less compared with laser therapy. Penetration depth and per-treatment effectiveness may be less than with laser therapy.

Electrocautery effects on tissue are similar to those of Nd:YAG laser with tissue destruction induced by coagulative necrosis (Video 34-3). APC is similar to electrocautery except that it uses argon gas to conduct the electrical current, rather than a contact probe. Electrocautery and APC have a 1- to 3-mm penetration depth and are, therefore, more suitable for the treatment of superficial and spreading lesions than large central tumors (Video 34-4).

In contrast with electrocautery or APC, cryotherapy induces tissue necrosis through hypothermic intracellular crystallization and microthrombosis. Specially designed cryoprobes are inserted through the bronchoscope until they contact target tissue. Cryoprobe activation introduces liquid nitrous oxide or carbon dioxide through a small orifice in the probe under pressure, resulting in rapid cryoprobe cooling with creation of an “ice ball” (approximate temperature, −40°C) at the probe tip on target tissue. This freezing effect is maintained for approximately 30 s; the area is then allowed to thaw, and freezing is repeated two to three times to achieve necrosis by cellular rupture from repeated cycles of intracellular microcrystallization. Cryospray technology utilizes administration of liquid nitrogen at −196°C to tissue of interest in a controlled fashion, using an open airway to prevent barotrauma. This modality freezes water in cells, resulting in cell death, while preserving tissue matrix and healing.

Electrocautery, APC, and cryotherapy have been used successfully to relieve airway obstruction and treat hemoptysis caused by benign and malignant tracheobronchial tumors, polyps, and granulation tissue.[5,9,14–19] These modalities have been used effectively in radiographically occult mucosal lung cancer, carcinoma in situ, and mucosal dysplasia. Cryotherapy may be advantageous in cryoextraction of foreign bodies that can be frozen to the probe and removed.[20] This technique works very well for mucoid plugs or blood clots in large airways where other modalities may be associated with difficult removal.

Although the range of complications from electrocautery and cryotherapy are the same as those discussed for laser therapy, the most common complication of each is bleeding secondary to disruption of endobronchial tumor without full-tissue coagulation. The estimated incidence of clinically significant bleeding in patients treated with electrocautery is 2.5%. Rarely, gas embolism can occur with APC.[21,22] Importantly, unlike the heat thermal modalities, cryotherapy can be performed in patients in whom

Video 34-3 A patient with a history of renal cell carcinoma who presented with dyspnea and left lung atelectasis. CT scan demonstrated left mainstem bronchus obstruction. The video shows a rigid bronchoscopy with electrocautery snare excision and removal of a large polypoid renal carcinoma metastasis. high oxygen levels are required due to hypoxemia without a risk of airway fire.

Endobronchial Brachytherapy

Endobronchial high-dose-rate brachytherapy (HDRB) refers to bronchoscopic radiation delivery to a localized airway lesion. The technique aims to delivery therapeutic radiation to localized lesions while minimizing exposure to nontarget tissues. Endobronchial brachytherapy involves the bronchoscopic insertion of a thin, hollow "afterloading" catheter across an area of interest (usually malignant tissue) under direct bronchoscopic and fluoroscopic guidance. The catheter is left in place, and the patient travels to the radiation oncology department where radioactive beads are inserted into the catheter at the desired location for a predetermined period, depending on the dose rate.

Relief of airway obstruction is the primary goal of HDRB, although curative treatment may be attempted in more advanced lesions by combining HDRB with external beam irradiation in selected patients. HDRB is not effective for rapid airway recanalization due to its delay in response of 14 to 21 days. It is best used as an adjunct to rigid bronchoscopy with or without thermal tumor ablation, endobronchial stent placement, or conventional external beam irradiation to recanalize an obstructed airway. HDRB appears safest and most effective for management of central airway lesions. Among patients with malignant airway obstruction, recanalization rates range from 60% to 90%, with decreased dyspnea, cessation of hemoptysis, and relief of cough in most cases.[16,23,24] HDRB has also been shown to be effective for radiographically occult, minimally invasive cancer in central airways, carcinoma in situ (CIS), or mucosal dysplasia. Moreover, accounts of the utility of HDRB in management of benign granulation tissue in lung transplant recipients or patients with subglottic stenosis have been reported.[25–27]

Serious complications of HDRB can occur, particularly massive hemoptysis from bronchovascular fistula formation secondary to necrosis of the airway wall and adjacent vascular structures. Because of the risk of fatal hemorrhage, every effort should be made to rule out central vascular tumor involvement before HDRB application.

Photodynamic Therapy

Photodynamic therapy (PDT) is FDA-approved for palliation of malignant airway obstruction and as an alternative to surgery in selected patients with minimally-invasive central lung cancer or CIS. PDT works on the principle that certain compounds, such as hematoporphyrin derivatives or aminolevulinic acid (ALA), function as photosensitizing agents, rendering malignant cells susceptible to damage from monochromatic light. Tumor necrosis occurs as a result of oxygen free-radical formation and ischemic vasculature necrosis mediated by thromboxane A_2 release.

The selective PDT effect on malignant cells is thought to be due to greater photosensitizing agent uptake and retention in neoplastic cells compared with normal cells; the exception is reticuloendothelial cells, particularly those in the skin. The relative tumor selectivity is most pronounced within 24 to 48 h after photosensitizing agent infusion; therefore, treatment of the target lesion should be performed within that time frame. Maximal tissue necrosis occurs 24 to 48 h after laser light administration and requires repeat bronchoscopy to debride the necrotic and sloughed area treated. Due to the delayed onset of PDT action, it is not useful in patients with acute respiratory distress from airway obstruction.

Ideal candidates for PDT include patients with airway obstruction caused by malignant endobronchial masses with minimal extrinsic airway compression, and patients with minimally invasive central airway tumors. Although surgical resection remains the treatment of choice for early lung cancer, some patients refuse surgery or have tumors that are deemed inoperable because of high surgical risk. In these cases, PDT may represent an appropriate alternative. Response rates are highest in patients with small tumors and minimal airway penetration depth.[28,29] In patients with bulky tumors, endobronchial PDT may substantially reduce the obstruction with objective increases in spirometric measurements and subjective improvement in dyspnea and quality of life; however, treatment is not curative.[30]

The main PDT complication is skin photosensitivity, which occurs in up to 20% of patients; it may persist for 6 weeks or longer and can be obviated by adequate sunlight precautions.

Tracheobronchial Stenting

Anecdotal reports of attempts to implant stents in the tracheobronchial tree date back to 1915. The Montgomery T-tube, designed in the 1960s, was the first reliable, dedicated airway stent.[31] However, stent implantation in the lower trachea and bronchi did not become standard medical practice until the 1990s, when Jean Francois Dumon reported the safe and effective placement of a dedicated silicone airway stent.[32]

Two main types of endobronchial stents are in use today—silicone or self-expanding metal stents (SEMS). Silicone stents generally are placed by rigid bronchoscopy with the patient under general anesthesia. Silicone stents are relatively inexpensive (~$500 USD) compared with SEMSs (~$2000 USD). Bifurcated silicone Y-stents also are available and have been effectively used in the management of carinal compression associated with malignant tumors, tracheoesophageal fistulas, and tracheobronchomalacia.

Unlike silicone stents, SEMSs may be placed using flexible bronchoscopy and require less technical rigor than silicone stent placement. The main limitation with SEMS is that uncovered varieties may induce mucosal inflammation and granulation tissue formation, which may require repeat endoscopic intervention to maintain airway patency.[33–35] For this reason, uncovered SEMSs have an FDA black-box warning against their utilization in *benign* airway stenosis, unless all other treatment options, including silicone stenting, have been explored and failed. An exception to this warning applies in bronchial anastomotic dehiscence in lung transplantation. In this setting, insertion of a temporary uncovered SEMS across the dehiscence exploits the fact that focal granulation tissue may develop and promote dehiscence closure.[36]

Endobronchial stents have a critical role in multimodality bronchoscopic approaches to both benign and malignant airway obstruction. Airway obstruction caused by locally advanced lung carcinoma may be treated with a combination of thermal tumor ablation and stent implantation to regain and preserve airway luminal diameter by preventing tumor ingrowth (Fig. 34-3). Stent placement may be combined with balloon dilatation in the endoscopic management of benign fibrotic strictures.

Dumon and colleagues reported excellent clinical outcomes and few complications with silicone stent placement in patients with malignant airway obstruction; a lower success rate was noted among patients with tracheal stenosis caused by other disorders.[32] Success, broadly defined as symptomatic relief, in limited studies has been reported to be achieved in between 78% and 98%, although none of the early trials used objective measures to determine efficacy.[37–39] In a small study in patients who were intubated because of respiratory failure secondary to unresectable tracheobronchial and mediastinal disease, stent placement facilitated extubation in most.[40] Stent placement benefits seem to persist in patients who survive for a period of several months or years after stent implantation.

Complications from endobronchial stents include stent migration, granulation tissue formation, tumor overgrowth, stent bacterial colonization and recurring infection, stent fracture, and inspissated secretions clogging the stent. In addition, massive and

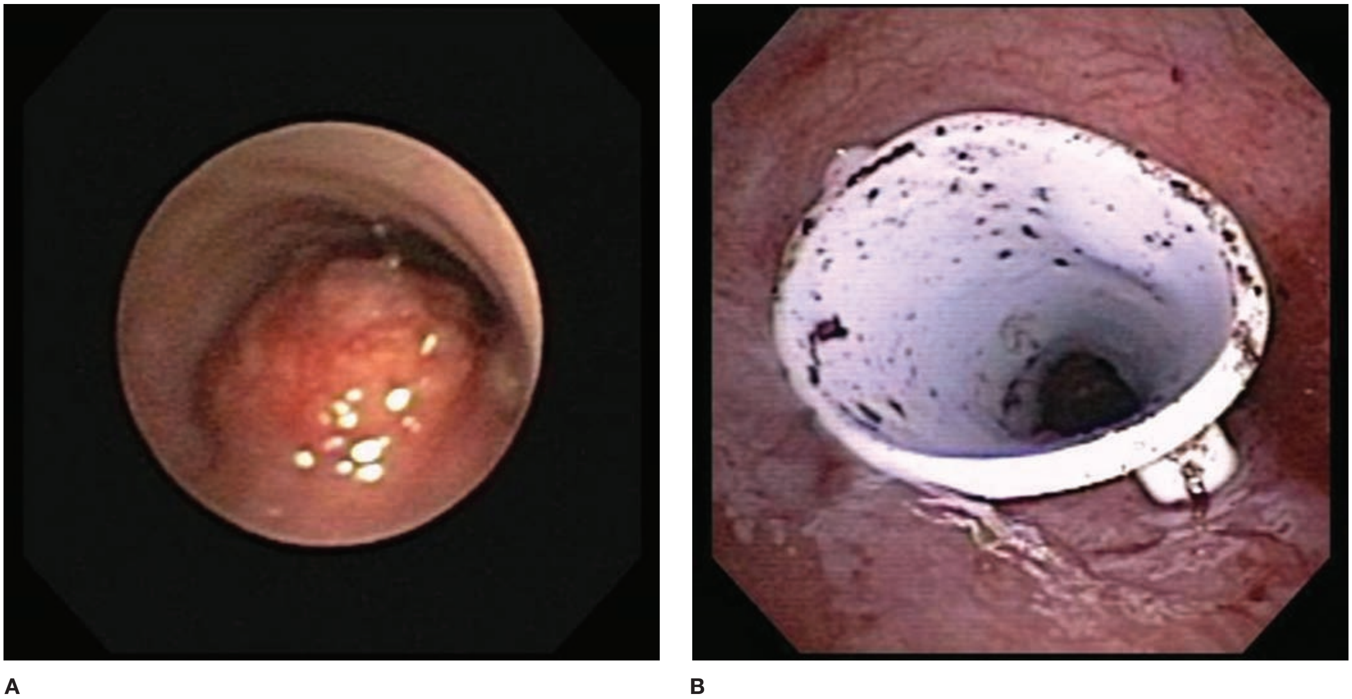

Figure 34-3 A large tumor nearly completely obstructs the tracheal lumen (**A**). Manual debulking using a rigid bronchoscope dramatically improved airway luminal diameter. An endotracheal silicone stent was placed to prevent tracheal re-occlusion (**B**).

fatal hemorrhage associated with stent erosion into central vascular structures can occur.

Stenting for Tracheobronchomalacia

Diffuse or focal tracheobronchomalacia is, perhaps, the most challenging disorder encountered by the therapeutic bronchoscopist. Cartilaginous tracheobronchomalacia refers to tracheal or main bronchi circumferential exhalational airway collapse due to loss of cartilaginous ring structural integrity. Membranous, or crescentic, tracheobronchomalacia, also known as excessive dynamic airway collapse (EDAC), is manifested by intact cartilaginous rings along with tracheal obstruction from anterior exhalational displacement of the posterior membrane from posterior membrane laxity. This condition is commonly seen with COPD, asthma, obesity, and chronic cough. Dynamic CT scanning may suggest tracheobronchomalacia or EDAC, but the gold standard remains flexible bronchoscopy performed while the patient is awake and spontaneously breathing to assess dynamic airway collapse.[41] Focal airway malacia may be a complication of long-standing intubation or an anastomotic complication following lung transplantation.[42]

The endoscopist must maintain restraint in therapeutic interventions for patients with tracheobronchomalacia or EDAC. Management of diffuse tracheobronchomalacia should focus on identifying and treating any underlying conditions that may perpetuate cartilaginous inflammation (e.g., relapsing polychondritis) and airway collapse. If the tracheobronchomalacia is symptomatic and progressive despite systemic therapy, initial consideration for tracheostomy should be entertained. If symptoms are not resolved with tracheostomy, or if they recur or progress after an initial improvement, evaluation for placement of a silicone bifurcation Y stent should be undertaken. These patients may also require nighttime ventilator support. Patients with EDAC may benefit from a trial of silicone stent placement as well, but this should not be considered definitive therapy.[43,44] For those who benefit in terms of decreased respiratory symptoms and improved pulmonary function, stent removal followed by surgical posterior membrane plication can be performed with acceptable clinical outcomes.[43,45] Recently, robotic tracheobronchoplasty with mesh has offered a minimally invasive surgical approach to treatment.[46] For many patients with focal tracheomalacia, particularly from postintubation injury, surgical resection with primary reanastomosis may be the best therapeutic option. If patients are not surgical candidates or prefer to avoid surgery, silicone stent placement often will provide the structural integrity necessary to obviate patient symptoms, at the risk of long-term stent complications.

■ Management of Hemoptysis

Bronchoscopy is valuable in hemoptysis for several reasons: to identify site of bleeding, to provide endobronchial therapy to reduce or stop bleeding, to clear blood clots that might impair gas exchange, or to place an endoluminal blocking device to prevent further airway occlusion with blood. Because of visualization difficulties during active bleeding, instruments with large and maximally effective suction channels should be used. Rigid bronchoscopy generally is preferred with massive bleeding or when the need to remove large clots is anticipated.

In attempts to cease bleeding, iced saline or an epinephrine solution can be instilled into a bleeding airway or applied topically onto a proximal bleeding site in an attempt to induce vasoconstriction. In addition, balloon catheters can be placed into the bleeding airway to tamponade bleeding to generate a hemostatic clot and prevent proximal airway soilage. Large endobronchial blockers are available to occlude the entire right or left mainstem bronchus to control bleeding. Other effective methods for control of proximal visible bleeding sources, particularly from endobronchial neoplasms, are thermal modalities such as Nd:YAG laser or APC photocoagulation.[47] In addition, flexible bronchoscopic endobronchial packing using oxidized regenerated cellulose can isolate a segmental or subsegmental bleeding site and promote endobronchial clot formation by induction of fibrin polymerization.[48,49] Frequently, these procedures are temporizing, while definitive management with surgery or bronchial artery embolization is undertaken.[50] Cryotherapy can be a valuable tool to remove a large central, organized clot from the airway by freezing the probe to the clot and removing the scope, probe, and clot en bloc.

Foreign Body Removal

Foreign body aspiration is more likely to occur in children than in adults with most foreign bodies occurring in children younger than 3 years. In children, the foreign body most often lodges in a mainstem bronchus, whereas in adults, foreign bodies usually are wedged distally, most commonly in the right lower lobe. Before bronchoscopic extraction was possible, most foreign body aspirations resulted in high morbidity and mortality, commonly from postobstructive pneumonia. Today, foreign bodies can be removed with either flexible or rigid bronchoscopy, depending on local expertise and foreign body size and composition. If available, rigid bronchoscopy remains the tool of choice for foreign body removal due to several factors: a larger access channel allowing use of larger and more adaptable retrieval tools; protection of the vocal cords from trauma upon foreign body removal; and ability to provide and maintain ventilation.

Various instruments have been developed for use with bronchoscopy for foreign body removal, including grasping forceps, balloon catheters, retrieval baskets, snares, and magnetic extractors. The instrument choice depends on the foreign body material composition, size, shape, and location in the tracheobronchial tree. Grasping forceps may be helpful in the retrieval of hard objects with an irregular surface. Smooth objects or organic material (e.g., nuts, food particles) may require use of expandable baskets or a combination of balloon catheters, suction devices, and grasping forceps. Balloon catheters frequently are used to dislodge a foreign body and bring it proximally into a larger airway before its removal with other instruments. Similar to clot extraction, cryotherapy can also be utilized by freezing the tip of the probe to the foreign body surface and subsequently withdrawing the catheter and object en bloc.

Secretion Aspiration

According to a survey of bronchoscopists in the United States, removal of retained secretions is cited as a leading indication for therapeutic bronchoscopy. Bronchoscopic secretion aspiration may be indicated in patients with respiratory muscle weakness who cannot generate adequate cough for secretion clearance. In critically ill or mechanically ventilated patients, secretion clearance may require flexible bronchoscopy. For ease of secretion removal, a flexible scope with a large working channel is ideal. Bronchoscopic secretion aspiration should not be considered “routine” in the postoperative period or in other conditions in which good chest physiotherapy and maintenance of adequate pulmonary toilet may be more effective.

Two specific disorders are worth highlighting in the context of therapeutic bronchoscopy: pulmonary alveolar proteinosis (PAP) and allergic bronchopulmonary aspergillosis (ABPA). In PAP, large-volume repeated bronchoalveolar lavage has been used for therapeutic clearance of alveolar surfactant material.[51,52] For patients with more extensive disease or impaired gas exchange, the standard approach is sequential whole-lung lavage.[53] In ABPA, lavage with saline solution may be insufficient to remove tenacious secretion impactions (described as “plastic bronchitis”), and cryoprobe extraction may prove helpful.

Closure of Bronchopleural or Alveolopleural Fistula

Persistent air leaks may be encountered following primary or secondary spontaneous pneumothorax. or following pulmonary resection. Traditional management for prolonged air leaks usually includes prolonged chest tube drainage using a Heimlich valve, attempts at surgical repair, pleural blood patch, or pleurodesis.

Therapeutic bronchoscopy may be a useful adjunct to persistent air-leak intervention in confirming suspected bronchopleural or alveolopleural fistulae and in specifying their precise location. The most common approach is to perform selective balloon catheter airway occlusion while observing the chest tube air-leak rate and volume. Depending on the fistula location and size, bronchoscopic procedures can be attempted with the goal of air leak reduction or elimination. Many different techniques for permanent closure have been reported. Several potentially useful agents have been described, including surgical gel, autologous airway blood patch, and thrombin injection to create fibrin clot, among a variety of others.[54–56] The most recent effective approach entails one-way endobronchial valve placement with complete or partial air leak resolution in the large majority of patients with persistent air leaks from diverse causes (Fig. 34-4).[57–60]

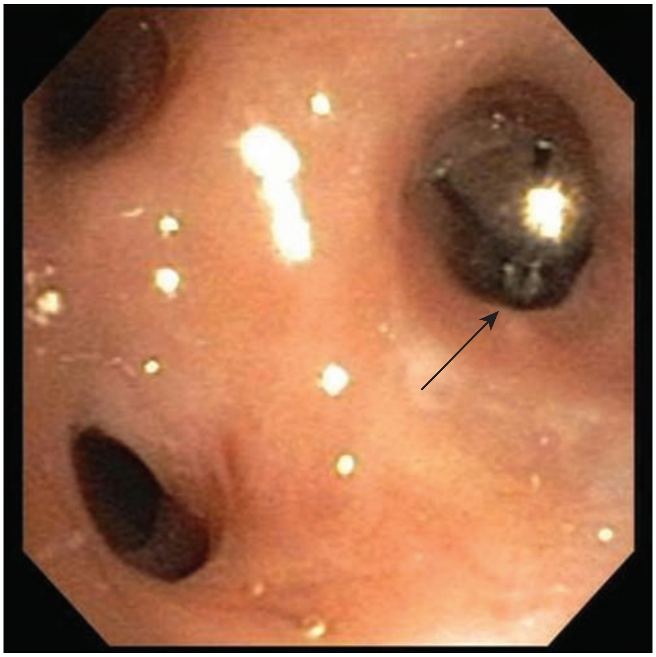

Figure 34-4 A patient presented with a spontaneous pneumothorax from severe emphysema. A chest tube was placed in the left chest and a persistent air leak was noted. Balloon occlusion localized the leak to the left upper lobe anterior segment. A one-way endobronchial valve was placed *(arrow)* with complete air leak resolution.

BRONCHOSCOPIC TREATMENTS FOR COMMON BENIGN LUNG CONDITIONS

One of the major advances in therapeutic bronchoscopy over the past decade has been the development of bronchoscopic interventions for highly prevalent lung diseases, such as asthma, chronic bronchitis, and emphysema.

Bronchoscopic Lung Volume Reduction

The National Emphysema Treatment Trial (NETT) demonstrated the role of lung volume reduction surgery (LVRS) as the first major surgical intervention for emphysema to improve patient symptoms, as well as mortality, in certain patient subsets.[61] Unfortunately, these benefits were associated with an approximate 5% procedural mortality and substantial perioperative morbidity, including persistent air leaks and cardiac arrhythmias. These factors spurred development of minimally-invasive bronchoscopic approaches to achieve similar clinical efficacy as achieved in the NETT trial, but with less morbidity and mortality.

Endobronchial valves (EBVs) have been studied most extensively and are designed to limit ventilation to the most severely involved lung regions in emphysema and to reduce total lung volume, residual volume, and dynamic hyperinflation.[62–65] When placed correctly, the valves allow one-way flow of secretions and air out of

Video 34-5 A patient with severe, heterogeneous, upper lobe-predominant emphysema who was enrolled in a clinical trial of endobronchial valves. The video demonstrates valve deployment device positioning and valve deployment. *Video available on AccessMedicine.com.*

the occluded pulmonary segment, but prevent air entry beyond the valve (Video 34-5).

The pivotal LIBERATE (Zephyr, PulmonX—Redwood City, CA, USA) and EMPROVE (Spiration, Olympus—Seattle, WA, USA) randomized controlled trials found that both EBVs were effective in improving forced expiratory volume in the first second (FEV_1) and multiple objective measures of patient symptoms and performance. The benefit was derived in patients with significant air trapping (residual volume >175%), hyperinflation, and heterogeneous, upper-lobe predominant emphysema with intact fissures and no collateral interlobar ventilation.[66,67] Benefit may also be derived in patients with homogeneously distributed emphysema, but to a lesser degree.[68] Proper patient selection is paramount; important considerations include the degree of heterogeneity of emphysema, the presence of significant air trapping and hyperinflation, and the presence of intact lobar fissures.

■ Bronchoscopic Airway Therapies in COPD and Asthma

While the available evidence is largely preliminary in nature, exciting new treatment modalities are at varying stages of development for airway-dominant COPD. In contrast to the aforementioned bronchoscopic lung volume reduction therapies that impart functional and symptomatic relief through targeted lung volume reduction, the following treatment strategies are aimed at reducing airway inflammation and peripheral airway resistance.

■ Targeted Lung Denervation

Targeted lung denervation (TLD) is another bronchoscopic adaptation of surgical vagotomy, which was commonly used to treat airway disease in the 1930s to 1950s. Using a dual-cooled radiofrequency (RF) catheter (Nuvaira—Minneapolis, MN, USA), parasympathetic nerves running along the outer surface of the bilateral mainstem bronchi are heated at a specific depth, producing ablation external to the airways, with minimal impact on the epithelium or cartilage. The AIRFLOW trial, the first randomized controlled trial studying this modality, demonstrated TLD-treated patients had significantly fewer respiratory adverse events between 3 and 6.5 months post-randomization compared with patients undergoing sham bronchoscopy.[69] An important, larger, multicenter trial is underway.

■ Cryospray

With use of a cryospray directed at treating the chronic bronchitis COPD phenotype, metered liquid nitrogen (MCS, Rejuvenair System, CSA Medical Inc—Lexington, MA, USA) is delivered bronchoscopically at −196°C in a circumferential pattern into the lobar and segmental airways. Rapid epithelial layer freezing preserves the extracellular matrix, allowing healthy cells to repopulate with fewer goblet cells without scarring or inflammation. To date, two small proof-of-concept studies have demonstrated safety and feasibility.[70] A pivotal trial in the United States is currently underway.

■ Bronchial Thermoplasty

Chronic asthma is a major cause of morbidity, increased health care utilization and cost, and death. Bronchial thermoplasty (BT) delivers controlled radiofrequency energy to the bronchial wall of conducting airways with the intent of inhibiting airway smooth muscle contractility, thereby attenuating bronchoconstriction during asthma exacerbations.

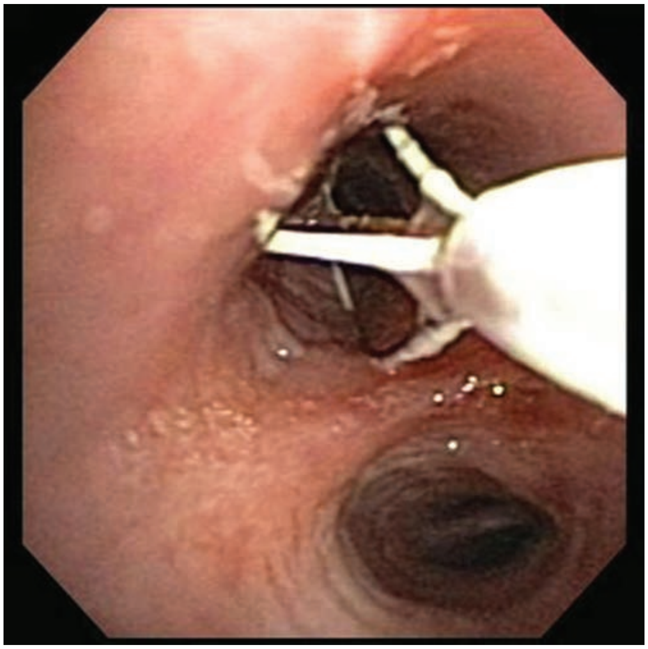

Figure 34-5 Radiofrequency array used in the airway for bronchial thermoplasty in patients with severe asthma.

BT is performed using a radiofrequency device that delivers thermal energy to the bronchial wall during an outpatient bronchoscopy. Three separate procedures are performed in order to treat all accessible upper and lower lobe airways ranging from 3 to 10 mm in diameter (Fig. 34-5). The initial randomized, multicenter Airway Intervention with Radiofrequency (AIR) trial in patients with moderate to severe disease demonstrated decreased asthma exacerbations in the group undergoing BT compared with patients on standard medical treatment alone.[71] This study was followed by a randomized, sham-controlled, multicenter trial (AIR2) that demonstrated significant improvement in the primary endpoint—asthma-related quality of life.[72] Although an increase was noted in early posttreatment asthma exacerbations requiring emergency department visits and hospitalizations, long-term follow-up data showed decreased asthma-related health care utilization for patients undergoing BT compared with those undergoing sham procedure.[73] Based on these data, BT received FDA approval for patients with severe asthma in April 2010, but procedural reimbursement remains problematic with many private insurers.

MEDICAL PLEUROSCOPY

Pleural effusions develop as a result in perturbations of the hydrostatic or oncotic pressure gradients that mediate normal pleural fluid production (transudates), or due to alterations in vascular permeability that lead to excess fluid accumulation (exudates). Congestive heart failure is the most common cause of transudates; management entails diligent diuresis and maintenance of optimal volume status. In contrast, exudates may be caused by a variety of inflammatory, infectious, or malignant etiologies. Utilizing a host of clinical, serologic, and pleural fluid–based evaluations, the etiology of an exudative effusion may be deciphered and managed accordingly. However, despite in-depth evaluation, the etiology and optimal management may remain elusive. In this setting, pleural inspection and biopsy may be necessary to identify the source of the effusion and to direct appropriate treatment.

Traditionally, pleural inspection and biopsy was performed by thoracic surgeons utilizing single-port, video-assisted thoracoscopic surgery. The procedure is performed under general anesthesia, most commonly with a double-lumen endotracheal tube used to isolate the involved hemithorax. Medical pleuroscopy was developed based on the concept that pleural inspection and biopsy can be performed without need for general anesthesia and intubation. With medical pleuroscopy, patients are given generous local anesthesia and breathe spontaneously while receiving moderate sedation for comfort. A single-entry port is created, and the semi-rigid or rigid pleuroscope is inserted into the chest. Due to the presence of the effusion and an open pleural space, adequate visualization for pleural inspection and biopsy can be acheived.[74,75] If necessary, talc poudrage may be performed following pleural biopsy, and a chest tube placed to achieve lung expansion.

SUMMARY

Technologic advances in bronchoscopy continue to improve the bronchoscopist's ability to perform minimally-invasive, accurate evaluations of the tracheobronchial tree and to implement an ever-increasing array of therapeutic and palliative airway interventions across broader disease processes. The role of therapeutic bronchoscopy will continue to evolve as further improvements are made in bronchoscopes, accessory equipment, imaging techniques, and novel technologies to treat lung diseases in which bronchoscopy was once thought to have no role. Therapeutic bronchoscopy may soon be used to provide treatment for conditions that traditionally have been treated with surgery. The major challenges in adopting many new bronchoscopic techniques into routine clinical practice include ensuring adequate procedural competence of bronchoscopists and having well-designed studies to delineate the appropriate use of the interventions.

CHAPTER 35

Diagnostic Thoracic Surgical Procedures: Thoracoscopy, VATS, RATS, and Thoracotomy

Robert E. Merritt

INTRODUCTION

Thoracoscopy, video-assisted thoracic surgery (VATS), robotic-assisted thoracic surgery (RATS), and thoracotomy are well-established surgical techniques used by thoracic surgeons to diagnose and treat benign and malignant diseases involving the thorax.

Thoracoscopy first emerged as a diagnostic tool in the early 20th century when therapeutic pneumothorax became the surgical treatment of choice for tuberculosis. In 1910, Hans Christian Jacobaeus performed the first thoracoscopic intrapleural pneumolysis for collapse therapy in the treatment of tuberculosis.[1–3] He used a rigid cystoscope with a light source to access the pleural cavity and perform a pneumolysis. After development of effective antimicrobial therapy for tuberculosis, thoracoscopy evolved as an effective diagnostic procedure to evaluate pleural effusions and pleural disease.[4] During direct diagnostic thoracoscopy, a fiberoptic mediastinoscope or bronchoscope was placed through a small intercostal incision; pleural fluid could be aspirated and sent for analysis (Fig. 35-1). In addition, the parietal pleura, visceral pleura, fissures, hilum, and diaphragm could be inspected directly.[5]

By 1990, thoracoscopy evolved into VATS. Development of high-resolution video cameras and endoscopic linear mechanical stapling devices allowed the expansion of application of VATS into the diagnosis and treatment of pulmonary nodules and interstitial lung diseases (ILDs).[6,7] The use of diagnostic thoracotomy has declined significantly since the emergence of VATS; however, the diagnostic thoracotomy may be necessary in cases in which VATS is not feasible (Table 35-1).

TECHNICAL CONSIDERATIONS

VATS is performed in the operating room under general anesthesia. A double-lumen tube is placed to isolate the lungs to enable establishment of one-lung ventilation, which is essential for performing the procedure. The use of one-lung ventilation creates sufficient space for maneuvering within the hemithorax to perform the planned procedure. Carbon dioxide (CO_2) insufflation also can be used to provide additional working space within the chest cavity by lowering the position of the diaphragm. The more inferiorly located diaphragm provides better exposure of the costophrenic sulci and lower lobes. When CO_2 is used, the maximum insufflation pressure is maintained below 6 mm Hg to avoid decreased venous return to the right heart and associated hypotension.

The typical VATS procedure utilizes three to four incisions that range from 5 to 12 mm in size. The incisions are usually arranged in a triangular configuration, with the area of interest located in the center of the triangle (Fig. 35-2). A 5- or 10-mm fiberoptic thoracoscope is connected to a video camera and is most commonly inserted into the most inferiorly placed VATS incision (Fig. 35-3). The chest cavity is clearly visualized on a video monitor and the parietal pleura, visceral pleura, hilum, diaphragm, and mediastinum can be directly inspected. Upon completion of the procedure, a chest tube is inserted under direct visualization through one of the VATS incisions to evacuate air and pleural fluid during the early postoperative period. Simple diagnostic VATS procedures are typically well tolerated, and patients can be discharged after 1 to 2 days in the hospital. Currently, the disease processes assessed using VATS are listed in Table 35-2.

Management of Pleural Disease

Both malignant and benign diseases of the pleura may be diagnosed and managed with VATS. Although thoracentesis (including pleural fluid cytology analysis) is the initial diagnostic tool of choice for an undiagnosed pleural effusion, VATS procedures provide a higher diagnostic yield: 90% to 100% compared with 60% to 80%

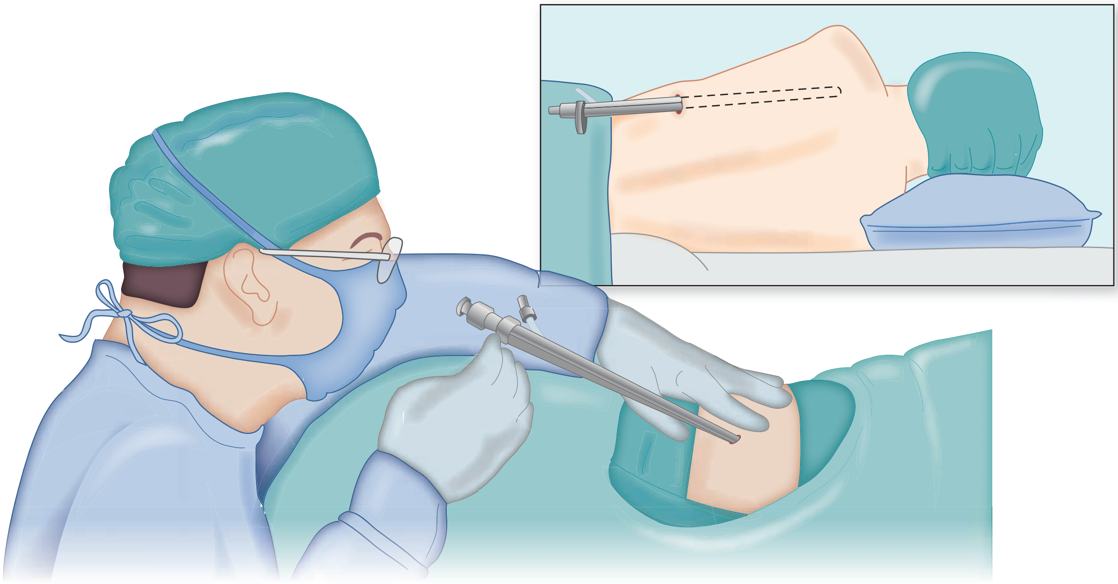

Figure 35-1 Use of a rigid bronchoscope as a thoracoscope.

TABLE 35-1 Contraindications to Video-Assisted Thoracic Surgery (VATS)

Severe hypoxia
Previous pneumonectomy or bilobectomy
Mechanical ventilator dependence
Severe chronic obstructive pulmonary disease
Pleural adhesions
Previous pleurodesis procedure
Coagulopathy
Recent acute myocardial infarction
Severe pulmonary hypertension

for thoracentesis.[8–10] When the diagnosis of a pleural effusion is not determined following thoracentesis, VATS can be utilized to obtain pleural fluid and pleural biopsies for definitive diagnosis.

Malignant pleural effusions usually present as a result of an obstruction of subpleural lymphatics and are associated with advanced primary lung cancer or metastatic epithelial carcinomas that involve the lung. VATS may provide both diagnostic and therapeutic value in the management of malignant pleural effusions. A pleurodesis can be achieved by instilling chemical agents, such as talc, doxycycline, bleomycin, or tetracycline into the pleural cavity to promote pleural adhesion formation. The process obliterates the potential space between the parietal pleura and visceral pleura, thus preventing accumulation of pleural fluid. Efficacy rates in the range of 94% to 96% for VATS pleurodesis for malignant pleural effusions have been reported,[11,12] along with a morbidity rate of 2.6%.[12] In essence, the VATS approach for diagnosis and management of malignant pleural effusions is highly effective because it provides minimally invasive access to the thoracic cavity for sampling of fluid and pleural tissue, and it enables lysis of loculated adhesions and instillation of a chemical pleurodesis agent.

The most common benign condition involving the pleura is an infection of the pleural space or empyema. Patients who present with pneumonia often have associated pleural effusions, which may be either a parapneumonic effusion or an empyema (Chapter 76). The pleural fluid should be sampled with thoracentesis to enable the distinction between parapneumonic effusion and empyema. If the pleural fluid Gram stain or culture is positive for a pathogen, or if the fluid pH is less than 7.1, an empyema is diagnosed.

TABLE 35-2 Current Indications for Video-Assisted Thoracic Surgery (VATS)

Diagnosis of pleural effusion
Drainage of empyema
Pleurodesis
Diagnosis of a suspicious pulmonary nodule
Biopsy of the pleura
Lung biopsy for diagnosis of interstitial lung disease
Resection of pulmonary metastatic nodules
Resection of primary lung carcinoma
Biopsy of mediastinal lymph nodes
Resection of blebs or bullae for treatment of spontaneous pneumothorax
Drainage of pericardial effusion

Video 35-1 Use of VATS in drainage of empyema. *Video available on AccessMedicine.com.*

The classification of empyema is based on the temporal evolution of the pleural space infection and dictates the optimal management. Three phases of empyema have been described: (1) The *exudative phase*, an initial phase characterized by free-flowing purulent fluid within the pleural space. Simple drainage with chest tube thoracostomy and intravenous antibiotics is usually sufficient to manage the pleural effusion. (2) The *fibropurulent phase*, characterized by loculated pleural fluid collections and fibrinous exudative deposits on the visceral pleural surfaces. In this phase, the empyema often requires VATS or thoracotomy to lyse adhesions, break up loculations, and promote drainage of the purulent pleural fluid (Video 35-1). (3) The *fibrous phase*, characterized by formation of a thick, fibrous rind on the visceral pleural surface of the lung. A thoracotomy is usually required to achieve a complete decortication.

Early decortication using a VATS-based approach during the fibropurulent phase is highly effective and may significantly decrease morbidity associated with empyema.[13] VATS offers a decided advantage over simple chest tube thoracostomy because of multiple factors: (1) Loculated purulent fluid may be completely drained, since adhesions are directly visualized and lysed during VATS. (2) Atelectatic lung may be re-expanded under direct vision. (3) Chest tubes can be placed in the appropriate position for optimal drainage in the postoperative period.

The definitive drainage of purulent fluid associated with empyema using VATS can significantly improve patient outcomes and prevent progression to a fibrothorax, which often requires an open thoracotomy.

Evaluation of Lung Parenchymal Disease

Diagnosis of the solitary pulmonary nodule remains one of the most common indications for VATS. A widely cited, multi-institution, randomized study demonstrating a 20% reduction in lung cancer mortality using low-dose computed tomography (CT) to screen for lung nodules in patients at risk for lung cancer[14] has certainly increased enthusiasm for screening programs and enhanced detection of indeterminate pulmonary nodules.

Currently available modalities for the diagnosis of indeterminate solitary pulmonary nodules include high-resolution CT, positron emission tomography (PET), CT-guided fine-needle aspiration (FNA), and VATS. In a randomized trial for evaluation of solitary lung nodules, CT scans performed with intravenous contrast administration have been shown to have an overall accuracy rate of 77%, sensitivity of 98%, and specificity of 58%.[15] The coupling of PET scan–based images with CT scans is often useful to determine if a lung nodule is hypermetabolic, which increases the probability of malignancy (Chapter 30). In cases of granulomatous diseases, PET scans may generate false-positive results, as inflammatory cells readily accumulate the tracer employed, 18-fluorodeoxyglucose (^{18}F-FDG). The sensitivity and specificity of PET–CT scanning in the evaluation of indeterminate solitary pulmonary nodules have been reported at 92% and 90%, respectively.[16]

Development of VATS has improved the diagnostic yield in evaluation of indeterminate solitary pulmonary nodules. This minimally invasive technique is well tolerated. Patients experience less postoperative pain and recover more quickly compared with patients who undergo conventional open thoracotomy.

Pulmonary nodules located in the outer third of the lung parenchyma are ideally suited for VATS wedge excisional biopsy. For lung lesions smaller than 10 mm, localization can be facilitated using transthoracic wire placement into the area of the lesion under CT guidance prior to the VATS procedure. In addition, the technique of navigational bronchoscopy (Chapter 34) can be employed to inject dye or place fiducial markers in close proximity to small nodules that might be difficult to locate during VATS. The diagnostic yield for VATS using wedge excision of a pulmonary nodule approaches 100%. Furthermore, since morbidity and mortality rates are exceedingly low, the VATS technique is ideal for evaluation of indeterminate pulmonary nodules (Video 35-2).

Video 35-2 Use of VATS in evaluation of indeterminate pulmonary nodule. *Video available on AccessMedicine.com.*

Although diffuse ILDs often present with characteristic patterns on CT scanning, histologic confirmation is often necessary to determine appropriate treatment. Reports indicate that in as many as 84% of cases of ILD evaluated with surgical lung biopsy, the course of therapy is altered by the biopsy findings.[17]

The VATS technique has been shown to result in less postoperative pain and lower morbidity compared with thoracotomy performed for purposes of lung biopsy.[18,19] Furthermore, in a randomized, controlled clinical trial, VATS and thoracotomy appear equivalent in postoperative outcomes when performed for diagnosis of ILD.[20] Given this diagnostic equivalency, and, in the author's experience, reduced postoperative pain, shorter hospital stay, and faster recovery associated with VATS, it remains the preferred diagnostic technique for patients with ILD who are ambulatory and have sufficient pulmonary reserve to tolerate one-lung ventilation. Thoracotomy is reserved for patients who are ventilator-dependent and too hypoxic to tolerate one-lung ventilation.

Robotic-Assisted Thoracoscopic Surgery (RATS)

The robotic surgery platform is becoming more commonly utilized for surgical management of early-stage non–small-cell lung cancer. According to data from the Society of Thoracic Surgery General Thoracic database, fewer than 50% of patients undergo thoracoscopic lobectomy for surgical management of early-stage lung carcinoma.[21] The impediments to the widespread application of VATS lobectomy may be related to the underlying limitations of the technique, which include two-dimensional optics, rigid instrumentation, and poor ergonomics. Robotic-assisted lobectomy has become more prevalent in surgical resection for lung carcinoma.[22–24] The Da Vinci Xi robotic platform (Sunnyvale, CA) has provided some improvements over conventional thoracoscopic surgery, such as a three-dimensional

high-definition video-monitoring system, multijointed instruments for better dexterity, and a fully integrated linear endomechanical stapler, which make robotic surgery more intuitive and closer to conventional open surgery. Comparative studies between RATS lobectomy and VATS lobectomy have produced mixed results. A large Society of Thoracic Surgeons database study demonstrated that RATS lobectomy operative times were longer, but the complication rate, hospital length of stay, lymph node upstaging, and 30-day mortality were equivalent with VATS lobectomy.[25] However, a large hospital database study demonstrated that robotic-assisted lobectomy was costlier and had longer operative times compared with VATS lobectomy. Similarly, a small, single-institution study reporting on the initial experience of robotic-assisted lobectomy demonstrated equivalent mortality, complications, and lymph node counts compared to thoracoscopic lobectomy. The RATS approach has the potential to supplant the traditional VATS approach as robotic technology becomes more widely adopted.

The standard port placement for a RATS lobectomy includes three 8-mm ports and one 12-mm port along the 8th intercostal space (Fig. 35-4). The pulmonary artery dissection is performed with the bipolar grasper, and the division of the pulmonary artery is performed with an integrated robotic linear stapler (Video 35-3). The pulmonary vein also is dissected with the bipolar grasper and divided with the linear robotic stapler (Video 35-4). The final step of the RATS lobectomy is the division of the bronchus with the robotic stapler (Video 35-5). The removal of lymph nodes is also a very important part of the RATS lobectomy, which provides important staging information.

SUMMARY

Thoracoscopy, VATS, RATS, and thoracotomy are valuable diagnostic tools employed in the evaluation of benign and malignant diseases of the pleura and lung. VATS has emerged as a primary diagnostic method for diagnosis and treatment of malignant pleural effusions and empyema. In addition, VATS has improved the diagnostic yield in evaluation of indeterminate solitary pulmonary nodules. VATS has largely replaced diagnostic thoracotomy for ILD, since VATS results in less postoperative pain, shorter hospital stay, and faster postoperative recovery. The RATS approach had demonstrated some improved outcomes compared to VATS for pulmonary lung resections for early-stage non–small-cell lung carcinoma.

CHAPTER 36

Evaluation of Respiratory Impairment and Disability

Lisa Ruvuna
Akshay Sood

INTRODUCTION

Management of a patient with chronic lung disease does not end with its treatment. Those with chronic pulmonary disorders need additional assistance and guidance on issues related to respiratory impairment, including causation or attribution; apportionment; eligibility for, and access to, various compensation systems; workplace modifications or removal from the workplace; and vocational and other forms of rehabilitation. Unfortunately, most physicians avoid providing these services, often with disastrous socioeconomic and medical consequences for the patient.

Multiple reasons underlie the general attitude of physician reluctance in addressing impairment. These include a fear and poor understanding of the legal system as it relates to work-related diseases, pervasive confusion about various compensation systems, a mistaken notion that those who seek impairment assistance are usually malingerers, lack of training in impairment evaluation, and a desire to avoid uncompensated, and often onerous, efforts in the context of an already burdensome clinical schedule. This chapter provides an understanding of this complex, but ignored, area in clinical pulmonary medicine.

TERMINOLOGY

This field of impairment and disability evaluation bridges medicine and law; hence, its terminology, drawn from both fields, can be confusing.

Impairment and Disability

The terms *impairment* and *disability* are often used interchangeably, but they are not synonymous. In 2001, the World Health Organization (WHO) developed the International Classification of Functioning, Disability and Health (ICF),[1] which identifies the dynamic relationship between impairment, disability, and disease. Impairments are problems in body function or structure, such as significant deviation or loss.[1,2] Disability is an umbrella term for activity limitations and participation restrictions in an individual with a health condition, disorder, or disease.[3]

For a patient with chronic lung disease, the goal of respiratory impairment evaluation is objective measurement of the extent of loss of function, primarily through application of pulmonary function or exercise testing. The physician plays a key role in impairment evaluation. On the other hand, the impact of the respiratory impairment on a person's ability to perform day-to-day activities or involvement in life situations, also termed *activity limitations* and *participation restrictions*, respectively, is called *disability*, which is typically determined through application of administrative and legal instruments by experts in these areas. The experts not only rely upon the evaluation of impairment provided by the physician, but also take into consideration other social and legal issues, as well as the energy requirements of the occupation. Impairment may occur without disability, and disability may occur without measurable impairment. Furthermore, two individuals with exactly the same respiratory impairment may suffer differing impacts on their lives and, consequently, have different levels of disability.

Respiratory impairment may be temporary or permanent. In contrast to temporary impairment, permanent impairment is not expected to improve with time or treatment. Disability may be partial or total. Total disability implies that an individual is unable to perform any work of the kind that he or she has the skills and qualifications to perform. Partial disability implies that an individual is able to perform some, but not all, of the work.

Causation

Causation or attribution refers to whether an exposure has been a "substantial" contributing factor in either causing or exacerbating lung disease. The level of certainty required in determining causation for occupational lung disease is different from the usual standard of 95% certainty used in medical research. The commonly accepted standard of certainty for occupational cases is that the illness is substantially caused, or exacerbated by, an occupational exposure on a "more probable than not" basis, or a level of certainty greater than 50%.

Apportionment

Apportionment describes the relative contribution of multiple factors to the total respiratory impairment. For instance, both chronic inhalational asbestos exposure and cigarette smoking may be contributory factors to lung cancer. From a scientific perspective, it is usually difficult, if not impossible, to "apportion" the relative roles of multiple exposures in causation of an individual's complex, multifactorial disease. Physicians are often asked to state their opinion on apportionment in the context of the body of available knowledge in that area.

AMERICANS WITH DISABILITIES ACT

Although many physicians think of impairment assessment as an evaluation that follows injury, or termination of employment, or is undertaken at an advanced stage of lung disease, in reality, important assessments also are made prior to the start of a job. The Americans with Disabilities Act (ADA), which was enacted by the United States in 1992, produced a fundamental change in the way in which physical impairments are viewed at the workplace.

Many of the regulations established by the ADA remove barriers to enable equal access to services and equal opportunities to societal needs such as employment. Prior to the ADA, it was common for employers to administer medical assessments (i.e., physical employment evaluations, comprehensive medical examinations) as part of the application process for employment.[4] During the interview stage, preemployment assessment are not allowed. Once a conditional offer is made, an employment entrance exam may be requested, with denial of employment if it is deemed that the individual is unable to perform the essential requirements of the job (with or without accommodations).[4,5]

The other major change in the determination of work-related physical fitness is that businesses are required to make "reasonable" accommodations for physical impairments, as long as the impairments do not interfere with the essential requirements of the job. Employers are not, however, required to make unreasonably extensive changes to a work area or to undertake "action requiring significant difficulty or expense" to accommodate an otherwise qualified applicant.

IMPAIRMENT SYSTEMS COMMONLY USED IN THE UNITED STATES

Patients seeking an impairment evaluation can be usually classified into three general types: (1) those with advanced lung disease who apply for disability benefits under the Social Security Impairment program; (2) those with work-related lung disease who apply under the Workers' Compensation System (but also specialized programs, such as the Black Lung Benefits Act for coal mine workers); and (3) those who develop lung disease while working for certain employers, such as the U.S. Veterans Administration. The most commonly used impairment guidelines in the United States are the Social Security Impairment program and the Workers' Compensation System. Each are discussed in greater detail in subsequent sections.

Social Security Impairment

The U.S. Social Security Administration incorporates two programs that provide financial and rehabilitative benefits to disabled individuals. Both require objective demonstration of disability using medical standards set forth in the Social Security Act.

The first program is orchestrated through Title II of the Act, known as Social Security Disability Insurance. The program is available to individuals who are insured as a result of their contributions to the Social Security Trust Fund (through federal taxes paid on employment earnings during their work careers). The second is orchestrated through Title XVI of the Act, known as Supplemental Security Income or SSI. This program is available to disabled individuals who have limited income or resources and who are not covered by contributions to the Social Security Trust Fund.

For adults, the definition of disability is the same whether the application for benefits is made under Title II or Title XVI of the Social Security Act. The Social Security Administration defines disability as "the inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment(s) which can be expected to result in death, or which has lasted or can be expected to last for a continuous period of not less than 12 months." The methods used for disability evaluation under Social Security are important for the physician to understand for two reasons: (1) disability designation under Social Security is a common and important source of financial support for many patients who are under the care of pulmonary physicians, and (2) the pulmonary physician often takes an active role in helping determine eligibility under this program.

Evaluation of disability under Social Security is a staged process, beginning with application to a local Social Security field office or the Office of Disability Determination Services (DDS). The Office of DDS gathers objective medical information primarily from the treating physician, who is the preferred source of medical evaluation. If the available information is insufficient to make a determination of disability, the DDS may purchase additional testing and/or request examination from a consultant, such as a pulmonary physician.

The Social Security Administration has decided that certain specific impairments of each major body system are severe enough to prevent a person from engaging in any gainful employment and, therefore, serve as prima facie evidence that disability exists. These impairments have been codified as the Listings of Impairments.[6] Listings under the respiratory system include specific categories of disease severity, including chronic respiratory disorders; asthma; cystic fibrosis; pneumoconiosis; bronchiectasis; mycobacterial, mycotic, and other chronic persistent infections of the lung; cor pulmonale due to chronic pulmonary vascular hypertension; sleep-related breathing disorders; and lung transplantation.

If a claimant cannot meet the severity criteria of the Listings, the claimant may still receive an award of benefits by presenting pertinent medical information to the DDS. An initial judgment may then be made by the DDS, but the claimant has the right to challenge an unfavorable decision and to have it reviewed by other members of the DDS staff. If the decision is still unfavorable, the claimant may appeal to the Office of Hearings and Appeals for review by an administrative law judge, who may request expert physician testimony before making a decision. Once again, the claimant may request that an unfavorable decision be reviewed by an appeals council.

The Social Security program has some unusual requirements that distinguish it from other compensation programs: (1) The program requires a "hard copy" of the volume–time curve of a recent spirogram obtained following administration of inhaled bronchodilator when obstruction is present. Similarly, the program requires legible tracings of the breath-hold maneuver for diffusing capacity. (2) The program incorporates arbitrary, height-specific cut points for men and women for spirometric parameters or diffusing capacity for deciding impairment status; these cut points are not determined by race or ethnicity. (3) The program accepts an arterial blood gas measured during steady-state *submaximal* exercise at a work rate of five metabolic equivalents (METs) for rating impairment in gas exchange. Alternatively, it accepts graphical printouts of pulse oximetry on room air at rest or after a 6-minute walk test for evaluating gas exchange impairment. (4) The program denotes the patient as either impaired or not impaired, rather than specifying a percent impairment. In this setting of binary categorization, those considered impaired under Social Security criteria are expected to have a level of impairment sufficient to prevent working for a period of 1 year or longer. (5) Unlike Workers' Compensation programs, the Social Security program does not focus on occupational causation. The sole criterion for granting benefits is whether the claimant is able to participate in gainful employment. (6) The Social Security program also takes into account impairment from coexisting nonpulmonary conditions, such as substance abuse.

Workers' Compensation System

The Workers' Compensation system is a "no-fault" system of medical care and disability insurance in which private insurers or self-insured employers pay benefits to an employee sustaining an injury or illness due to workplace exposure. Under Workers' Compensation rules, workers cannot sue their employer for injury or illness.

The rules for the Workers' Compensation system vary from one state to another, but they usually follow one of the six editions of the American Medical Association (AMA) Guides to the Evaluation of Permanent Impairment.[3] The various editions of the AMA Guides contain markedly different sets of recommendations on impairment evaluation, so one must choose the right edition for the purpose. Use of the wrong edition may result in an erroneous impairment rating. While other guidelines are available on the Internet without charge, use of web-based AMA Guides carries a fee.

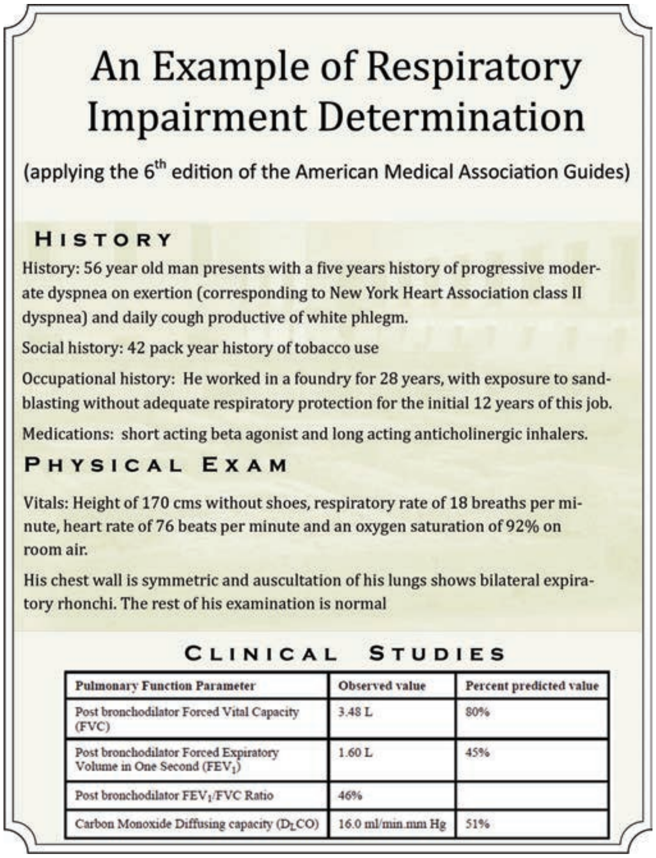
The sixth edition of the AMA Guides uses a standardized grid that incorporates five classes of impairment severity.[3] The grids incorporate objective, test-based key criteria for defining the impairment class, along with other criteria for fine-tuning the severity grade within a given class. Among the various objective tests, *the most severely affected test result is used to define the impairment class* (Fig. 36-1).

Although the American Thoracic Society (ATS) has also developed consensus guidelines for rating impairment from chronic respiratory conditions and asthma,[7,8] these guidelines may not be accepted by a specific compensation program. While the AMA Guides generally follow the ATS schema, there exist substantial differences between the two guidelines.

FIVE GENERAL STEPS FOR IMPAIRMENT RATING

Five steps constitute the process of completing a respiratory impairment evaluation (Fig. 36-2).

The first step is confirmation of the diagnosis of lung disease. Because of the medicolegal nature of the evaluation, the physician should have greater certainty of the medical diagnosis than is sometimes used in clinical practice. In other words, objective confirmation of the diagnosis is preferable.



An Example of Respiratory Impairment Determination

(applying the 6th edition of the American Medical Association Guides)

HISTORY

History: 56 year old man presents with a five years history of progressive moderate dyspnea on exertion (corresponding to New York Heart Association class II dyspnea) and daily cough productive of white phlegm.

Social history: 42 pack year history of tobacco use

Occupational history: He worked in a foundry for 28 years, with exposure to sandblasting without adequate respiratory protection for the initial 12 years of this job.

Medications: short acting beta agonist and long acting anticholinergic inhalers.

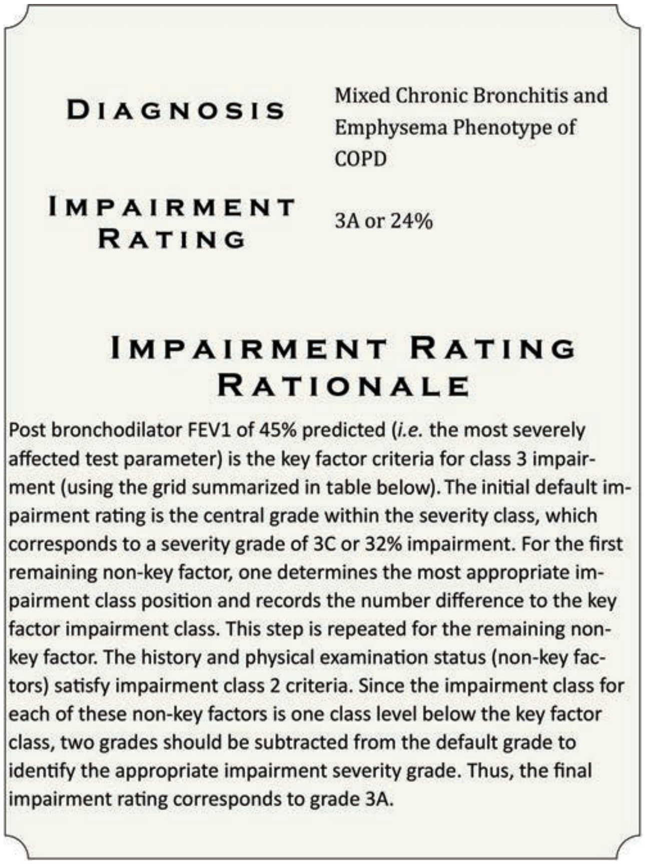
PHYSICAL EXAM

Vitals: Height of 170 cms without shoes, respiratory rate of 18 breaths per minute, heart rate of 76 beats per minute and an oxygen saturation of 92% on room air.

His chest wall is symmetric and auscultation of his lungs shows bilateral expiratory rhonchi. The rest of his examination is normal

CLINICAL STUDIES

Pulmonary Function Parameter	Observed value	Percent predicted value
Post bronchodilator Forced Vital Capacity (FVC)	3.48 L	80%
Post bronchodilator Forced Expiratory Volume in One Second (FEV_1)	1.60 L	45%
Post bronchodilator FEV_1/FVC Ratio	46%	
Carbon Monoxide Diffusing capacity (D_LCO)	16.0 ml/min.mm Hg	51%



DIAGNOSIS Mixed Chronic Bronchitis and Emphysema Phenotype of COPD

IMPAIRMENT RATING 3A or 24%

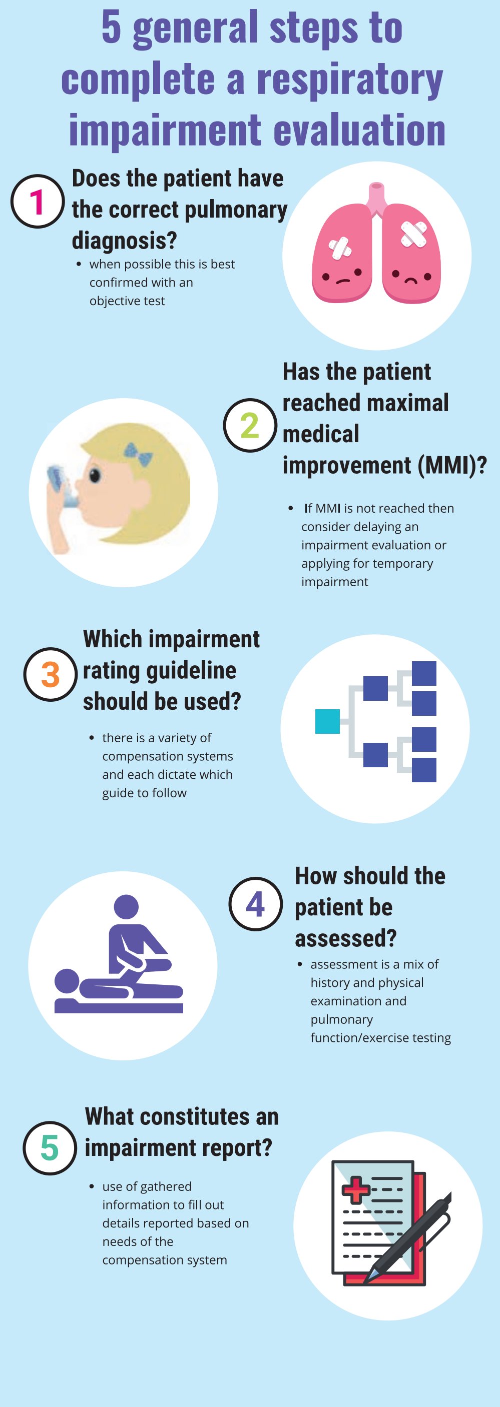
IMPAIRMENT RATING RATIONALE

Post bronchodilator FEV1 of 45% predicted (*i.e.* the most severely affected test parameter) is the key factor criteria for class 3 impairment (using the grid summarized in table below). The initial default impairment rating is the central grade within the severity class, which corresponds to a severity grade of 3C or 32% impairment. For the first remaining non-key factor, one determines the most appropriate impairment class position and records the number difference to the key factor impairment class. This step is repeated for the remaining non-key factor. The history and physical examination status (non-key factors) satisfy impairment class 2 criteria. Since the impairment class for each of these non-key factors is one class level below the key factor class, two grades should be subtracted from the default grade to identify the appropriate impairment severity grade. Thus, the final impairment rating corresponds to grade 3A.

TABLE

	Class	Class 0	Class 1	Class 2	Class 3	Class 4
	Whole Person Impairment Rating (%)	0	2–10%	11–23%	24–40%	45–65%
	Severity Grade (%)		2 4 6 8 10 (A B C D E)	11 14 17 20 23 (A B C D E)	24 28 32 36 40 (A B C D E)	45 50 55 60 65 (A B C D E)
Key Factor: FEV_1					FEV_1 between 45% and 54% of predicted	
	Class	**Class 0**	**Class 1**	**Class 2**	**Class 3**	**Class 4**
	Whole Person Impairment Rating (%)	0	2–10%	11–23%	24–40%	45–65%
	Severity Grade (%)		2 4 6 8 10 (A B C D E)	1114 17 20 23 (A B C D E)	24 28 32 36 40 (A B C D E)	45 50 55 60 65 (A B C D E)
Non-Key Factor: History				Intermittent, moderate dyspnea despite continuous treatment		
	Class	**Class 0**	**Class 1**	**Class 2**	**Class 3**	**Class 4**
	Whole Person Impairment Rating (%}	0	2–10%	11–23%	24–40%	45–65%
	Severity Grade (%)		2 4 6 8 10 (A B C D E)	11 14 17 20 23 (A B C D E)	24 28 32 36 40 (A B C D E)	45 50 55 60 65 (A B C D E)
Non-Key Factor: Physical Findings				Intermittent, moderate findings		

Figure 36-1 An evaluation of respiratory impairment using the American Medical Association (AMA) Guides' 6th edition. The FEV_1 (the most severely impacted parameter) is used as the key factor to identify the initial impairment class with the middle impairment grade of C as the default, in impairment class 3. Non-key factors in history and the physical are each rated as impairment class 2, reducing the severity grade from C to A with an overall impairment rating of 3A.



5 general steps to complete a respiratory impairment evaluation

1 Does the patient have the correct pulmonary diagnosis?
- when possible this is best confirmed with an objective test

2 Has the patient reached maximal medical improvement (MMI)?
- If MMI is not reached then consider delaying an impairment evaluation or applying for temporary impairment

3 Which impairment rating guideline should be used?
- there is a variety of compensation systems and each dictate which guide to follow

4 How should the patient be assessed?
- assessment is a mix of history and physical examination and pulmonary function/exercise testing

5 What constitutes an impairment report?
- use of gathered information to fill out details reported based on needs of the compensation system

Figure 36-2 Infographic of the five steps for a physician to complete a respiratory impairment evaluation.

The second step is defining maximal medical improvement (MMI). MMI occurs at the point when, following maximal therapy, no further clinical or physiologic improvement is expected to occur (although deterioration might). If therapy has not been maximized, the physician should either delay impairment evaluation or give a temporary rating. A permanent impairment evaluation should be performed only at, or after, MMI has been reached.

The third step is identifying the correct guideline for rating impairment. As discussed previously, several compensation systems exist, each with its own unique guideline. Therefore, identification of the compensation system for which the patient is eligible is essential, and the evaluating physician must be familiar with the specific guideline to be used. Of course, some patients may be eligible for more than one compensation program and may apply for more than one program contemporaneously.

The fourth step is to supplement the history and physical examination findings with appropriate objective tests. Performance of these tests should strictly adhere to standards of the ATS.[9–12]

The fifth and final step requires writing a comprehensive report of the patient's history, physical examination, and review of objective tests. The assessment should provide clear and accurate answers, in lay terms, to the questions asked. The evaluation should state the diagnosis and whether MMI has been reached, and it should make note of the presence and degree of respiratory impairment. The specific impairment scheme used, including the specific page and table of the guideline used, should be referenced. In work-related respiratory disorders, causation, apportionment, and work restrictions should also be addressed, as requested.

GENERAL APPROACH FOR EVALUATING RESPIRATORY IMPAIRMENT

After determining patient eligibility for a specific compensation system, as described previously, the physician gathers data relevant to rating respiratory impairment. In general, impairment criteria are based upon history, physical examination, and objective test results.

The medical history focuses on detailed past and present occupational history, tobacco use and environmental exposures, presence and severity of respiratory symptoms, such as dyspnea, cough, sputum production, and wheezing, and medication history. Relevant features in the physical examination include breathing pattern, shape of chest wall, adventitious lung sounds, cyanosis, digital clubbing, and evidence of cor pulmonale.

■ Resting Pulmonary Function Tests

Pulmonary function tests (PFTs) (Chapter 31) are the cornerstone of rating respiratory impairment and should be performed according to the most recent ATS standards.[9–12] Spirometry and diffusing capacity are the key PFTs for assessing respiratory impairment for chronic respiratory conditions. Postbronchodilator spirometry is used when airflow limitation is present. Methacholine challenge tests are used for rating impairment for asthma under the AMA Guides.[3]

Reference standards for rating severity of PFT abnormality may vary based on the impairment rating guidelines used. Adjustment of PFTs for race, ethnicity, and gender is recommended by most impairment guidelines, with the notable exception of the Social Security impairment system, which currently uses uniform height-specific cut points for all individuals, irrespective of race and ethnicity.[13,14] Furthermore, subjects 20 years or older use the same cut points under the Social Security impairment system, without accounting for the normal age-related decline in lung function. Thus, under the Social Security impairment system, older individuals are more likely to be rated as disabled than are younger individuals.

The sixth edition of the AMA Guides uses spirometric reference standards based on the National Health and Nutrition Examination Survey (NHANES) III for Caucasian Americans, Mexican Americans, and African Americans.[3,15] For the remaining population subgroups, no clear guidelines are provided. The latest ATS guidelines recommend using the Global Lung Function Initiative (GLI)-2012, multiethnic spirometry reference ranges, or NHANES III if needed for continuity.[16] For the most part, GLI-12 and NHANES III equations agree when classifying obstructive lung disease except in the elderly.[17,18] However, lack of data from many non-Caucasian populations limits the current utility of GLI-12 reference equations to Caucasians only.[19] Corrected single-breath carbon monoxide diffusing capacity (DLCO) is used under the AMA Guides, ATS guidelines, and Social Security Impairment guidelines for impairment rating, but it is not used under the Veterans

TABLE 36-1 Classification of Respiratory Impairment from Chronic Lung Diseases, Using the Sixth Edition of the American Medical Association (AMA) Guides to the Evaluation of Permanent Impairment

American Medical Association Class	Class 0	Class 1: 2%–10% Impairment of the Whole Person	Class 2: 11%–23% Impairment of the Whole Person	Class 3: 24%–40% Impairment of the Whole Person	Class 4: 45%–65% Impairment of the Whole Person
Severity grade (%)		A (2%), B (4%), C (6%), D (8%), E (10%)	A (11%), B (14%), C (17%), D (20%), E (23%)	A (24%), B (28%), C (32%), D (36%), E (40%)	A (45%), B (50%), C (55%), D (60%), E (65%)
Objective Tests					
FVC (% predicted)	≥80% predicted and	70%–79% predicted or	60%–69% predicted or	50%–59% or	<50% or
FEV_1 (% predicted)	≥80% predicted and	65%–79% predicted or	64%–55% predicted or	45%–54% or	<45% or
FEV_1/FVC%	>Lower limit of normal and/or >75% predicted) and	N/A	N/A	N/A	N/A
D_{LCO} (% predicted)	≥75% predicted	65%–74% predicted	55%–64% predicted	45%–54%	<45%
$\dot{V}_{O_2max}$					
mL/kg/min	>25 or	22–25 or	21–18 or	15–17 or	<15 or
METs	>7.1	6.1–7.1	5.1–6.0	4.3–5.0	<4.3
History	No current symptoms and/or intermittent dyspnea that does not require treatment	Dyspnea controlled with intermittent or continuous treatment or intermittent mild dyspnea despite continuous treatment	Constant mild dyspnea despite continuous treatment or intermittent moderate dyspnea despite continuous treatment	Constant moderate dyspnea despite continuous treatment or intermittent severe dyspnea despite continuous treatment	Constant severe dyspnea despite continuous treatment or intermittent extreme dyspnea despite continuous treatment
Physical Findings	No current signs of disease	Physical findings not present with continuous treatment or intermittent mild physical findings	Constant mild physical findings despite continuous treatment or intermittent moderate physical findings	Constant moderate physical findings despite continuous treatment or intermittent severe physical findings	Constant severe physical findings despite continuous treatment or intermittent extreme physical findings

FVC, forced vital capacity; FEV_1, forced expiratory volume in the first second; D_{LCO}, diffusing capacity of carbon monoxide; $\dot{V}_{O_2max}$, measured maximal exercise capacity; MET or metabolic equivalent is the multiple of basal oxygen consumption, approximately 3.5 mL/kg/min; N/A, not applicable.

Administration guidelines. Crapo's reference standards for D_LCO are used for comparison with measured values with a correction factor used for African Americans and Asian Americans. ATS has recently updated criteria on acceptability and repeatability for D_LCO.[20]

The cut points for impairment classification, as suggested by the various impairment guidelines (Tables 36-1–36-3), are set arbitrarily and may differ from those recommended for assessing degree of lung disease severity by other professional organizations, such as the 2005 ATS statement,[10] or by the Global Initiative for Chronic Obstructive Lung Disease (GOLD).[21] Some investigators have suggested that lung function thresholds should be expressed as a z-score, which converts a raw measurement on a test to a standardized score expressed in units of standard deviations.[22,23] This strategy, although scientifically valid, is not currently used for impairment evaluation.

Methacholine bronchoprovocation tests are useful for assessing bronchial hyperresponsiveness and in rating impairment from asthma under the AMA Guide and ATS guidelines (Tables 36-1 and 36-2).[3,8] The methacholine PC_{20} (provocative concentration of methacholine, expressed as mg/mL that results in at least 20% drop in FEV_1 compared to the pretest baseline; also known as PD20, or "provocative dose," as discussed in Chapter 31, Pulmonary Function Testing) is a key parameter for rating asthma impairment under the sixth edition of the AMA Guides.[3] The performance of methacholine bronchoprovocation tests should also strictly adhere to the ATS guidelines.[24]

■ Exercise Tests

Maximal cardiopulmonary exercise tests are difficult to perform due to need for specialized equipment and trained personnel, are expensive and not readily available, and carry a risk to the patient. Test performance should strictly adhere to the ATS guidelines.[25] Clear agreement on the role of exercise tests in the evaluation of respiratory impairment is lacking. Generally, in cases in which subjective dyspnea is disproportionate to the resting PFT results, or when PFTs are difficult to interpret because of submaximal performance, cardiopulmonary exercise tests may be considered. Such tests may also help identify unanticipated coexisting conditions, such as cardiovascular or pulmonary vascular disease, as the cause of exercise limitation.

Exercise testing may also be useful in determining whether an individual can perform a specific job with a known energy requirement. Under the ATS guidelines, the estimation of impairment from oxygen consumption at peak exercise ($\dot{V}_{O_2peak}$) is based on the

TABLE 36-2 American Thoracic Society (ATS) Classification of Respiratory Impairment

Impairment Class	Normal	Mildly Impaired	Moderately Impaired	Severely Impaired
Work ability		Usually able to perform most jobs	Diminished ability to perform many jobs	Unable to meet physical demands of most jobs including travel to work
FVC (% predicted)	≥80%	60%–79%	51%–59%	≤50%
FEV_1 (% predicted)	≥80%	60%–79%	41%–59%	≤40%
FEV_1/FVC	≥75%	60%–74%	41%–59%	≤40%
D_{LCO} (% predicted)	≥80%	60%–79%	41%–59%	≤40%
$\dot{V}_{O_2max}$ (mL/kg/min)	≥25 (or 7.1 METs)			≤15 (or 4.3 METs)

FVC, forced vital capacity; FEV_1, forced expiratory volume in the first second; D_{LCO}, diffusing capacity of carbon monoxide; $\dot{V}_{O_2max}$, measured maximal exercise capacity; MET or metabolic equivalent is the multiple of basal oxygen consumption, approximately 3.5 mL/kg/min.

TABLE 36-3 Impairment Rating Guidelines for Chronic Obstructive Lung Diseases Using the Social Security, Veterans Administration, American Medical Association (AMA) Guides, and American Thoracic Society (ATS) Guidelines

(A) SOCIAL SECURITY

Height Without Shoes (cm)	Height Without Shoes (in.)	FEV_1 Equal to or Less than (L, BTPS)
≤154	≤60	1.05
155–160	61–63	1.15
161–165	64–65	1.25
166–170	66–67	1.35
171–175	68–69	1.45
176–180	70–71	1.55
≥181	≥72	1.65

(B) VETERANS ADMINISTRATION

Chronic Bronchitis

Pronounced (100% rating): with copious productive cough and dyspnea at rest; PFTs showing a severe degree of chronic airway obstruction with symptoms of associated severe emphysema or cyanosis and findings of right-sided heart involvement

Severe (60% rating): with severe productive cough and dyspnea on slight exertion and PFTs indicative of severe ventilatory impairment

Moderately severe (30% rating): persistent cough at intervals throughout the day, considerable expectoration, considerable dyspnea on exercise, rales throughout chest, beginning chronic airway obstruction

Moderate (10% rating): considerable night or morning cough, slight dyspnea on exercise, scattered bilateral rales

Mild (0% rating): slight cough, no dyspnea, few rales

Emphysema

Pronounced (100% rating): intractable and totally incapacitating; with dyspnea at rest, or marked dyspnea and cyanosis on mild exertion; severity of emphysema confirmed by CXR and PFTs

Severe (60% rating): exertional dyspnea sufficient to prevent climbing one flight of steps or walking one block without stopping; ventilatory impairment of severe degree confirmed by PFTs with marked impairment of health

Moderate (30% rating): with moderate dyspnea occurring after climbing one flight of steps or walking more than one block on a level surface; PFTs consistent with findings of moderate emphysema

Mild (10% rating): with evidence of ventilatory impairment on PFTs and/or definite dyspnea on prolonged exertion

(C) AMA GUIDES AND ATS GUIDELINES

Use criteria outlined in Tables 36-1 and 36-2, respectively, in the text

FEV_1, forced expiratory volume in the first second; BTPS, body temperature and pressure saturated with water vapor.
For mixed obstructive and restrictive lung diseases with gas exchange impairment, evaluate under any of the criteria listed in Tables 36-3(A), 36-6(A), or 36-7.
Social Security impairment system has separate guidelines for patients with bronchiectasis.
Data from Social Security Administration and Veterans Administration.

widely held, but untested, assumption that a worker involved in manual labor can comfortably work at 40% of $\dot{V}_{\mathrm{O_2peak}}$ (corresponding to lower limit of generally accepted normal values for anaerobic threshold) for prolonged periods,[7] and that $\dot{V}_{\mathrm{O_2}}$ requirements can be assigned to specific occupations. Individuals whose $\dot{V}_{\mathrm{O_2peak}}$ is ≤ 15 mL/kg/min would be uncomfortable performing most jobs because they would find it difficult to travel back and forth to their place of employment (Table 36-2).[7] Unfortunately, data on $\dot{V}_{\mathrm{O_2}}$ requirements of most jobs in modern workplaces are not currently available. Furthermore, jobs with the same title may vary considerably in their $\dot{V}_{\mathrm{O_2}}$ requirements from one work site to another.

Submaximal exercise tests at a workload of approximately 17 mL O_2/kg/min (5 METs) or less of exercise can be performed at steady state to obtain arterial blood gases, which are then used to evaluate impairment of gas exchange under the Social Security impairment system when criteria for neither obstructive nor restrictive disorders are met. Oxygen saturation measured by pulse oximetry either at rest or during/after a 6-minute walk test can be alternatively used to evaluate impairment of gas exchange under the Social Security impairment system. Use of submaximal exercise tests or pulse oximetry is however not currently recommended by any other impairment guideline.

For additional information on exercise testing, the reader is referred to Chapter 32, Principles and Application of Cardiopulmonary Exercise Testing.

■ Imaging

Imaging studies are primarily useful for confirming the diagnosis of lung disease. They are less useful in rating respiratory impairment, since the correlation between radiographic abnormality and physiologic dysfunction is imperfect.

Chest radiographic evidence of pneumoconiosis is rated according to the 2011 International Labor Organization's (ILO) International Classification of Radiographs of Pneumoconiosis scheme (also called "B-reading"). The 2011 standards extended the applicability of the Classification to digital chest radiographs. The extent or profusion of small-sized parenchymal opacities is rated as 0, 1, 2, or 3. An intermediate score of 1/0 (i.e., profusion of small opacities greater than 0 but less than 1 profusion score) is often used to confirm the presence of pneumoconiosis.

Some determinations of respiratory impairment are not dependent on PFTs. They are based on environment-related diagnoses (e.g., occupational asthma or hypersensitivity pneumonitis) and warrant proscription of continuing exposure to inciting agents. In addition, impairment may be based on prognosis (e.g., unresectable lung cancer) or public health considerations (e.g., pulmonary tuberculosis).

SCIENTIFIC RATIONALE FOR CHOICE OF TESTS USED FOR IMPAIRMENT EVALUATION FOR CHRONIC RESPIRATORY DISORDERS

Impairment evaluation for chronic respiratory conditions is based on PFT values at rest and with exercise. The premise for these tests is that $\dot{V}_{\mathrm{O_2peak}}$ reasonably measures ability to work, and that resting PFTs, such as forced expiratory volume in 1 s (FEV_1) and D_LCO, reasonably predict $\dot{V}_{\mathrm{O_2peak}}$ values.

■ Oxygen Consumption at Peak Exercise as the Gold Standard for Measuring Ability to Work

Most of the available medical literature appears to support the view that $\dot{V}_{\mathrm{O_2peak}}$ value, expressed as mL/kg/min, is the gold standard for assessing impairment.[26,27] With exercise on a cycle ergometer, $\dot{V}_{\mathrm{O_2}}$ increases linearly with external work,[17] and $\dot{V}_{\mathrm{O_2peak}}$ represents the maximal work an individual can perform during a short burst of activity. Some have advocated use of percent predicted $\dot{V}_{\mathrm{O_2peak}}$ values (i.e., loss of aerobic capacity), instead of $\dot{V}_{\mathrm{O_2peak}}$ expressed in mL/kg/min (i.e., remaining aerobic ability) for evaluating impairment in patients with respiratory disease, since the latter approach overestimates impairment in older and obese subjects (Fig. 36-3).[28,29] In addition, some consider the value for $\dot{V}_{\mathrm{O_2}}$ at anaerobic threshold ($\dot{V}_{\mathrm{O_2}}$ AT) as a better index for work ability than $\dot{V}_{\mathrm{O_2peak}}$.[21] Individuals are unable to sustain work rates above anaerobic threshold values. However, no major guidelines currently use percent predicted $\dot{V}_{\mathrm{O_2peak}}$ values or $\dot{V}_{\mathrm{O_2}}$ AT to rate impairment.

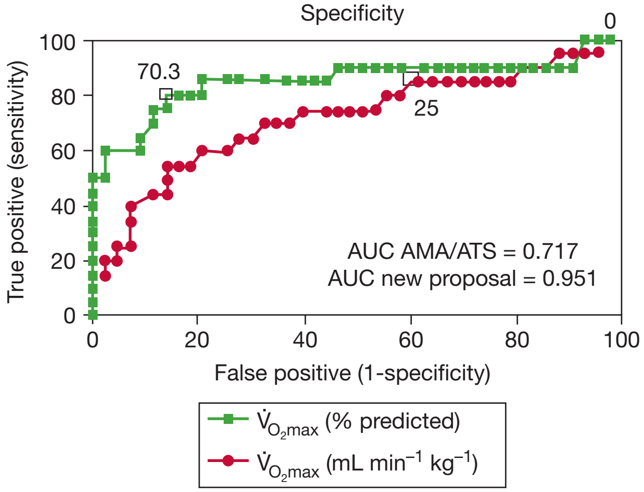

Figure 36-3 Receiver operating characteristics (ROC) curves of two classifications (AMA/ATS vs. new classification proposed by Neder et al.), using the $\dot{V}_{\mathrm{O_2}}$ at anaerobic threshold ($\dot{V}_{\mathrm{O_2}}$AT) as the "gold standard." The *open squares* represent the cutoffs for normality for $\dot{V}_{\mathrm{O_2peak}}$ using the two-classification schema. Neder et al. have advocated the use of percent predicted $\dot{V}_{\mathrm{O_2peak}}$ values (i.e., loss of aerobic capacity) instead of $\dot{V}_{\mathrm{O_2peak}}$ in mL/kg/min (i.e., remaining aerobic ability) for the evaluation of impairment in patients with respiratory disease since the latter approach overestimates impairment in older and obese subjects. AMA, American Medical Association; ATS, American Thoracic Society; AUC, area under the ROC curve; $\dot{V}_{\mathrm{O_2}}$, oxygen consumption. *(Reproduced with permission from Neder JA, Nery LE, Bagatin E, et al. Differences between remaining ability and loss of capacity in maximum aerobic impairment. Braz J Med Biol Res. 1998;31(5):639–646.)*

■ Comparison of Resting Pulmonary Function Tests with Oxygen Consumption at Peak Exercise

Low values for resting PFTs (i.e., FEV_1 or D_LCO) predict low $\dot{V}_{\mathrm{O_2peak}}$ levels; poor scores on the Short Physical Performance Battery (tests that assess lower extremity function); less distance walked during the 6-minute walk test; and a greater risk of self-reported functional limitation.[30,31]

FEV_1 is linearly correlated with $\dot{V}_{\mathrm{O_2peak}}$ levels,[31] but the reported correlations vary widely between studies, resulting in variance values ranging from 0.25 to 0.71.[31–36] Use of absolute versus percent predicted values largely yields similar correlation measures.[35] Although some studies demonstrate that FEV_1 and forced vital capacity (FVC) have similar predictive value for $\dot{V}_{\mathrm{O_2peak}}$ levels,[35] most report FEV_1 to be a stronger predictor than FVC. The 2005 ATS statement indicated that percent predicted FEV_1, rather than FVC, should be used to categorize severity of impairment for all respiratory diseases.[10] The predictive ability of FEV_1 for $\dot{V}_{\mathrm{O_2peak}}$ increases if it is used in combination with another variable, such as D_LCO, minute ventilation ($\dot{V}_E$), or dead space ventilation measure during exercise (V_D/V_T).[35] D_LCO does not predict $\dot{V}_{\mathrm{O_2peak}}$ among healthy controls,[32] but it does so among subjects with COPD and those with occupational lung diseases, where it may account for a variance of 0.25 to 0.76 in various studies.[34,35,37]

Despite the previously noted correlations in population studies, resting PFTs cannot accurately predict $\dot{V}_{\mathrm{O_2peak}}$ values among

TABLE 36-4 Degree of Impairment, as Assessed by Resting Pulmonary Function Tests and Cardiopulmonary Exercise Tests[a19]

Degree of Impairment	Resting PFT (%)	CPET (%)
None	6	28
Mild	26	36
Moderate	38	20
Severe	30	16

PFT, pulmonary function test; CPET, cardiopulmonary exercise test; FEV_1, forced expiratory volume in 1 s.

[a]Among 216 ambulatory patients with COPD with mean percent predicted FEV_1 of 54.1 ± 16.8% and mean age of 57.9 ± 6.9 years

Reproduced with permission from Fink G, Moshe S, Goshen J, et al. Functional evaluation in patients with chronic obstructive pulmonary disease: pulmonary function test versus cardiopulmonary exercise test. J Occup Environ Med. 2002;44(1):54–58.

individuals, particularly those with occupational lung diseases. In a comparison study of impairment ratings obtained using simultaneous resting PFTs and cardiopulmonary exercise tests conducted in 216 ambulatory patients with COPD, the two methods resulted in similar impairment rating in only 30.1%. Ratings were similar between the two methods in the extreme subgroups of normal or severely impaired individuals. 61.1% were found to be less impaired according to exercise testing than according to resting PFTs, and 8.8% were more impaired according to exercise testing than resting PFTs (Table 36-4). These data suggest that use of resting PFTs and exercise testing for rating impairment often yields discrepant results.

PFTs other than FEV_1 and D_LCO also may help predict $\dot{V}_{O_2peak}$ values. These include inspiratory capacity in flow-limited obstructive diseases;[38] peak inspiratory pressure in chronic obstructive diseases;[34] exercise ventilation ($\dot{V}_E$) in both obstructive and restrictive lung diseases;[27] and submaximal exercise tests, including 6-minute walk test duration.[28] Use of these tests is however not currently recommended by any impairment guideline. Performance of maximal voluntary ventilation (MVV) is not recommended except under the Black Lung Benefits Act.[39] MVV is markedly effort dependent and bears a fixed relationship with FEV_1;[40] therefore, it is of limited value.

Finally, both baseline oxygen saturation and the lowest oxygen saturation measured with a finger oximeter probe during a submaximal test correlate with $\dot{V}_{O_2peak}$ in patients with idiopathic pulmonary fibrosis,[28] but not in those with COPD.[41]

SCIENTIFIC RATIONALE FOR CHOICE OF TESTS USED FOR IMPAIRMENT EVALUATION FOR ASTHMA

Asthma is a very common disorder, the presence of which may profoundly impact an individual's ability to perform various kinds of work. Considerations of disability in asthma are discussed below.

Determinants of Work Ability in Asthma

Among subjects with methacholine-confirmed asthma, a lower self-reported work ability is associated with lower PC_{20} value (i.e., higher degree of airway hyperresponsiveness), greater clinical severity of disease (based on minimum medication need to maintain asthma control), and the presence of respiratory symptoms in the workplace.[42] However, no relationships are evident with regard to baseline FEV_1 or FVC in both unadjusted and adjusted analyses.[42] Although controversial, methacholine PC_{20} has been accepted as the key parameter for rating asthma impairment under the sixth edition of the AMA Guides.[3]

Comparison Between Respiratory Symptoms and PC_{20}

For most subjects with asthma, greater breathlessness perceived during asthma attacks is not correlated with greater decline in peak expiratory flow rate[43] or with a lower PC_{20}.[44]

Comparison Between Minimum Medication Need and PC_{20}

Almost all medications used to treat asthma improve PC_{20} values, that is, decrease bronchial hyperresponsiveness.[45–57] In one study, patients with asthma with the minimum medication needed to control symptoms were divided into four groups: (1) those who required no medication; (2) those who required short-acting β_2-agonist occasionally, but not daily; (3) those who required daily short-acting β_2-agonist; and (4) those who required additional inhaled corticosteroid dosing. The mean PC_{20} value was highest in group 1 and lowest in group 4; the differences between each group were significant.[58] Minimum medication need is, therefore, an important predictor for both work ability and airway hyperresponsiveness in asthma.

Comparison Between Percent Predicted FEV_1 and PC_{20}

In a small clinical population of smokers and nonsmokers, as well as in a population of subjects with asthma with concomitant stable bronchiectasis, baseline FEV_1 has been shown to correlate with methacholine PC_{20} values.[59]

IMPAIRMENT RATING FOR SPECIFIC LUNG CONDITIONS

Impairment evaluation for selected populations, including those with asthma or coal workers' pneumoconiosis, and in workers in nuclear weapons factories, is discussed below.

Asthma

Unlike most chronic respiratory conditions, asthma is an episodic disease, and impairment evaluation for asthma is particularly difficult. Therefore, most impairment rating schemes incorporate separate guidelines for rating asthma impairment. Further, the rating schemes differ dramatically with respect to the level of impairment (Tables 36-5A–36-5C).

The methacholine PC_{20} is the key parameter for rating asthma impairment under the sixth edition of the AMA Guides (Table 36-5B).[3] On the other hand, PC_{20} and extent of FEV_1 reversibility are given less weight than are either minimum medication need or postbronchodilator FEV_1 in the multicomponent asthma impairment scoring scheme recommended by the 1993 ATS guidelines (Table 36-5C).[8] Under Social Security impairment criteria, patients with asthma may be rated by FEV_1 or by a clinical history of frequent, severe exacerbations, despite maximal asthma therapy; a methacholine PC_{20} measurement is not required (Table 36-5A). On the contrary, AMA Guides and ATS guidelines do not incorporate frequency of acute exacerbations in the impairment rating for asthma. Given the efficacy of currently recommended asthma therapies, frequent emergency room visits or hospitalizations generally reflect inadequate treatment and failure to achieve the objectives of treatment. The AMA Guides and ATS guidelines instead use minimum medication need for asthma control as a better reflection of the severity of disease for the purpose of impairment assessment than frequency of asthma exacerbations. Hence, it is easy to see why impairment ratings for the same patient with asthma might vary widely among various compensation systems.

Impairment rating for occupational asthma is even more problematic. In these cases, both temporary and long-term impairment evaluation may be performed.[8] Temporary impairment for patients with sensitizer-induced occupational asthma should be performed after removing the worker from exposure. Early cessation of exposure improves prognosis in sensitizer-induced occupational asthma. Sometimes, physiologic tests may be normal, and symptoms and

TABLE 36-5A Impairment Rating Guidelines for Asthma Using the Social Security, Veterans Administration, American Medical Association (AMA) Guides, and American Thoracic Society (ATS) Guidelines

(A) SOCIAL SECURITY
(1) Asthma with chronic asthmatic bronchitis: evaluate under the criteria for chronic obstructive airway disease (Table 36-3A)
(2) Attacks, in spite of prescribed treatment and requiring physician intervention, occurring at least once every 2 months, or at least 6 times a year. Each in-patient hospitalization >24 h for control of asthma counts as two attacks. An evaluation period of at least 12 consecutive months must be used to determine the frequency of attacks
(B) VETERANS ADMINISTRATION[a]
Pronounced (100% rating): asthmatic attacks very frequently with severe dyspnea on slight exertion between attacks and with marked loss of weight or other evidence of severe impairment of health
Severe (60% rating): frequent attacks of asthma (one or more attacks weekly), marked dyspnea on exertion between attacks with only temporary relief by medication; more than light manual labor precluded
Moderate (30% rating): asthmatic attacks rather frequent (separated by only 10- to 14-d intervals) with moderate dyspnea on exertion between attacks
Mild (10% rating): paroxysms of asthmatic type breathing (high-pitched expiratory wheezing and dyspnea) occurring several times a year with no clinical findings between attacks
(C) AMA GUIDES AND ATS GUIDELINES
Use scoring criteria in Tables 36-5B and 36-5C, respectively

[a] In the absence of clinical findings of asthma at time of examination, a verified history of asthmatic attacks must be on record.
Data from Social Security Administration and Veterans Administration.

need for treatment may subside after early cessation of exposure, resulting in 0% measurable impairment. However, such an individual should be considered as 100% disabled on a permanent basis from working in a job that exposes him or her to the specific sensitizing agent.[8] It is not necessary to wait for long-term impairment rating to initiate vocational rehabilitation in such a case.[8] The long-term impairment evaluation is performed using the rating systems devised for nonoccupational asthma at least 2 years after cessation of exposure, when improvement has been shown to plateau.[60]

■ Pneumoconioses

According to the AMA Guides, those who develop pneumoconiosis should limit further exposure to the offending agent, “particularly if radiographic changes have occurred at a relatively young age or if there is associated physiologic impairment.”[3] It follows that an older patient who is nearing retirement, with minimal radiographic change after a long history of exposure, could elect to continue in the workplace under the assumption of a lower risk of developing future disabling disease. Such discretionary decisions should be made

TABLE 36-5B Classification of Respiratory Impairment from Asthma, Using the Sixth Edition of the American Medical Association (AMA) Guides to the Evaluation of Permanent Impairment

Class	Class 0	Class 1	Class 2	Class 3	Class 4
Whole person impairment rating (%)	0	2%–10%	11%–23%	24%–40%	45%–65%
Severity grade (%)		A (2%), B (4%), C (6%), D (8%), E (10%) (minimal)	A (11%), B (14%), C (17%), D (20%), E (23%) (mild)	A (24%), B (28%), C (32%), D (36%), E (40%) (moderate)	A (45%), B (50%), C (55%), D (60%), E (65%) (severe)
Clinical parameters (minimum medication need)	No medication required	Occasional bronchodilator, not daily	Daily low-dose inhaled steroid (<500 μg beclomethasone or equivalent)	Daily medium or high-dose inhaled steroids (500–1000 μg beclomethasone or equivalent) and/or short periods of systemic steroids and a long-acting bronchodilator. Daily use of steroids (systemic and inhaled) and daily use of maximum bronchodilators	Asthma not controlled by treatment
Maximum postbronchodilator percent predicted FEV$_1$	>80%	70%–80%	60%–69%	50%–59%	<50%
PC$_{20}$ (key factor)[a]	6–8 mg/mL	3–5 mg/mL	>0.5–3 mg/mL	0.25–0.5 mg/mL	0.125–0.24 mg/mL

FEV$_1$, forced expiratory volume in the first second; PC$_{20}$, provocative concentration of methacholine associated with 20% decrease in FEV$_1$ from baseline.
[a] The methacholine PC$_{20}$ is the key parameter for rating asthma impairment. If PC$_{20}$ cannot be obtained, postbronchodilator percent predicted FEV$_1$ is used as the key factor.

1	10–19	8–>0.5
2	20–29	0.5–>0.125
3	≥30	≤0.125

(C) MINIMUM MEDICATION NEEDS[b]

Score	Medication
0	No medication
1	Occasional bronchodilator, not daily, and/or occasional cromolyn, not daily
2	Daily bronchodilator and/or daily cromolyn and/or daily inhaled low-dose inhaled steroid (<800 μg beclomethasone or equivalent)
3	Bronchodilator on demand and daily high-dose inhaled steroid (>800 μg beclomethasone or equivalent) or occasional course (1–3/year) of systemic steroid
4	Bronchodilator on demand and daily high-dose inhaled steroid (>1000 μg beclomethasone or equivalent) and daily systemic steroid

(D) SUMMARY OF IMPAIRMENT RATING CLASSES

Impairment Rating	Sum of Scores from Sections A, B, and C
0	0
I	1–3
II	4–6
III	7–9
IV	10–11
V	Asthma not controlled despite maximal treatment, i.e., FEV_1 remaining <50% despite use of ≥20 mg prednisone per day

FEV_1, forced expiratory volume in the first second; PC_{20}, provocative concentration of methacholine associated with 20% decrease in FEV_1 from baseline.

[a] *When the postbronchodilator FEV_1 value is above the lower limit of normal, the PC_{20} value should be determined and used for rating of impairment; when the post-bronchodilator FEV_1 value is <70% of the predicted value, the degree of reversibility is used; when the FEV_1 value is between 70% of the predicted value and the lower limit of normal, either the degree of reversibility of FEV_1 or the PC_{20} can be used.*

[b] *The need for minimum medication should be demonstrated by the treating physician, for example, previous records of exacerbations when medications have been reduced.*

based on a discussion between the patient and physician.[3] While the Veterans Administration has specific guidelines for impairment ratings for pneumoconiosis, the Social Security construct is based upon standard criteria for assessing impairment from any chronic respiratory disorder, as listed in Tables 36-3(A), 36-6(A), and 36-7.[6,61]

Coal Workers' Pneumoconiosis

In 1972, the Black Lung Benefits Act set eligibility criteria for the awarding of benefits to coal miners and their survivors in the United States. The Act defines pneumoconiosis as "a chronic dust disease of the lung and its sequelae, including respiratory and pulmonary impairments arising out of coal mine employment." This definition encompasses two classes of coal dust–related lung diseases: medical or "clinical" pneumoconiosis and statutory or legal pneumoconiosis. Medical or "clinical" pneumoconiosis includes diseases that pulmonologists usually consider as pneumoconiosis (such as coal workers' pneumoconiosis, anthracosis, anthracosilicosis, massive pulmonary fibrosis, silicosis, or silicotuberculosis). Statutory or legal pneumoconiosis includes any chronic pulmonary disease arising out of coal mine employment, including chronic bronchitis and emphysema.

A coal miner applying for Black Lung benefits must show that he or she has pneumoconiosis, that the pneumoconiosis resulted from coal mine employment, and that it has resulted in "total disability." The latter is defined by any one of the following: (1) Department of Labor thresholds of FEV_1, FVC, FEV_1/FVC ratio, MVV, or arterial blood gas values delineating criteria for "total disability;"[39] (2) presence of cor pulmonale; (3) radiographic evidence of complicated pneumoconiosis or progressive massive fibrosis; or (4) reasoned

Leaves the rating to the judgment of the physician, according to symptoms, anatomic extent, pulmonary functions, and complications		
(C) AMA GUIDES AND ATS GUIDELINES		
Use criteria outlined in Tables 36-6A and B, respectively		

BTPS, body temperature and pressure saturated with water vapor.
In severe kyphoscoliosis, the measured span between the fingertips when the upper extremities are abducted 90 degrees should be substituted for height.
For mixed obstructive and restrictive lung diseases with gas exchange impairment, evaluate under any of the criteria listed in Tables 36-3A,36-6A, or 36-7.
Data from Social Security Administration and Veterans Administration.

medical evidence by a physician describing an inability to perform the last coal mine employment of at least 1 year duration from respiratory or pulmonary impairment.

The miner must supply medical evidence of pneumoconiosis that includes: (1) a posteroanterior chest radiograph, along with a report of the findings using the ILO classification system; (2) a physician report detailing the occupational, medical, and smoking history, as well as all manifestations of chronic respiratory disease; (3) spirometric results; (4) altitude-adjusted arterial blood gas results; and (5) biopsy or autopsy evidence, if available. Other medical evidence accepted includes diffusing capacity.

Chest radiographic findings are accepted to show pneumoconiosis if they demonstrate the presence of either small parenchymal opacities of at least category 1/0 profusion or large opacities. The

absence of radiographic evidence of pneumoconiosis makes medical or clinical pneumoconiosis unlikely, but it may be noted in patients with statutory or legal pneumoconiosis.[39]

Pneumoconiosis in U.S. Department of Energy Employees in Nuclear Weapons Factories

The U.S. Energy Employees' Occupational Illness Compensation Program Act (EEOICPA) was enacted to provide compensation and medical benefits to workers who acquired disease in the course of their work in the nuclear defense industry. Those eligible include employees and former employees of the Department of Energy at nuclear weapons factories, as well as private contractors and subcontractors at those locations. In addition to exposure to silica, asbestos, or mixed dusts that occurred during uranium ore extraction, many workers were also exposed to beryllium (used in the manufacture of ballistic missile nose cones) and radiation. In contradistinction to Black Lung evaluation, the Part E of the EEOICPA has adopted the standards of the fifth edition of AMA Guides to the Evaluation of Permanent Impairment as the method of rating impairment.

■ Lung Cancer

According to the AMA Guides, lung cancer is a cause of severe impairment for the period extending from the time of diagnosis to 1 year thereafter. If no evidence of tumor is found at re-evaluation at 1 year, then impairment is recalculated based on the degree of physiologic impairment present at that time. On the other hand, if there is evidence of tumor, the patient remains classified as severely impaired.

Under the Social Security system, lung cancer produces impairment if it is inoperable, unresectable, recurrent, or metastatic to or beyond hilar nodes; is of small-cell histology; or involves the superior sulcus (including Pancoast tumors) with multimodal anticancer therapy. Under the Veterans Administration system, degree of impairment is not categorized clearly, but rather, is left to the judgment of the physician.

■ Sleep Apnea

Impairment ratings for sleep apnea are problematic and vary widely among compensation systems. Resting and exercise PFTs are not useful for rating impairment related to sleep apnea. Therefore, the AMA Guides recommend assessment of complications of sleep apnea, such as the presence of cor pulmonale or polycythemia, and rate the complications according to the appropriate organ systems. Any "add-on" for strictly defining respiratory impairment must be determined by a sleep specialist and should not exceed 3% of total impairment.[3] Under the Social Security system, sleep apnea is rated according to the complications related to the affected body system(s), such as chronic pulmonary hypertension; chronic heart failure; or disturbances in mood, cognition, and behavior.[6]

CHAPTER 37

Pathology of Chronic Obstructive Pulmonary Disease: Diagnostic Features and Differential Diagnosis

Joanne L. Wright
Andrew Churg

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a general name for the chronic airflow obstruction that develops most often as a result of chronic tobacco smoking, but also after exposure to biomass fuels and air pollution. The pathology of COPD encompasses a variety of pathologic lesions in the airways, lung parenchyma, and pulmonary vasculature, and these lesions can be correlated, to a greater or lesser degree, with changes in pulmonary function tests and clinical appearances. In general, although the mechanisms involved are complex, airflow obstruction can be attributed largely to a marked increase in airway resistance secondary to a variable mix of structural abnormalities involving all or many of the compartments of the airway. However, in individual cases, it may be difficult to prove associations between physiologic abnormalities and pathologic changes. The Global Initiative on Obstructive Lung Disease (GOLD), revised in 2017,[1] classifies patients with COPD upon a combination of indices of airflow, assessment of symptoms, and exacerbation history; thus far there is only limited integration with pathologic findings.

This chapter presents the pathologic features of COPD and how these findings can be differentiated from other lesions associated with airflow obstruction.

HISTORY OF PATHOLOGIC DESCRIPTIONS OF COPD

The word emphysema is derived from Greek and means "to blow into," hence "air-containing" or "inflated." Although "voluminous lungs" and lungs "turgid particularly from air" were described respectively by Bonet in 1679[2] and Morgagni in 1769,[3] the first description of enlarged airspaces in emphysema in the human, together with illustrations, was furnished by Ruysh in 1721,[4] followed by Matthew Baillie in 1807, who not only clearly recognized and illustrated emphysema, but also pointed out its essentially destructive character.[5,6]

Laennec,[7] writing in the early 1800s, made a number of seminal contributions to the basic descriptions of pathologic changes in COPD. He was the first to make a clear-cut distinction between interstitial emphysema and emphysema proper, and related the enlarged airspaces to the clinical syndrome of emphysema. He also recognized that air trapping and increased collateral ventilation were features of emphysematous lungs, and that the peripheral airways were the primary site of obstruction in emphysema. Furthermore, he noted that airspaces enlarged with increasing age, and he distinguished these changes from emphysema. He was the first to describe an association of emphysema with chronic bronchitis and to clearly describe the pathology of bronchiectasis.

Little of major importance was added to the gross descriptive morphology of emphysema for almost the next 150 years. The foundation of modern knowledge of the pathologic anatomy of pulmonary emphysema was laid by J. Gough in 1952[8] when he described centrilobular emphysema and distinguished it from panlobular emphysema. The paper section technique developed by Gough and Wentworth[9] was largely responsible for this advance, as it made examinations of sections of entire inflated lungs possible and simple (Fig. 37-1). A comprehensive microscopic description of emphysema was then provided by McLean,[10,11] who demonstrated the relationship of destruction to inflammatory alterations of the bronchioles and discussed the observed alterations of the vasculature.

LESIONS OF THE LUNG PARENCHYMA IN COPD: EMPHYSEMA

A major problem in describing the pathologic features of emphysema has been the lack of a generally accepted and easy to apply definition. In 1959, a Ciba Guest Symposium defined emphysema in anatomic terms as "a condition of the lung characterized by increase beyond the normal of airspaces, distal to the terminal bronchiole, either from dilatation or from destruction of their walls."[12] Subsequent definitions differed in that destruction of respiratory tissue became a requirement:[13–15] "Emphysema is a condition of the lung characterized by abnormal, permanent enlargement of the

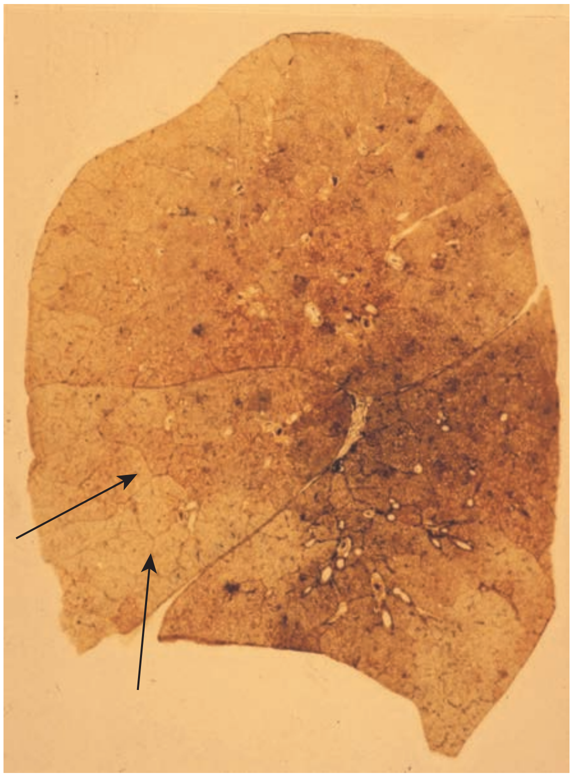

Figure 37-1 Gough sagittal section. Paper mount. Normal lung.

airspaces distal to the terminal bronchiole, accompanied by destruction of their walls." This requirement separates emphysema from enlargement of airspaces unaccompanied by destruction, the latter now being termed "overinflation."

Destruction has been similarly difficult to define in an unambiguous way. A committee of the National Institutes of Health[16] proposed that destruction was present when "there was nonuniformity in the pattern of respiratory airspace enlargement so that the orderly appearance of the acinus and its components is disturbed and may be lost." They recognized that emphysema was a subset of airspace enlargement defined as "an increase in airspace size as compared with the airspace of normal lungs. The term applies to all varieties of airspace enlargement distal to the terminal bronchioles, whether occurring with or without fibrosis or destruction." While these definitions, when strictly applied, would eliminate airspace enlargement due to overinflation or failure of septation, they would not eliminate airspace enlargement due to reorganization of the airspaces, such as is found in honeycomb lung. This may be part of the confusion when combined emphysema and fibrosis is considered (see below).

CLASSIFICATION OF EMPHYSEMA

Not only is emphysema defined in terms of lung structure, it is also classified in similar terms; therefore, several anatomic definitions are important. The part of the lung involved in emphysema is the acinus, which is defined as the unit of lung structure distal to the terminal bronchiole (final generation membranous bronchiole) and that consists of three orders of respiratory bronchioles: a single order of alveolar ducts, followed by the alveolar sacs, and finally the alveoli. Alveolar ducts are entirely alveolated and characteristically contain smooth muscle around the mouths of their alveoli. While the walls of alveolar sacs are also formed entirely by alveoli, muscle is absent. Alveolar pores of Kohn (also known as vents, stomata, or fenestrae) are normal components of adult alveoli, responsible for collateral ventilation. However, they may also be an initial site of destruction in the development of emphysema, particularly centriacinar emphysema.

The acinus is a three-dimensional anatomic structure, but it cannot be easily identified by gross examination. What can be seen instead on the surface of lung slices is the secondary lobule of Miller, defined as the tissue bounded on four sides by interlobular septa or pleura (Fig. 37-1). Lobules vary tremendously in size but are generally 2 to 4 cm on a side and contain between three to five acini. The terminal bronchiole and subtending respiratory bronchioles tend to be situated in the center of the lobule. For this reason, "centrilobular" emphysema (CLE) and "panlobular" emphysema (PLE) are reasonable and widely used approximations for the more accurate "centriacinar" and "panacinar" emphysema (see below).

The ways in which the acini are involved determine the classification of emphysema. There are four recognized patterns (Fig. 37-2). The acinus (and lobule) may be more or less uniformly involved; this is panacinar (panlobular) emphysema. The proximal portion of the acinus (center of the lobule) may be dominantly involved; the best term for this lesion is proximal acinar emphysema, although the usual term is centrilobular or centriacinar emphysema. Alternately, the proximal portion of the acinus may be normal, and the distal part (alveolar sacs and ducts) may be dominantly involved. This is distal acinar emphysema, more commonly referred to as paraseptal emphysema since the lesion is accentuated along lobular septa where the peripheral parts of the acini lie. Finally, the acinus may be irregularly involved, producing irregular emphysema or paracicatricial emphysema, so called because it is usually associated with obvious adjacent scarring.

MORPHOLOGY OF EMPHYSEMA

The morphologies of the principal types of emphysema are discussed below.

■ Centrilobular Emphysema

This destructive lesion of the respiratory bronchioles has a number of characteristic features on gross examination of the lung. In the *classic* lesion, the enlarged, destroyed respiratory bronchioles coalesce in series and in parallel to produce sharply demarcated emphysematous spaces, separated from the acinar periphery (the lobular septa) by intact alveolar ducts and sacs of normal size. The walls of the emphysematous spaces and adjacent tissue characteristically contain variable amounts of black pigment.

The lesions vary qualitatively as well as quantitatively even within the same lung. There is striking irregularity of involvement of lobules, and even within the same lobule.[17,18] The lesions are usually more common and become more severe in the upper than in the lower zones of the lung (Figs. 37-3A and 37-4A, B).[19–24] Most affected are the upper lobe, particularly the posterior and apical segments, and the superior segment of the lower lobe. In cases of severe CLE, the destruction proceeds toward the periphery of the lobule, and the distinction between CLE and PLE becomes blurred.

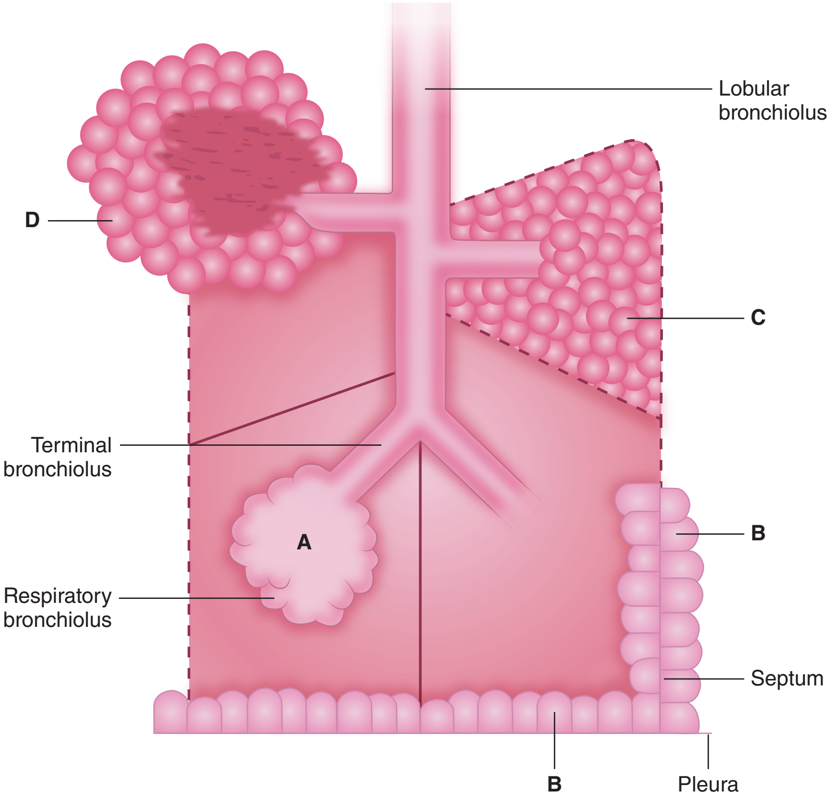

Figure 37-2 Anatomic varieties of emphysema. **A.** Centriacinar (centrilobular). **B.** Paraseptal (distal acinar). **C.** Panacinar (panlobular). **D.** Irregular (scar). The *dashed lines* mark the edge of the acinus. Only centriacinar and panacinar emphysema are commonly observed in COPD, although paraseptal emphysema often can be found in focal areas in lungs with centriacinar emphysema.

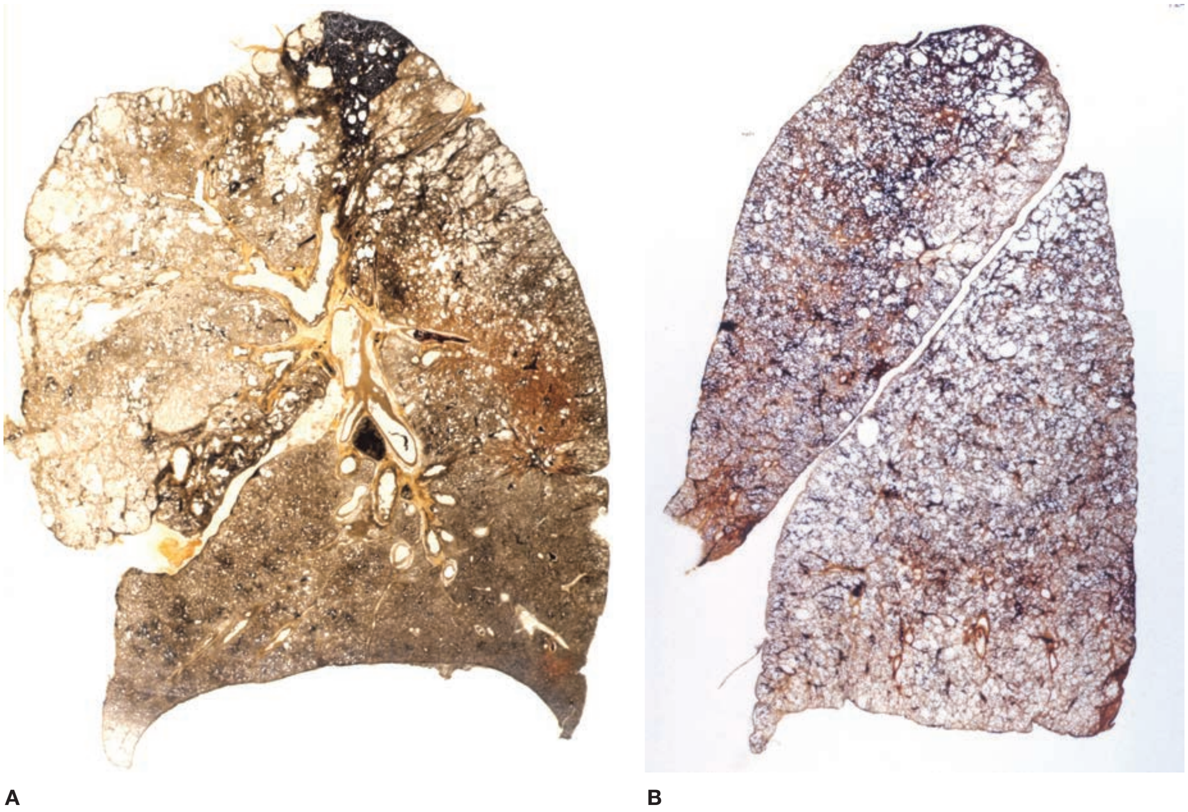

Figure 37-3 Pathologic subtypes of emphysema. **A.** Predominantly centriacinar emphysema. Emphysema is more severe in upper lobes. **B.** Predominant panacinar emphysema. Emphysema is more severe in the lower lobes.

In CLE, alveolar pores are abnormal in size and shape, and occasionally contain epithelial debris and macrophages. Although there are numerous pores of variable size in the emphysematous areas,[25] there are also increased numbers of pores in the grossly normal areas, and accentuation of these changes in the center of the lobule.[26] Thus, it appears that in CLE the pores of Kohn are possibly the initial site of destruction.

There is increased cellularity in the alveolar walls of cigarette smokers,[27] and when this has been quantified, the parenchyma in severe emphysema has increased numbers of neutrophils, macrophages, eosinophils, and both CD4 and CD8 T lymphocytes.[28] There is also a significant inflammatory cell infiltrate in the airspaces in severe emphysema, with the same cell types increased.[28] Although not readily apparent grossly or on standard histologic stains, use of histochemical stains or biochemical analysis demonstrates that collagen is increased in both centrilobular and panlobular emphysema.[29–31]

■ Panlobular Emphysema

The gross recognition of mild panlobular emphysema can be very difficult. The normal lung has a very characteristic appearance when seen through a dissecting microscope: The multifaceted alveoli form a contrast to the larger, cylindrical conducting structures that are alveolar ducts and respiratory bronchioles. In panlobular emphysema, the distinction between alveolar ducts and alveoli becomes lost as alveoli lose their sharp angles, enlarge, and then lose their contrast in size and shape with the ducts, resulting in simplification of the lung architecture, with formation of small box-like structures. As the process worsens, the architectural derangement becomes more obvious, with progressive effacement and loss of the orderly arrangement of the lung until little remains other than the supporting framework of vessels, septa, and bronchi. The best way to see panlobular emphysema grossly is to examine lung slices immersed in a water or fixative bath and then immediately after removal from the bath. The immersed specimen shows enlarged airspaces and, when the slices are lifted from the bath, panlobular emphysema can be suspected because the lung parenchyma "falls away" from the supporting structures which then protrude slightly above the parenchyma. In contrast to centrilobular emphysema, panlobular emphysema is usually worse in the lower lobes (Fig. 37-3B).

Histologic examination is a sensitive method of recognizing panlobular emphysema. The pattern is again one of simplification with diminishing contrast between alveoli and alveolar ducts (Fig. 37-4C, D). Despite the greater extent of tissue destruction, in panlobular emphysema the pores of Kohn are more uniform and inconspicuous than those found in centrilobular emphysema.[32]

Panlobular emphysema is the characteristic lung lesion seen in α1-antitrypsin deficiency,[33] but may also occur as a consequence of permanent obliteration of airways (obliterative bronchiolitis, constrictive bronchiolitis). Most often, obliteration of airways results in collapse of the distal lung parenchyma and dilatation of the bronchi proximal to the obliterated airways. This is the sequence of events in postinfective bronchiectasis. In some instances, however, the lung parenchyma does not collapse, but remains fully expanded or becomes emphysematous. The parenchymal sequel to bronchial and bronchiolar obliteration depends on the extent of the obliteration and the amount of collateral ventilation between adjacent airspaces distal to unobstructed airways. If collateral ventilation is present, then the units distal to the obliterated airways will remain expanded by virtue of the air reaching them by collateral ventilation, producing overexpansion and destruction of lung parenchyma beyond the obliterated airways. The terms *Swyer–James* or *MacLeod syndrome* are applied when this process affects most of one lung, or lobe of lung, but spares the remainder.

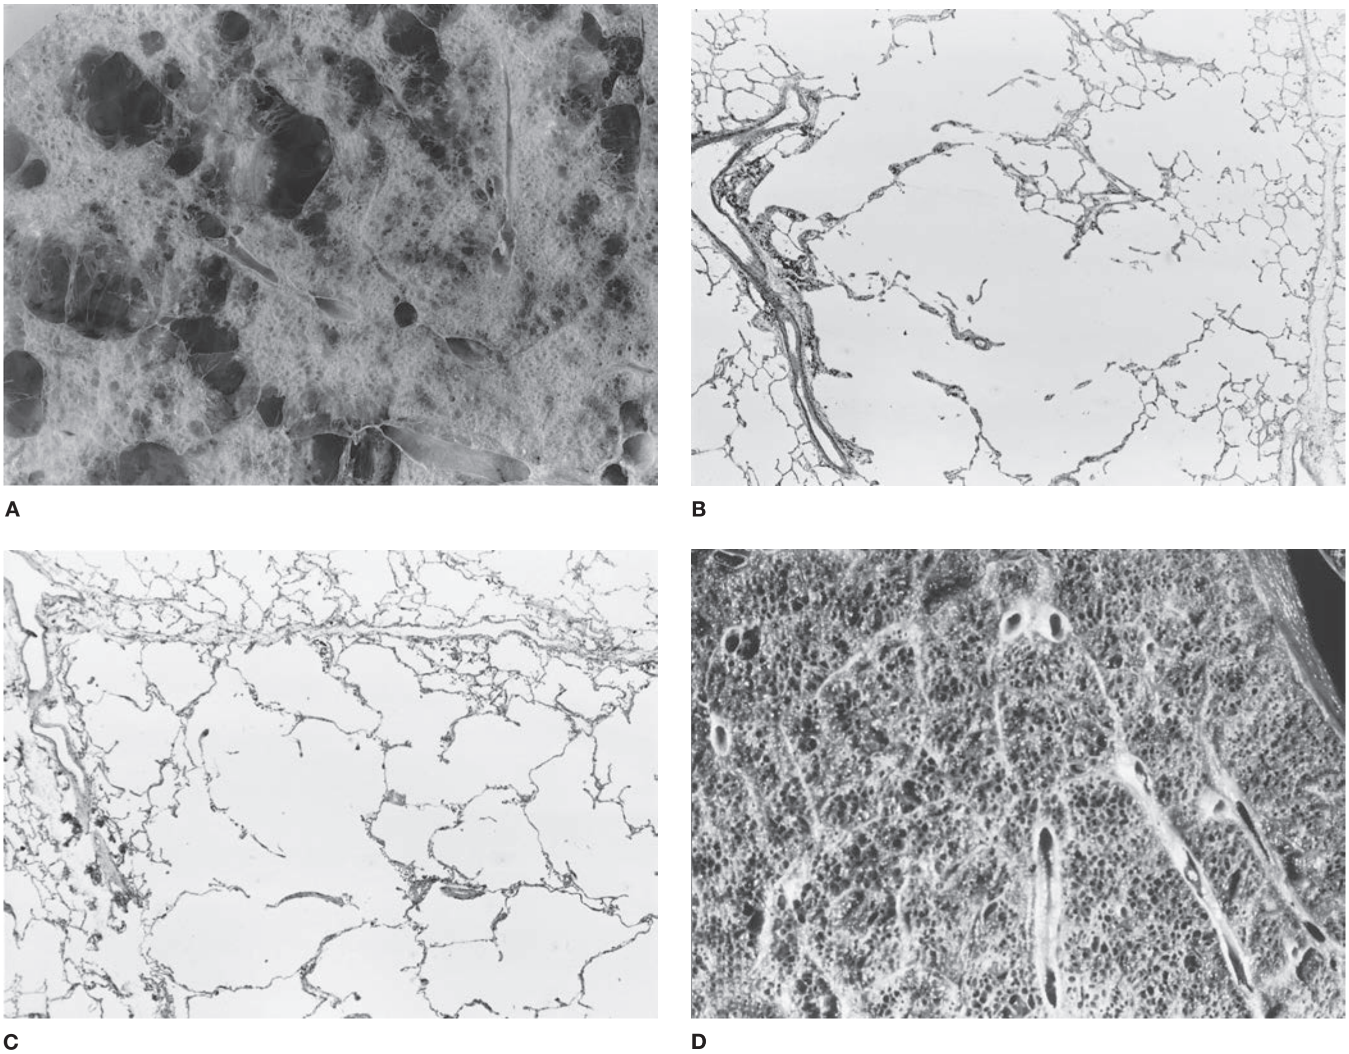

Figure 37-4 **A, B.** Gross and histologic sections illustrating centriacinar; and (**C, D**) panacinar emphysema. **A.** Cut surface from a lung with centriacinar emphysema showing holes in the center of lobules surrounded by relatively normal parenchyma. The severity varies among lobules. **B.** Microscopic section showing that the airspace enlargement in centriacinar emphysema is most marked adjacent to the abnormal respiratory bronchiole, corresponding to the center of the lobule. Also, some of the alveolar walls of the abnormal airspaces are thickened and fibrotic (H&E, ×16). **C.** Cut surface of a lung slice showing how the entire lobule is uniformly affected in panacinar emphysema. **D.** Microscopic section demonstrating that in panacinar emphysema, the airspaces adjacent to the lobular septa are enlarged to the same degree as those in the center of the lobule (H&E, ×16).

■ Distal Acinar Emphysema: Paraseptal Emphysema

The original description of distal acinar emphysema is generally credited to Loeschcke,[34] who described collections of subpleural bullae. It was Heard,[24,35] however, who first noted that the lesions could extend into the substance of the lung, where they lay along the septa, and coined the term "paraseptal" emphysema. Since the distal part of the acinus (alveolar sacs and ducts) is dominantly involved, emphysema is most striking adjacent to the pleura (superficial emphysema or mantel emphysema), along lobular septa (paraseptal emphysema), at the margins of lobules and acini (periacinar emphysema), and along vessels and airways, which, when cut longitudinally, display a linear pattern. The characteristic morphology is that of multiple contiguous, enlarged airspaces, varying from <0.5 mm to >2 cm in diameter.

Paraseptal emphysema is usually limited in extent and is found most commonly along the anterior and posterior parts of the upper lobe and along the posterior surface of the lower lobe. When extensive, it is usually more severe in the upper half of the lung. Gough has stressed that it is associated with fibrosis of the tissue between the enlarged airspaces, and this is certainly a common finding.[36] Paraseptal emphysema is frequently found in association with centriacinar emphysema,[20] but it is most known for its association with spontaneous pneumothoraces in young thin adults.[37]

■ Irregular Emphysema

Irregular emphysema is logically named, because the acinus is indeed irregularly involved in it. Irregular emphysema is almost invariably adjacent to a scar, giving name to the synonyms *scar* or *paracicatricial emphysema*. Most scars within the lung are usually small and the emphysema is limited in extent. The severity of irregular emphysema depends on the extent of damage to lung tissue, and multiple scars through the lung may lead to multiple foci of irregular emphysema.

DIFFERENTIAL DIAGNOSIS OF EMPHYSEMA

Distinctions among conditions characterized by gas trapping, nonemphysematous airspace enlargement, honeycomb lung, and combined emphysema and fibrosis are considered below.

TABLE 37-1 Differential Diagnosis of Airspace Enlargement

	Distribution	Enlarged Structure
Centrilobular emphysema	Upper lobes, center of lobule	Alveolar ducts, alveoli
Panlobular emphysema	Lower lobe, uniform in lobule	Alveoli
Paraseptal emphysema	Apical, adjacent to septum	Alveoli
Irregular emphysema	No typical site, adjacent to scars	Alveoli
Aging	Uniform in lung	Alveolar ducts
Compensatory alterations	Uniform in lung	Alveoli
Obstructive alterations	Affected area	Alveoli
Genetic alterations	Uniform in lung	Lack of septation
Asthma	During acute attack	Alveoli
Honeycomb lung	Variable—often subpleural	Total remodeling

Gas Trapping

Gas trapping may be seen in a variety of other conditions, not all of which are usually thought of as COPD. The lungs of an asthmatic who has succumbed during an attack are usually characterized by gas trapping, and thus remain inflated, with focal areas of atelectasis (Table 37-1). In a patient with long-standing asthma who has died from other causes, or has had a lung resection, there may still be areas of atelectasis. Focal bronchiectasis can be found also, particularly in the anterior segment of the upper lobe. However, parenchymal destruction is not a feature of asthma, and thus gross, microscopic, and morphometric analyses will all be normal in the chronic asthmatic. Gas trapping is also a feature of hypersensitivity pneumonitis and is a feature of connective tissue disease when it involves the small airways.

Nonemphysematous Airspace Enlargement

Although not part of the differential diagnosis of COPD, nonemphysematous airspace enlargement also occurs in infancy. In congenital lobar hyperinflation (emphysema), the lobes are overinflated rather than emphysematous, but in some instances, they may be polyalveolar.[38,39] Some other genetic abnormalities will also give enlarged airspaces, but this is due to failure of septation with a simplified rather than a destroyed alveolar framework.

At the other side of the age spectrum, the term senile emphysema was once used to describe the enlarged airspaces found in the aged. On gross examination, lungs round out with increasing age. An analysis of Gough sections showed increases in anteroposterior distance, height, perimeter, and area of the lung up to the age of 59 years. After this age, only the anteroposterior diameter continued to increase significantly, thus "rounding" the lung dimensions.[40] This change is due to an increase in the volume proportion of alveolar duct air,[41] with shallower and flatter alveoli,[42] a process termed *ductectasia*. There is no evidence of lung destruction; thus, the condition does not fulfill the criteria for emphysema.

If a part of the lung collapses or is removed, the remaining lung can expand to fill the increased amount of space available, a process known as *compensatory overinflation*. The exact way that this happens and the limits of the process are unknown. However, no tissue destruction has occurred, and, by definition, this is not emphysema. It is not clear how much larger the overinflated lung can become, or how it expands to reach the new and larger volume. It is generally thought that the possible extent of overinflation is modest and that all the parts of the acinus are equally expanded.

Obstructive overinflation can occur in adults, and two mechanisms may be involved. In one, the obstruction in the bronchus may act as a ball valve, so that air enters on inspiration but does not leave on expiration. Alternatively, the bronchus may be completely obstructed, and air may be trapped behind channels of collateral ventilation. Whatever the mechanism, the affected part of the lung can expand considerably. Obstructive overinflation differs in a number of ways from compensatory overinflation, although, in both, the lung contains too much air per unit of lung and lung tissue.

Honeycomb Lung

The airspace enlargement that occurs in cryptogenic fibrosing alveolitis (usual interstitial pneumonia [UIP]) and other fibrotic lung diseases could possibly be confused with emphysema. While honeycomb spaces are enlarged airspaces, they are the result of parenchymal remodeling with formation of new airspaces, rather than destruction of normal airspaces, and thus have thickened and irregular walls with none of the structure of an acinus. They are lined by bronchiolar epithelium, and often contain mucus; the walls have abundant and well-collagenized connective tissue, which may also contain impressive amounts of muscle and sometimes fat or even bone. There is usually interstitial inflammation in the form of varying degrees of lymphocytic and plasma cell infiltration.

Combined Emphysema and Fibrosis

Despite the definition of emphysema, which limits fibrosis, the significance of a mixture of fibrosis and emphysema has been reevaluated in relationship to its clinical, radiologic, and pathologic components.[43] The problem is that people who smoke cigarettes not only can develop respiratory bronchiolitis-interstitial lung disease (RB-ILD), but also have a higher incidence of developing UIP (idiopathic interstitial fibrosis), and mixtures of these with emphysema are not uncommon. When the combination of emphysema and UIP occurs, lung volumes can be preserved, but the diffusing capacity becomes markedly decreased, and pulmonary hypertension develops, with its associated significant negative prognosis. CT scans generally show centrilobular or mixed centrilobular and paraseptal emphysema in the upper lobes, with increased reticular markings and honeycomb remodeling in the lower lobes. Pathologically, there is both gross and microscopic emphysema and interstitial fibrosis with fibroblast foci in the areas of active fibrosis.[44] We have previously reviewed this topic with a focus on the pathologic differential diagnosis (Fig. 37-5A–D).[45] However, whether combined pulmonary fibrosis and emphysema represents a distinct entity or simply represents clustering of the two smoking conditions of emphysema and interstitial fibrosis has not yet been decided.

LESIONS OF THE LARGE AIRWAYS IN COPD

The majority of studies in this area have focused upon the lesions present when the clinical signs and symptoms of chronic bronchitis are also present.

Gross Findings

Gross lesions in the large airways are few and subtle. Bronchial pits are the dilated openings of one or more mucus glands into the epithelium. They are most often found along the margins of the cartilaginous rings and at the bifurcations of the airways. In nonbronchitis, the pits can be seen using a hand lens or a dissecting

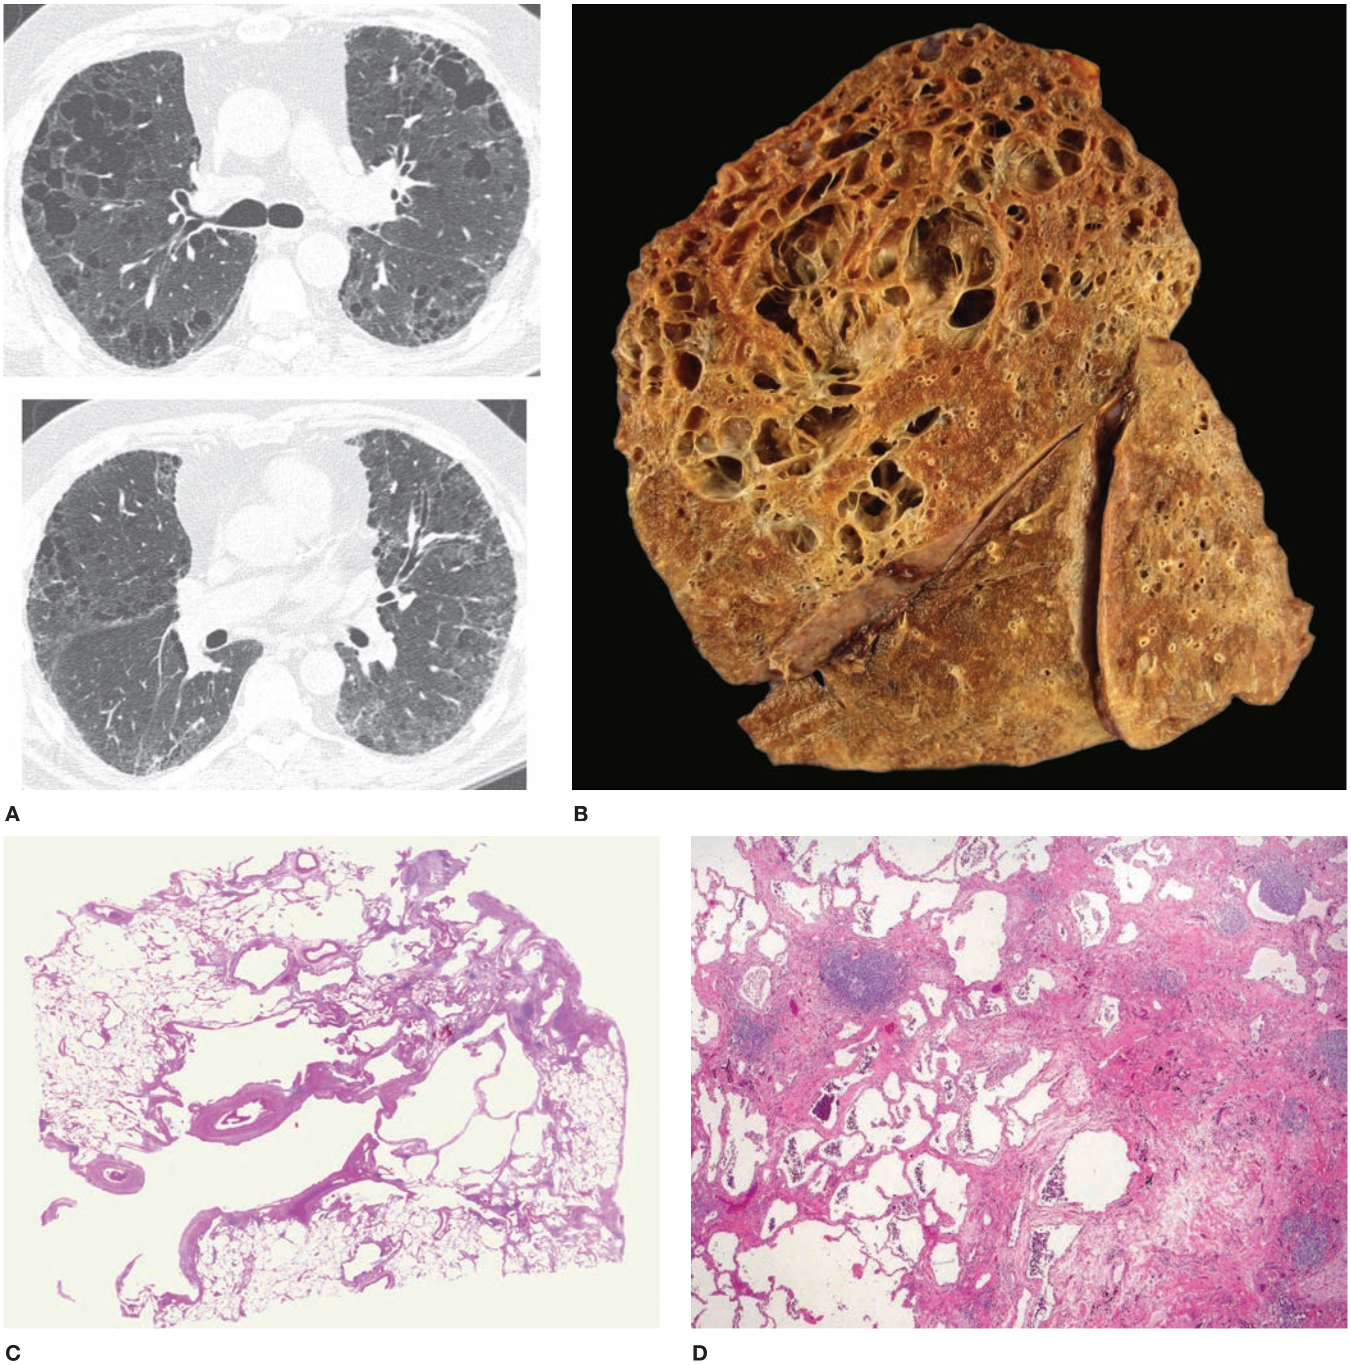

Figure 37-5 Combined fibrosis and emphysema in a case of chronic (fibrotic) hypersensitivity pneumonitis. **A.** Computed tomography scan from upper zone *(top)* shows emphysema and a suggestive of reticulation; lower image from midlung zone shows extensive reticulation indicating the presence of underlying fibrosis. **B.** Gross photo (sagittal slice) from this case showing marked upper zone emphysema, with fibrosis evident in the most posterior portion of the upper lobe, and the posterior portions of the lower lobe. **C.** Whole mount from the upper lobe. There are large emphysematous spaces, several with extensive surrounding fibrosis; at higher magnification, many of these fibrotic rims had fibroblast foci (not shown), indicating that this process is really interstitial fibrosis stretched around pre-existing emphysema. **D.** Image from lower lobe showing a UIP-like area, a common finding in chronic hypersensitivity pneumonitis. Elsewhere there were noncaseating granulomas (not shown). *(Reproduced with permission from Wright JL, Tazelaar HD, Churg A. Fibrosis with emphysema. Histopathology. 2011;58(4):517–524.)*

microscope, but in chronic bronchitis, the ducts may be distended with mucus and the mucus may protrude into the lumen of the bronchus and be visible grossly. It is not correct to refer to these as diverticula. First, these are protrusions of normal ducts; and second, they do not extend through all of the muscle coats of the bronchial wall.

While enlarged bronchial pits are the most obvious gross lesions in COPD, careful examination of lung specimens will show that the bronchi do not taper progressively as they approach the pleura,[46] and they also display prominent circular ridges, probably due to bands of hypertrophic smooth muscle.[47,48] Gross mucus may be present in the airway lumen, particularly in subjects with chronic bronchitis.[49]

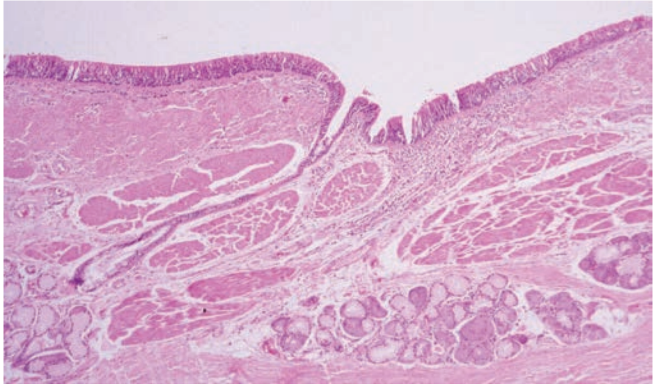

Figure 37-6 Large airway from a subject with chronic bronchitis. The overall wall is thickened with inflammation and fibrosis, and there is prominence of the smooth muscle in addition to the bronchial mucus glands.

■ Microscopic Findings

The intraluminal mucus found in the airways of subjects with COPD contains a mixed population of epithelial cells and acute and chronic inflammatory cells; large numbers of neutrophils can be found during an exacerbation.

Detailed microscopic analysis of the large airways in COPD reveals alterations in the entire airway wall (Fig. 37-6). Epithelial changes are mild in degree and are not necessarily consistent from patient to patient. Epithelial sloughing can occur, but in most instances the epithelium is generally intact and shows only mild goblet cell or squamous cell metaplasia, both of which appear to be more marked if the subject has symptoms of chronic bronchitis.[50,51] The reticular basement membrane thickness is within the normal range.

The thickness or area of mucus glands in subjects with COPD in general, or chronic bronchitis in particular, is increased over a population mean, but has a distribution that extensively overlaps that of normals and asthmatics.[52–55] Interestingly, there appears to be a decreased percentage of serous acini in these glands, a feature that apparently does not occur in asthma (discussed below).[56]

Thickening of the inner wall (area internal to the muscular layer) appears to be the most consistent component of airway wall thickening in the large airways of subjects with COPD, and appears to be generalized.[57,58] This increase in thickness can be partially attributed to edema and hyperemia of the bronchi,[59] but is also due to an increase in fibrous tissue or other matrix proteins.

In the large airways of subjects with COPD, increases in the thickness of the muscular layer have not been consistently identified. Although some studies[60] have found that the average proportion of muscle in main, lobar, and segmental bronchi was approximately doubled in patients with chronic bronchitis and airflow obstruction, others have found that a substantial number of patients fell within the normal range.[54,55,61]

Alteration in the amount of cartilage in COPD does not appear to be a consistent finding. While some studies[59,62,63] described cartilage atrophy in chronic bronchitis and/or emphysema, or circumferentially arranged cartilage that extended farther distally in nonbronchitis than bronchitis,[64] this was not supported by other reports.[54,65] However, histologic signs of cartilage damage, as judged by loss of cellular or pericellular metachromasia and vacuolated or empty lacunae, can be consistently identified.[66]

The large airways in COPD show a mild, usually mixed, inflammatory infiltrate. Bronchus-associated lymphoid tissue (BALT) is not consistently found, but its frequency appears to be considerably higher (82%) in smokers than nonsmokers (14%).[67] Bronchial biopsy analysis consistently shows an increase in CD8 T cells, with eosinophils and neutrophils found during exacerbations.[50,68] Chronic inflammation can also be found around the bronchial glands, particularly in subjects with chronic bronchitis.[69]

■ Differential Diagnosis

A number of common and uncommon disorders constitute the differential diagnosis for airways disease seen in COPD.

Asthma

In asthma the large airways are not dilated, but mucus plugs are classically identified in the large airways of subjects with fatal or near-fatal asthma,[70] and the mucus may be continuous with that present in the ducts of the mucus glands (Table 37-2). Visible bronchial pits are not a standard feature of asthma, and although the airway wall may be thickened, this is usually not apparent grossly.

In the large airways of subjects with asthma, desquamation of the epithelium is a common feature,[71,72] and this may be worse in people who have persistent rather than intermittent activity. Sloughing of cohesive epithelial clusters produces the creola bodies found in cytology specimens. Goblet cell metaplasia can be marked in both

TABLE 37-2 Pathologic Differential Diagnosis of Large Airway Lesions in COPD

	Dilatation	Structural Distortion	Pits	Glands	Submucosal Fibrosis	Basement Membrane	Epithelium	Luminal Mucus	Cartilage	Muscles
Chronic bronchitis	✓	Fibrosis and inflammation	✓	✓	✓	X	Goblet cell metaplasia	✓	✓	✓/X
Asthma	Focal	Focal	X	✓	✓	✓	Goblet cell metaplasia	✓	X	✓
Bronchiectasis	✓	Fibrosis and inflammation	✓	✓/X	✓	X	Focal goblet cell metaplasia	✓	✓	X

Relapsing polychondritis	✓	✓	X	X	X	X	X	X	✓	X

Check mark indicates that the feature is present; X indicates that the feature is absent.

asthma and bronchiectasis,[73] but there is a considerable degree of variability, so that this feature cannot be used in isolation to distinguish among the airways of subjects with COPD, asthma, and bronchiectasis. These epithelial cell changes result in an overall thickening of the epithelium in asthma, but not in COPD.[58] In asthma, the reticular basement membrane (lamina reticularis) is characteristically thickened. This alteration occurs early in the course of disease and remains even when the asthma is mild or well controlled.[56]

The airways of asthmatics demonstrate a greater severity of inner wall thickening, with values double those found in patients with COPD.[58] The increase in thickness is due to variable increases in fibrous tissue, inflammatory cells, edema fluid, and vascular prominence.[50,56] Analysis of the muscular wall in subjects with severe or fatal asthma compared with normal subjects or those with COPD shows a marked increase in amount of muscle, with a lesser increase in asthmatics who died with rather than from their asthma.[74] There has also been a suggestion that the increase in muscle mass may occur relatively early during childhood.[56]

Neutrophils are the predominant cells present in the mucus of patients with bronchiectasis, while eosinophils and accompanying Charcot Leyden crystals are the hallmark of asthmatic mucus. As noted, the cartilaginous destruction present in polychondritis is severe and associated with chronic inflammation, thus easily distinguishing the two processes. Depending upon the severity of the inflammation in bronchiectasis, there may be significant cartilaginous destruction.

Airways from fatal and near-fatal asthma also contain isolated aggregates of lymphoid cells, roughly in the same proportion as that present in COPD.[75] However, in asthma, by contrast to COPD, there is an inflammatory infiltrate consisting of activated eosinophils, and activated CD4 T cells in the submucosa,[76] and both mast cells and neutrophils within the glands.[70] There is little in the literature regarding the inflammatory cell infiltrates present in the airway walls in bronchiectasis. Compared with asthma, there appear to be fewer eosinophils, but a similar population of CD45 (as opposed to any specific subtype) lymphocytes, with both cell types having a greater density in the inner, as opposed to the outer aspect of the airway.[77]

Bronchiectasis

In bronchiectasis, there is, by definition, an abnormal and permanent dilatation of the bronchi; this is usually present to a much greater degree than is found in COPD and is often accompanied by airway distortion. There is exaggeration of the muscular ridges and the presence of multiple bronchial gland–based pits. The large airway walls can be thickened and/or irregularly thinned as a result of inflammation and fibrosis, and there is often inspissated mucus or actual purulent material.

Miscellaneous Conditions

Tracheobronchomegaly (Mounier-Kuhn syndrome) is characterized by a marked dilatation of the trachea and major bronchi, with diameters 5 to 10 cm above normal values.[78] In this condition there are multiple true diverticula, with outpouchings formed of membranous tracheal tissue between the cartilaginous rings,[79] with atrophy or absence of elastic fibers.[80]

Patients with tracheobronchopathia osteoplastica have an obstructive pulmonary function pattern;[81] however, unlike the trachea and large airways in COPD, cartilaginous and bony nodules are present in the subepithelial space (submucosa). Relapsing polychondritis[82,83] shows variable dynamic expiratory and/or inspiratory obstruction depending on the size and location of the airways involved. In this disease, however, the obstruction is due to impaired airway clearance of inflammatory debris, and an ineffective cough because of dynamic upper airway collapse. The airways are dilated and the walls are thickened because of the extensive fibrosis and chronic inflammation due to the immunologic nature of this condition. In particular, the cartilaginous plates show extensive destruction.

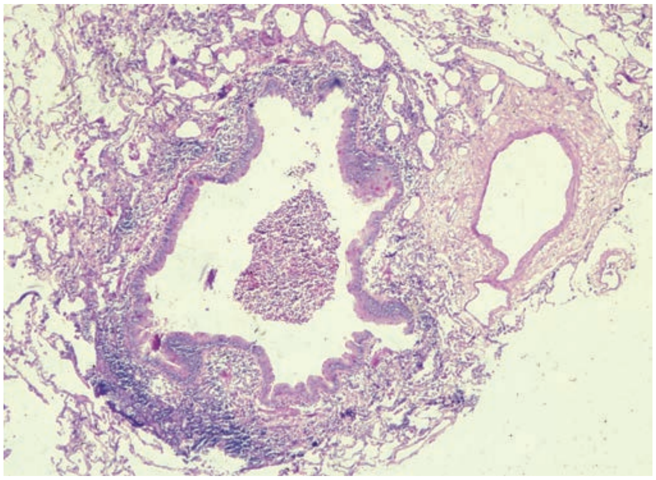

Figure 37-7 A small airway from a subject with COPD. The lumen contains mucus and inflammatory debris. There is goblet cell metaplasia of the epithelium. The subepithelial (submucosal) layer is increased in thickness due to an increase in fibrous tissue and inflammatory cells.

LESIONS OF THE SMALL AIRWAYS IN COPD

In the context of COPD, small airways refer to airways with an internal diameter of 2 mm or less. In COPD, intraluminal mucus can be found in the small airways, and there appears to be an overall relationship between the degree to which the airways are occluded by mucus and the FEV_1.[84] Goblet cells are rare in normal small airways, but goblet cell metaplasia is a frequent finding in the airways of patients with COPD.[85–87]

Similar to the large airways, there is alteration of all of the small airway wall compartments in patients with COPD (Fig. 37-7). These changes result in an overall decrease in the internal bronchiolar diameter and, as assessed by a conformity index, produce significant deformity. Similar results are obtained from three-dimensional reconstructions.[74] Detailed measurements of the airway walls show that the increased wall thickness is due to increases in the epithelium, subepithelial fibrous tissue compartment (submucosa, lamina propria), smooth muscle, and adventitia.[58,84] While there is no direct evidence, it seems appropriate that these changes would result in airway obliteration, a process that appears to happen relatively early in airflow obstruction, with the number of airways in patients with severe airflow obstruction reduced to one-tenth of the numbers calculated in the normal lung (Fig. 37-8A, B).[88] Reduction in airways of 2 to 2.5 mm can be identified using multidetector-row computed tomography (CT), and decreased numbers of terminal bronchioles can be found using a micro-CT approach. Interestingly, this latter technique has also found a decreased luminal area in these airways, again suggesting an obliterative process has occurred.[89] Although the adventitia is thickened, there is a loss of alveolar attachments to the airway wall,[90,91] an important process because it allows early airway collapse on expiration.

One of the earliest histologic abnormalities that can be detected in cigarette smokers is the presence of macrophages in the lumen of the respiratory bronchioles.[92] However, an inflammatory infiltrate can also be identified within the walls of both membranous and respiratory bronchioles in subjects with COPD. When examined in conjunction with the GOLD (Global Strategy for the Diagnosis, Management, and Prevention of COPD) stage, the proportion of airways that had measurable neutrophils appears to be increased in GOLD stages 2 to 4, and airways with measurable macrophages

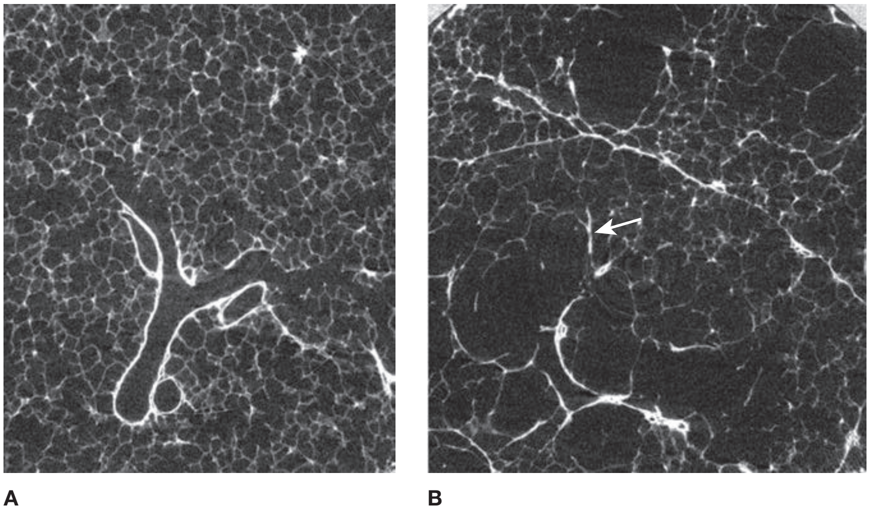

Figure 37-8 **A.** Micro-CT scan image of an airway from a normal lung. Note the regular progression from membranous bronchiole to respiratory bronchiole to alveolar duct. **B.** Micro-CT scan image of an airway from a lung with centrilobular emphysema. Note the irregular airway emptying into a centrilobular hole. Partially obliterated airway is seen at the *arrow*. *(Reproduced with permission from Dr. James C Hogg.)*

show a progressive increase from GOLD stage 0 to 4, while there does not seem to be any alteration in the percentage of airways that contain eosinophils among the GOLD stages.[93] The percentage of airways with CD4, CD8, and B cells also increase with GOLD stage, but when these data are expressed as total accumulated volume, only the B cells and CD8 cells show progressive increases. The presence of lymphoid follicles is markedly increased in GOLD stages 3 and 4. Interestingly, histone deacetylase 2 (HDAC2) appears to be downregulated in the small airways of smokers with COPD,[94] a finding that may be of considerable importance since downregulation of the HDAC system is associated with a proinflammatory cytokine profile.

■ Differential Diagnosis

A number of important clinical entities constitute the differential diagnosis of small airways disease in COPD.

Asthma

A comparison of the inflammatory and cellular mechanisms present in asthma and COPD has recently been reviewed.[95] Mucus plugs and goblet cell hyperplasia are markedly increased in the small airways of asthmatics,[73,96] and this increase is generally much greater than that seen in COPD. In addition, the basement membrane thickness is approximately 20% greater than that found in either normal subjects or patients with COPD.[73] The peripheral airways of asthmatics have an inflammatory infiltrate that features lymphocytes and eosinophils,[73,77,97] with many of the inflammatory cells in the adventitial, as opposed to the submucosal, compartment. The data regarding the vessels in the submucosa are controversial, with some studies suggesting that they are congested, but not increased in number, in asthmatics compared with COPD,[74] and others demonstrating an increased number of vessels, but a lesser total area in asthma compared with COPD.[98] Although smooth muscle is increased in asthmatics, the increase is not as great as that present in the large airways.[99] Moreover, the distribution of smooth muscle increase in the bronchial tree may be quite different, with some patients displaying a generalized increase, while in others the increase is restricted to the larger airways.[100] Overall, the small airways in asthmatic subjects who have died because of their disease have a greater area of subepithelial fibrous tissue, smooth muscle, and adventitial fibrous tissue than do subjects who died with their disease, which in turn have a greater area than do the airways of subjects with COPD.[101] Thus, although the same qualitative changes are present in both asthmatics and COPD, they are more severe in asthmatics and most severe in cases of fatal asthma. Interestingly, there appears to be a loss of alveolar attachments in cases of fatal asthma,[102] although this is less than that present in the airways of patients with COPD.

Follicular Bronchiolitis

Follicular bronchiolitis is characterized by narrowing of the bronchioles due to adventitial and subepithelial lymphoid follicles and accompanied by a lymphoplasmacytic inflammatory infiltrate.[103] The condition is classically found in patients with rheumatoid arthritis or those with IgA deficiency or common variable immune deficiency. This process can mimic severe COPD small airway disease, but the inflammatory infiltrate is generally magnified compared to COPD, while there is little goblet cell metaplasia in the airway epithelium.

Panbronchiolitis

The presence of foamy macrophages in the airway wall and lumen and extending down into the alveolar ducts and alveoli is a feature of the condition known as panbronchiolitis, originally described in Japan but now known to occur worldwide.[104,105] Follicular hyperplasia of the peribronchiolar lymphoid tissue is frequent, and bronchiolectasis is found in the more advanced lesions.

Constrictive Bronchiolitis

The term *constrictive bronchiolitis* appears to have been coined by Gosink et al.[106] In constrictive bronchiolitis, the airway lumen is occluded by a progressive thickening of the subepithelial (submucosal) space. Both the membranous and respiratory bronchioles are involved and show transmural inflammatory cell infiltrates, occasionally with epithelial necrosis. Mucus plugs also can be identified. As the process evolves, the inflammatory infiltrate wanes, and greater amounts of fibrous tissue can be demonstrated both in the peribronchial and subepithelial portions of the airway, acting to narrow or obliterate the airway lumen.[107] Lesions of constrictive bronchiolitis, particularly in the organized phase, may be difficult to demonstrate and may require elastic stains to outline the obliterated airway. Thus, the lesions in COPD differ from constrictive bronchiolitis only in degree.

Mineral dust–induced airway disease is a distinctive type of constrictive bronchiolitis, characterized by a stereotypic response of the small airways to high doses of particulate, regardless of the specific mineral dust involved. The lesions consist of fibrosis and thickening of the walls of both the membranous and respiratory bronchioles, sometimes extending down the alveolar ducts, the latter finding providing diagnostic discrimination from tobacco smoke–induced airway disease, which tends not to involve the alveolar ducts. Pigment deposition is highly variable and is not a diagnostic feature.[106] Other forms of constrictive bronchiolitis may be related to ingestion of toxic compounds such as *Sauropus androgynus* ingestion,[109–112] or related to diffuse neuroendocrine cell hyperplasia.[113–116]

Proliferative Bronchiolitis

The lesions of proliferative bronchiolitis have been elegantly described and illustrated.[115–117] Within the lumens of the membranous and respiratory bronchioles are plugs of organizing fibroblastic (granulation) tissue. Occasionally, ulceration of the epithelium can be seen, and early lesions may have fibrin. The granulation tissue is formed of a pale matrix with proliferating spindle cells, accompanied by chronic inflammatory cells. As the lesions age, the granulation tissue usually shrinks and contracts. However, in a certain proportion of cases, the bronchiolar cells proliferate over the granulation tissue and incorporate it into the subepithelial space, leaving an irregular airway lumen.

Although acute bronchiolitis, be it bacterial or viral in nature, is usually easily distinguished from the lesions of COPD by the presence of extensive epithelial damage, healed lesions may show nonspecific airway fibrosis and chronic inflammation, or the residua of proliferative bronchiolitis. Interestingly, latent adenoviral infection has been suggested as a contributor to airflow obstruction in adults by amplifying the inflammatory response in the bronchioles of cigarette smokers.[120] Airway disease complicating other diseases may also need to be distinguished from that of COPD. For example, posttransplant bronchiolitis[118,121] or airway disease in patients with inflammatory bowel disease (both Crohn disease and ulcerative colitis)[122] include both proliferative and constrictive bronchiolitis. Inflammatory bowel disease may also have large airway involvement.

LESIONS OF THE VESSELS IN COPD

There are no consistent alterations in the large elastic pulmonary arteries of subjects with COPD. Atheromata can be found,[123] but unless there is pulmonary hypertension, the incidence is probably not greater than that found in a carefully matched population.

Cigarette smokers, with or without pulmonary hypertension, have an increase in arterial muscle media thickness as well as intimal fibrosis in the muscular arteries, and progressive muscularization of the small arterioles.[122] Increases in intimal thickness with longitudinal muscle formation are a common feature in lungs of patients with COPD (Fig. 37-9).[11,125,126] There appears to be a progressive increase in the numbers of smaller muscularized arteries, percent medial thickness, and percent intimal thickness of muscularized arteries from nonsmokers, to smokers without obstruction, to smokers with airflow obstruction.[127]

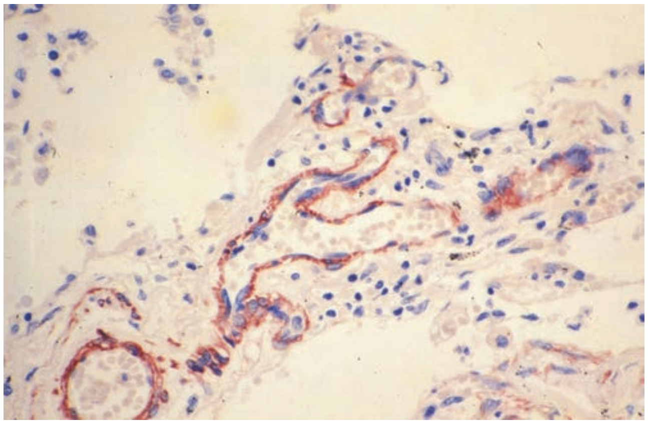

Figure 37-9 A small pulmonary artery from a subject with COPD. These vessels, situated adjacent to the alveolar ducts, are normally poorly muscularized, but in this case, the vessel has a distinct circumferential muscular layer.

The lesions of primary pulmonary hypertension and hypertension secondary to vascular shunting also include intimal fibrosis and increased muscular media thickness. Intimal fibrosis is often cellular in its early phases, but progresses to concentric laminar fibrosis, which can almost totally obliterate the vessel lumen. These changes are of much greater severity than those identified secondary to COPD. Vasculitis, fibrinoid necrosis, and plexiform lesions are never found in COPD. Lesions of chronic thromboembolic disease include eccentric intimal thickening and the occasional formation of webs due to recanalization of the thrombi.

NONPATHOLOGIC, CT SCAN–BASED, EVALUATION OF TISSUE COMPARTMENTS IN COPD

CT scanning has provided useful information on the lung parenchyma, airways, and pulmonary vasculature in patients with COPD.

■ Emphysema

The advent of high-resolution CT scanners has allowed identification of even mild emphysema and can distinguish between emphysema and senile lung airspace enlargement. When combined with general morphometric principles, emphysema can be quantified, and emphysema progression can be monitored.[128–131]

■ Airways

Evaluation of this compartment is in its developmental phase, with much of the work being performed on phantom airways or in large animals. In humans, thin-section CT scans are able to demonstrate evidence of airway wall remodeling in the more proximal airways (first- to sixth-generation airways) of subjects with COPD or asthma, and it has been suggested that changes in these airways can be extrapolated to the smaller airways.[132] Use of multidetector-row CT has extended these data.[89] Certainly, the data do suggest that these measurements correlate with lung physiology, independent from emphysema.[133]

■ Pulmonary Arteries

Measurements of the mainstem pulmonary artery are easily performed on CT scans using contrast, and these data have shown prognostic significance. Evaluation of the smaller vessels is much more difficult, but initial work has found that determination of the total cross-sectional area of the vessels that have an individual cross-sectional area of less than 5 mm^2 has a significant negative correlation with pulmonary arterial pressure, at least in patients with severe emphysema.[134,135]

SUMMARY

There are a number of pathologic alterations of the lung in COPD. These involve almost all of the lung compartments, including the parenchyma, vasculature, and large and small airways. These changes can overlap the pathologic findings present in other diseases associated with airflow obstruction, or other diseases that are manifested in the lung. It is important to be able to make the distinction among these diseases. Although the pathologic alterations roughly correlate to alterations in pulmonary function, it is important to remember that their individual contributions are not well worked out. Thus, it may be difficult on an individual patient basis to proceed from a clinical classification such as the GOLD classification to a mechanistic/pathologic explanation of the airflow obstruction. Advances in CT scanning technology have allowed evaluation and quantification of emphysema, and there is developing work suggesting that evaluation of the airways and pulmonary arterial system also may be possible.

CHAPTER 38

Chronic Obstructive Pulmonary Disease: Epidemiology, Pathophysiology, Pathogenesis

Takudzwa Mkorombindo
Mark T. Dransfield

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a heterogeneous disease characterized by persistent respiratory symptoms and airflow limitation due to airway and alveolar abnormalities. The causative agent is usually significant exposure to noxious particles or gases and influenced by host factors, including abnormal lung development.[1] COPD includes a spectrum of pathology that involves damage to the lung parenchyma (emphysema) and abnormalities of the tracheobronchial tree (bronchitis). The manifestation of the disease varies greatly, and despite the knowledge acquired in the past 300 years, our understanding of factors that influence disease phenotypes remains incomplete. In the 16th and 17th centuries, we had the earliest descriptions of COPD, with the description of emphysematous lungs as "voluminous lungs."[2] Later, chronic bronchitis and other features were identified. While different clinical and biologic phenotypes exist, airflow obstruction characterized using spirometry is the hallmark.

Spirometry is essential in the diagnosis and is beneficial for prognostication and monitoring treatment outcomes. The most accepted criteria for airflow obstruction by spirometry is a reduction of the post-bronchodilator FEV_1/FVC ratio below 0.7. While the 0.7 cutoff value for the FEV_1/FVC ratio may underrecognize patients in the early stages and may overdiagnose disease in healthy middle-aged and older individuals, it has been the most accepted because it balances disease detection sensitivity and specificity.[3–6] Historically, further classification of severity was based strictly on airflow limitation. Over the past decade, guidelines have evolved to incorporate a multimodality assessment of symptom burden and exacerbation risk (Fig. 38-1). Additionally, there has been an interest in going beyond symptom burden (dyspnea and history of exacerbations) to incorporate the different chest imaging patterns.[7] Chapter 40 comments

further about risk stratification. There is increasing evidence that current and former smokers can have parenchymal and airway abnormalities and can have respiratory symptoms and exacerbation-like events, even in the absence of airflow limitation. At present, these patients are not included in COPD management guidelines.[1,8,9]

EPIDEMIOLOGY

COPD is a significant health problem affecting more than 400 million people worldwide. In 1990, COPD was the sixth most common cause of disease worldwide but now ranks as the third leading cause of death, according to the Global Burden of Disease Study, after cardiovascular disease and stroke.[10] The impact of respiratory diseases, and specifically COPD, is wide-reaching as it affects countries at all levels of development (Fig. 38-2). The World Economic Forum estimates that the global costs of COPD will reach U.S. $50 trillion annually by 2030.[11]

Often viewed as a self-inflicted disease of tobacco smokers, the paradigm is shifting with an increased understanding of the disease. Fletcher and colleagues in the 1960s showed increased lung function decline in susceptible smokers and that smoking cessation would decelerate the decline of lung function.[12] Smoking remains prevalent worldwide, and while smoking is decreasing in developed nations, the global burden of disease continues to grow (Figs. 38-2 and 38-3).[13,14] Reasons for the increasing global burden of disease include an increasing burden of tobacco smoke exposure in low to middle-income countries, persistent problems with preterm birth, poor nutrition and childhood infections, toxic nontobacco exposures, and an expanding number of older adults.[15–18] Exposure to indoor and outdoor pollution from the combustion of clean fuels (gas stoves and burning petroleum) and unclean fuels (coal, charcoal, wood, or dung) plays a significant role in developing COPD in never smokers.[19–21] In areas where indoor air pollution is generated by burning biomass for heating and cooking, COPD disproportionately affects women and children.[22,23]

COPD has a high prevalence and poses a significant burden with astounding morbidity, mortality, and financial and social impact. Surveys, such as the 2017 Behavioral Risk Factor Surveillance System (BRFSS), suggest that an estimated 15 million people in the United States have COPD. The estimated worldwide prevalence ranges from 7% to 19%. Despite its wide-reaching effects, current data underestimate the burden of disease as it is underrecognized and underdiagnosed.[24–28] In the United States, the age-adjusted prevalence of COPD was 6.2%, with a higher prevalence among the less educated, lower socioeconomic status, rural communities, women, older adults, and American Indians/Alaska Natives.[26] Other statistics support these national surveys. In a study of 1575 cigarette smokers, aged 30 or older, with a 10 or more pack-year smoking history, approximately 20% met spirometric criteria for COPD.[29] The Third National Health and Nutrition Examination Survey (NHANES III) showed that life expectancy is shortened by 5.8 years for men aged 65 with GOLD stage 4 COPD, and an additional 3.5 years if smoking is continued.[30] With the growing impact of COPD, there is an urgent need for primary prevention efforts and improved recognition and management of this deadly disease.

ETIOLOGY

Risk factors for COPD development are environmental and host-based (Table 38-1, Fig. 38-4). Throughout the human lifespan, several host factors have unique and dynamic interactions with the environment that mediate one's likelihood of disease.[31] These host factors include the balance of mechanisms responsible for tissue maintenance, tissue repair, tissue regeneration, and the mechanisms associated with tissue damage and aging.[32] The interaction of host and environmental factors determines the likelihood of activating the cellular and biochemical mechanisms responsible for developing COPD. In developed countries, smoking tobacco is the predominant risk factor; however, never-smokers also develop COPD, and women predominate in this cohort.[16,33] In places where solid fuels are burned, indoor air pollution is a dominant risk factor. Other factors associated with COPD include second-hand tobacco exposure, a family history of COPD, age, socioeconomic status, education level, history of tuberculosis, prematurity, in utero

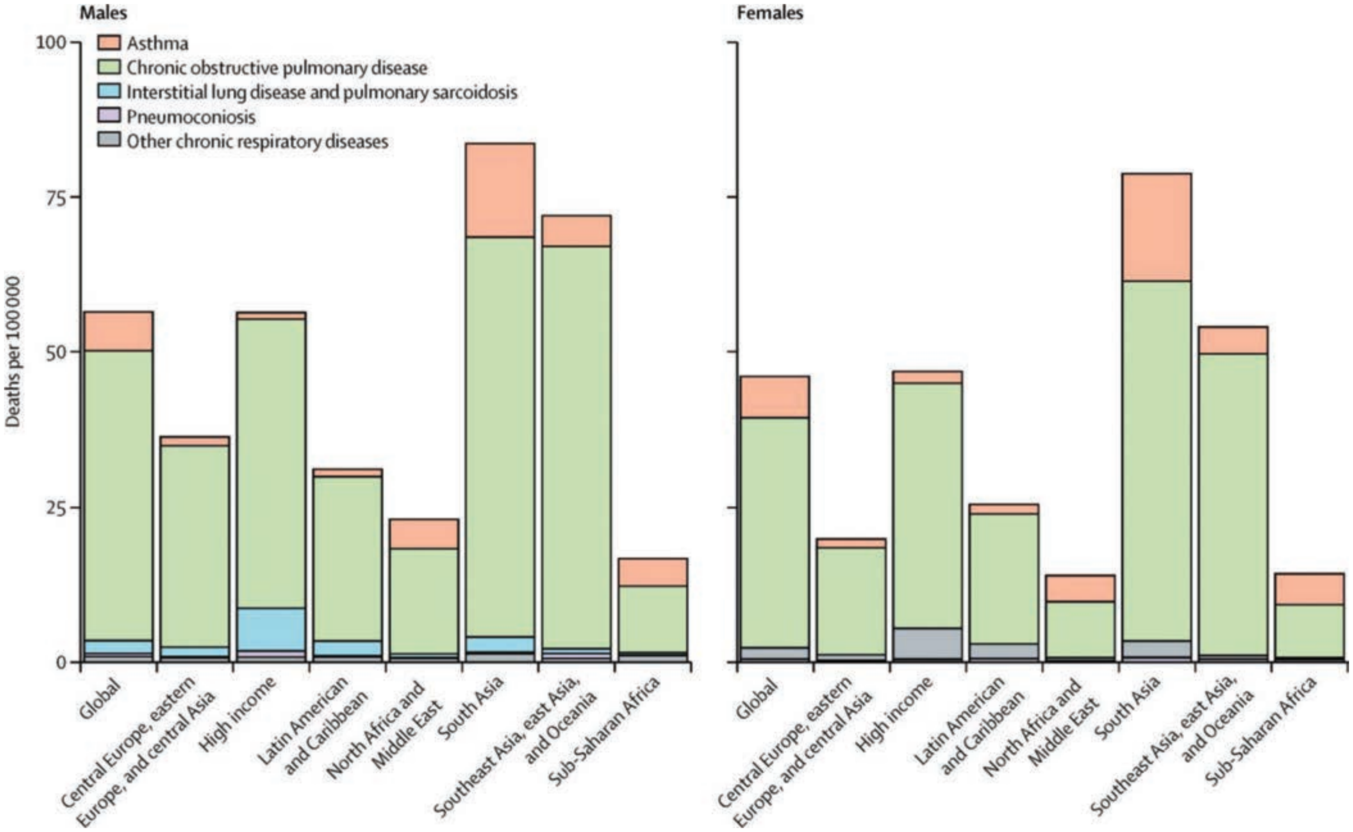

Figure 38-3 COPD accounts for the majority of respiratory disease-related mortality globally, for all ages, and in all regions of the world. *(Reproduced with permission from GBD Chronic Respiratory Disease Collaborators. Prevalence and attributable health burden of chronic respiratory diseases, 1990–2017: a systematic analysis for the Global Burden of Disease Study 2017. Lancet Respir Med. 2020;8(6):585–596.)*

exposures, hospitalizations for respiratory illness in early childhood, and occupational exposures.[34] Multiple risk factors may be present in a single individual.

■ Environmental

Environmental exposures include tobacco exposure, indoor pollution, occupational exposures, geography, and socioeconomic status, impacting the disease's regional burden.

Smoking

Worldwide, between 20% and 40% of all COPD patients are never-smokers.[33] This ratio is not the same in developed countries where tobacco smoke-related COPD accounts for approximately 80%.[35] In the United States, there is an overlap between smokers' geographic distribution and the geographic distribution of individuals with COPD. Although the relationship between COPD and tobacco smoke exposure is not linear, there is a correlation between overall lung health, including airflow obstruction based on FEV_1 and duration of tobacco smoke exposures. Traditionally reported as pack-years smoking, there is a growing body of evidence showing that monitoring smoking duration is more sensitive and reliable because it is more precise and not as affected by reporting and recall bias.[36–38] Tobacco smoke exposure early in childhood is even more critical as it results in stunted lung maturation. By middle age, the rate of lung function deterioration with continued tobacco smoke in children with early tobacco smoke exposure outpaces that of former smokers and never-smokers.[39–41]

TABLE 38-1 Risk Factors for COPD

Environmental	Host-based
Smoking	Genetic
Indoor air pollution	Airway hyperreactivity
Occupation	
Low socioeconomic status	

There may be other unrecognized environmental factors. For poorly understood reasons, women have more lung function reduction with early onset of COPD with lower total exposure and a higher proportion of never-smokers with COPD.[42,43] Some data indicate racial disparities in the risk of developing COPD, with African Americans showing similar severity of COPD to whites with fewer pack-years of smoking.[25,44,45] While a decline in FEV_1 is not inevitable in all smokers, those with sustained reductions in FEV_1 and continued smoking have more adverse effects on ventilatory function.[37,46–48]

Environmental Tobacco Smoke Exposure

Human exposure to environmental tobacco smoke (ETS) is associated with an increased incidence of pulmonary and cardiovascular disease and is a possible risk for carcinogenesis.[49–51] ETS is implicated in the loss of many years of the life of adults and children in the United States, with observable sociodemographic disparities.[52] Controlled experimental studies with healthy volunteers indicate that short-term exposures to ETS levels comparable to those in real-life situations affect serum cytokine levels and pulmonary function and, if recurrent or chronic, might translate into COPD.[17,53] In utero effects of maternal smoking on lung growth and subsequent risk of childhood wheezing, asthma, and lung diseases in adulthood are evident.[41,54] The association between ETS and COPD is not a direct

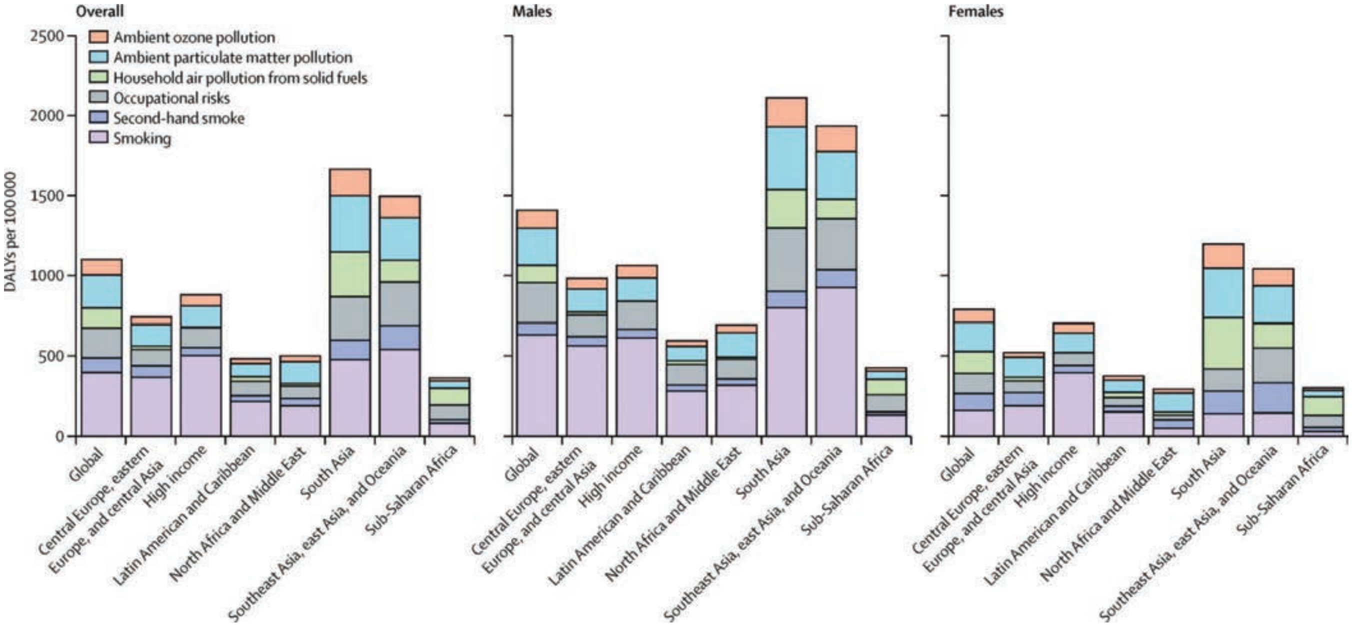

Figure 38-4 The impact of tobacco smoke exposure remains large; however, the effect of non-tobacco exposures is substantial as represented by attributable disability-adjusted life year (DALYs) rates for each risk factor across regions in 2017. *(Reproduced with permission from GBD Chronic Respiratory Disease Collaborators. Prevalence and attributable health burden of chronic respiratory diseases, 1990–2017: a systematic analysis for the Global Burden of Disease Study 2017. Lancet Respir Med. 2020;8(6):585–596.)*

association; however, the effect of ETS in early childhood results in alteration and limitations in the maximally attained lung function, and in some, it adversely impacts the rate of decline, thus contributing to increased COPD risk.[41,55] Like chronic smoking and occupational exposures, ETS is an independent risk factor for developing chronic lung disease, so avoidance is recommended.

Air Pollution

Long-term exposure to air pollution increases COPD risk and increases the symptom burden for those with respiratory and allergic illnesses.[56] These adverse effects on the respiratory system are observed even with very low air pollution levels, below national standards for acceptability.[20,57] The effects of outdoor air pollution are well established; however, a growing body of evidence has shown that indoor air pollution is a significant health concern. Sources include burning solid fuels such as wood and animal dung for cooking and heating. This practice is widespread in parts of the world and disproportionately exposes women and children to high smoke concentrations containing respirable particles. These complex gas mixtures are often inhaled for many hours daily. Cough and sputum often occur among those exposed to indoor air, with decreased bronchitic symptoms coincident with measures that reduce smoke levels.[19,58] The World Health Organization estimates that more than one million people a year die of COPD precipitated by indoor air pollution, so international advocacy organizations are working diligently to curb its impact.[59,60]

Occupation-Related Exposures

Many studies have assessed the relationship between COPD outcomes and occupational exposures, and about 15% of COPD cases are attributed to occupational exposures, even after accounting for tobacco smoke exposures.[61] The possibility that occupation-related inhalation of particulates and gases carries a risk for COPD was slow in gaining acceptance, but acceptance is widespread now.[62,63]

Prolonged exposure to a range of substances has the potential to cause COPD. The majority of available information on occupational exposures has focused on a few substances and industries. Most data available focuses on exposure to dust and fumes and less so on other airborne pollutants such as gas, fumes, and vapors.[64] Challenges to quantify the burden of disease related to occupational exposures include the difficulty that results from workplace heterogeneity. Most risk assessment tools do not accurately adjust for the variability in exposures based on the workplaces, country, or evolution of workplace hazards over time.[65,66] Agents that increase risk include but are not limited to dust from cadmium, grain, flour silica, minerals and other organic dusts, cadmium fumes, welding fumes, and wood ash.[67,68] In addition to the well-recognized risk of occupations involving exposure to organic and inorganic dusts, other less “risky” occupations, such as construction, plastics manufacturing, and utility work, may carry an increased risk of COPD.[69,70] The risk of adverse occupational exposure is particularly crucial in workers who smoke or have other host-based factors that raise their risk for COPD, such as genetic variants including α1-antitrypsin deficiency.[71] Occupational risks are modifiable and provide a unique opportunity for disease prevention.

■ Social Determinants of Health

Socioeconomic status plays a significant role in health outcomes. Like in many other chronic illnesses, health disparities exist in COPD-related health outcomes. Rural residence, low socioeconomic status, and potentially ancestry are identified as risk factors for COPD in the United States and other countries worldwide.[72–75] The relationship is linked to increased tobacco exposure and exposure at earlier times in life, low birth weight, respiratory infections in early childhood, limited access to medical care, rates of HIV and tuberculosis, occupational exposure to inhaled particulates, and increased exposure to household allergens.

In the United States in 2011, 45% of adults with a General Education Diploma (GED) were smokers compared to 10% of individuals with a college degree, and for adults living below the poverty level, 33% were smokers in contrast to 20% of individuals living above the poverty level.[76] Focused efforts at addressing factors that reduce health disparities have proved effective in many diseases and may impact the burden of COPD.

Infections

COPD is characterized by chronic inflammation, and while the host–pathogen interaction is not fully understood, the role of chronic and frequent infection in the pathogenesis of COPD is an area of research. Several pathogens, such as HIV and tuberculosis, have been associated with increased COPD risk. Furthermore, lower respiratory infections in childhood have been shown to affect lung health in adulthood adversely.

Tuberculosis

Tuberculosis (TB) is the most common infectious cause of death worldwide, with an estimated 1.3 million deaths in 2019. Pulmonary TB is the most common form of the disease and is associated with significant chronic pulmonary sequelae, even despite microbiologic cure.[77] Tuberculosis is a significant risk factor for COPD; however, the mechanism remains unclear and whether the airflow obstruction is from scarring and other postfibrotic changes.[78,79]

Human Immunodeficiency Virus (HIV) Infection

First identified in 1989, HIV-associated COPD has a reported prevalence of between 6% and 15%.[80,81] Individuals with HIV who smoke have an increased risk of COPD with a propensity toward emphysema development.[82–84] The risk is modulated by increased oxidative stress, systemic inflammation with chronic immune activation, and endothelial dysfunction.[81,85–87] It is unclear if these mechanisms are a direct alteration due to HIV infection or a downstream response to alteration of innate immune responses. COPD and pulmonary hypertension in smokers with HIV appear to be more common in individuals with a high viral load and lower CD4 cell counts and not an adverse consequence of antiretroviral therapy.[88,89] Despite the association of HIV disease control and adverse COPD outcomes, emphysema seen in HIV patients is not reversible in relation to viral load or recovery of CD4 cell counts.

Childhood Lower Respiratory Tract Infections

The complex interaction of host-based factors and environmental predisposition to disease is of particular significance in childhood. In utero events and exposures, early childhood infections, and other events impact peak lung function. Stunted lung maturation increases the risk of developing lung diseases such as COPD later in life.[41] Continued smokers experience further declines in FEV_1 in adulthood.[31] Since the status of lung function in very early childhood predicts ventilatory function many years later, it is essential to promote overall lung health. This can be done by efforts to minimize exposure to allergens, decreasing tobacco exposure, and optimizing access to healthcare and management of respiratory diseases.[90]

Genetic Factors

There is marked variability in COPD development among smokers, with an estimated 10% to 15% of smokers developing clinically significant disease. Genetic variation has significant effects on COPD susceptibility, and heritability estimates for COPD range from 37% to 50%.[91–93] A complex genetic disorder, COPD is caused by the interaction of multiple genes and the environment. Endotypes of COPD are when a known molecular mechanism results in observable disease such as seen in telomerase reverse transcriptase (TERT) gene polymorphisms that affect the action of telomerase and mutations that result in α1-antitrypsin deficiency. Alpha-1-antitrypsin deficiency is autosomal recessive and the most apparent genetic link to COPD.

Alpha-1 Antitrypsin Deficiency Laurell and Erikson in 1963 identified that a deficiency in the neutrophil elastase inhibitor α1-antitrypsin (α1-AT) was associated with COPD.[94] Genetic variants in *SERPINA1* (serpin peptidase inhibitor, clade A, member 1) are responsible for α1-AT. Genetic variants in *SERPINA1* result in an imbalance between α1-AT and neutrophil elastase, increasing the risk of emphysema. Most of the mutations in the 12.2-kb gene that encodes α1-AT are single nucleotide polymorphisms (SNPs) with letters specifying the allelic variants. The original letters were chosen to reflect electrophoretic mobility: F = fast, M = medium, S = slow, and Z = ultraslow (Fig. 38-5). Homozygosity for the M allele, Pi MM, is present in about 95% of adults in the United States. Homozygotes for the Z allele (ZZ), S allele (SS), and compound heterozygotes (ZS) have lower serum α1-AT levels and an increased risk for COPD and emphysema.[95–97] The relationship of heterozygosity to COPD risk had been controversial, but it is increasingly evident that Pi MZ individuals have more airflow impairment, as measured by FEV_1/FVC and more emphysema on CT scans than matched Pi MM individuals.[98,99] Even after accounting for the genetic variants in *SERPINA1* and the strong association with COPD, there remains unexplained variability in COPD risk.[100,101]

Telomerase Polymorphisms Deleterious mutations in the telomerase reverse transcriptase gene (TERT) affect the stability and processing of the enzyme.[102] TERT mutations are associated with aging effects that increase COPD susceptibility.[103] Telomeres are DNA-protein structures located at the end of the chromosome and

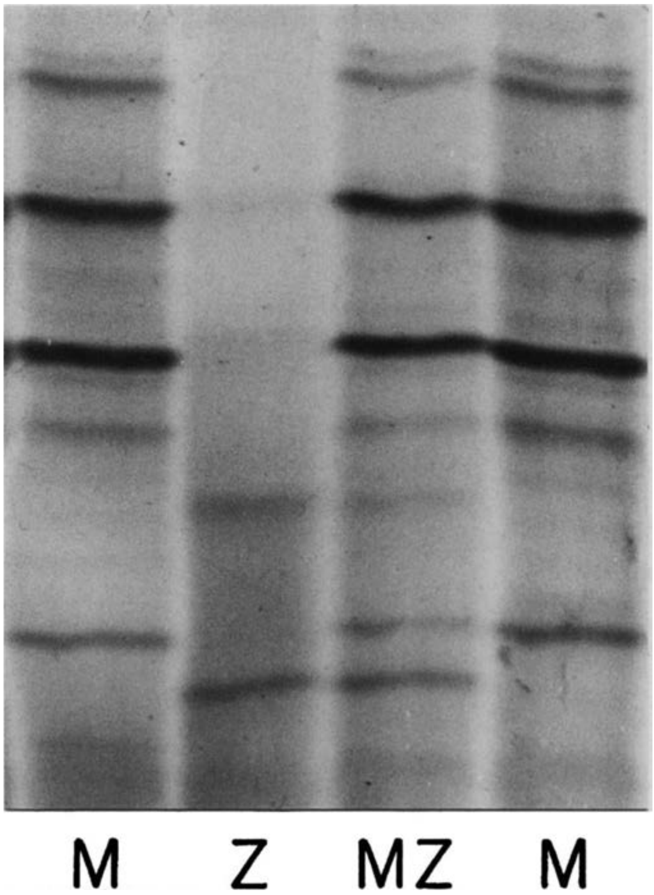

Figure 38-5 Patterns of Pi M, Pi Z, and Pi MZ α1-AT on isoelectric focus. By this analysis, α1-AT has microheterogeneity and thus appears as multiple bands. Pi M and Pi Z have distinctly different band patterns, while Pi MZ has a pattern that combines both Pi M and Pi Z. *(Reproduced with permission from John A. Pierce, M.D.)*

are responsible for protecting the chromosome's integrity throughout the cell cycle. Telomeres gradually shorten with cell division and maturation, and when they reach a certain threshold, they result in cell senescence and apoptosis.[104] TERT polymorphisms disproportionately affect women, increase the pneumothorax risk, and are associated with early-onset emphysema in smokers.[105] They are seen in approximately 1% of COPD patients and are described in familial idiopathic pulmonary fibrosis.[106] TERT polymorphisms highlight that small changes combined with exposures such as tobacco smoke and air pollutants contribute to increased susceptibility.[107]

Other Genetic Variants Efforts to identify other genetic loci are ongoing in multiple cohorts. The Framingham Heart Study cohort was the first genome-wide association study (GWAS) to assess lung function. In this cohort, a variant in interleukin 6 receptor (IL6R) and glutathione-S-transferase omega-2 (GSTO2) were associated with the degree of airflow obstruction.[108] COPD is heterogeneous, and mutations in several disease pathways have been associated with COPD risk and outcomes (Figs. 38-6 and 38-7). The inflammatory pathways (IL6, IL6R), protease imbalance (SERPINA1), oxidant stress (GSTO2), nicotine metabolism, and dependence (cytochrome P-450 2A6) are just a few pathways with disease-associated genetic variants.[108–112] The cholinergic nicotinic acetylcholine receptor exemplifies COPD's genetic complexity. Several mutations in this pathway, including HHIP and CHRNA3/5, have been associated with COPD risk; further, several factors, including epigenetic factors, mediate the expression and subsequent disease associations. The CHRNA3/5 locus is associated with increased smoking intensity and emphysema while the HHIP locus with COPD exacerbation frequency.[113]

Given the polygenic pathogenesis, polygenic risk scores have been shown to increase the predictive power for COPD, and this has the potential to identify susceptible individuals at an earlier age.[114–116]

PATHOPHYSIOLOGY

COPD represents the clinical expression of complex alterations in the structure and function of alveolar tissue and small airways. Many processes at the tissue and cellular levels can be implicated, including inflammation, cell proliferation, apoptosis, the altered phenotype of lung cells, and remodeling of the extracellular matrix. Numerous mediators, most notably proteinases, oxidants, and cytokines, are involved in these processes mediate the observable physiology in COPD.

Hogg and colleagues observed that airways 2 mm or less in internal diameter typically contribute only a minor part of the total airway resistance, but these airways are the principal sites of increased airway resistance in COPD.[117] The physical basis for small airway resistance in COPD has been considered a combined result of emphysema causing minor airway instability and collapse along

AL GRAWANY

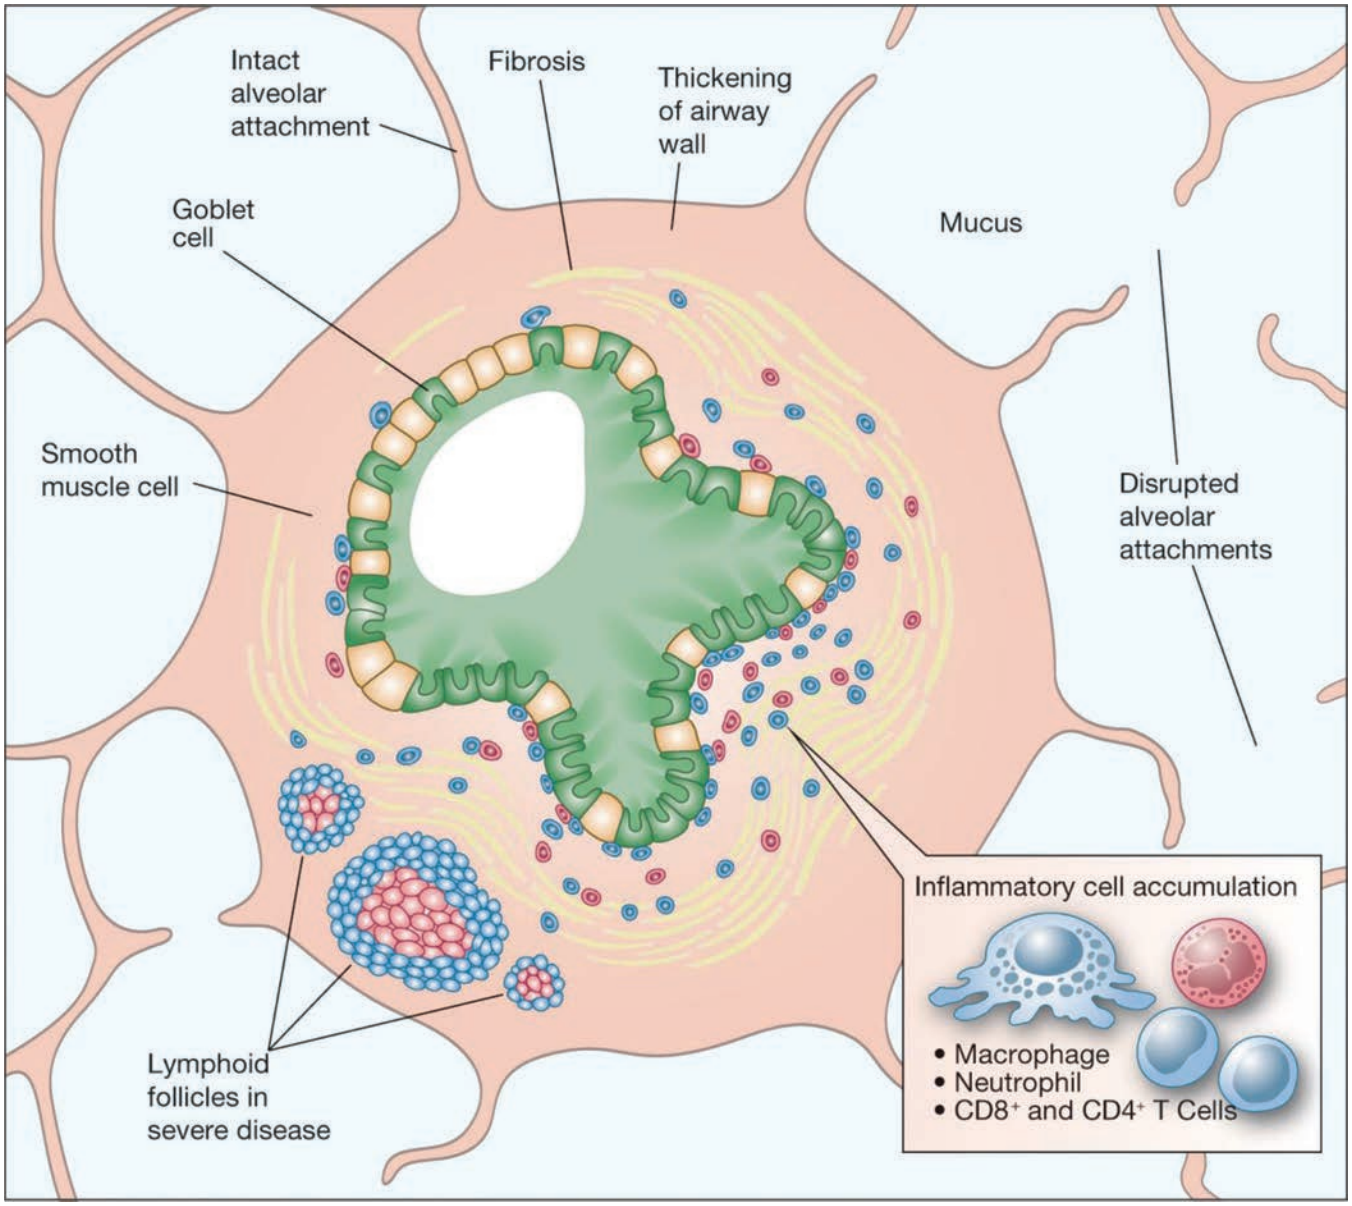

Figure 38-7 The differences in lung function decline exemplify heterogeneity of COPD outcomes. Histogram of the mean annual FEV_1 decline (L) for 751 patients with COPD followed for a median of 64 months and up to 10 years, with an average of 5.44 annual measurements (stratified by ATS/ERS and GOLD severity classification as follows: 32 [4%] mild [FEV_1% ≥80]; 256 [34%] moderate [FEV_1% 50–79]; 245 [33%] severe [FEV_1% 30–49]; and 218 [29%] very severe [FEV_1% <30]). *(Reproduced with permission from Nabel EG: ACP Medicine: Pulmonary, Hamilton, Ontario. Canada: Decker Publishing; 2011.)*

with multiple anatomic abnormalities narrowing the lumens of small airways. Because emphysema and small airway pathology are common in individuals with COPD, their relative contributions to airflow obstruction have been difficult to discern.

A fixed reduction in airflow is associated with several specific pathologic findings in the small airways of advanced COPD (Fig. 38-8). Small airways in the lungs of individuals with COPD typically show goblet cell metaplasia, replacement of Clara cells with mucus-secreting cells, and infiltration of the airway walls by inflammatory cells that, in severe disease, include an increased surface area of lymphoid follicles.[118] The cellular changes are accompanied by increased connective tissue in the subepithelial and adventitial compartments of the airway walls.[118] Alveolar tissue surrounding small airways usually provides radial traction on bronchioles at points where alveolar septa attach. Loss of these bronchiolar attachments resulting from proteolytic destruction may contribute to airway distortion, narrowing, and instability.

Advances in CT image analysis techniques, such as parametric response mapping (PRM), have identified earlier, more predictive manifestations of disease to analyze emphysema pattern and location, measures of airway caliber such as degree of expiratory central airway collapse, and distal airway dropout, among others.[119–122] The large-scale pathologic loss of terminal airways in advanced disease contributes significantly to the small airway resistance. It is unclear if the radiographic loss of small airway surface area in early disease is pathologic destruction, severe wall thickening, or mucus plugging that obscures the lumen below the radiographic resolution. However, more severe airflow obstruction is associated with increases in the thickness of all components of the airway wall.[120] The most significant relative increase in the airway wall components is in the

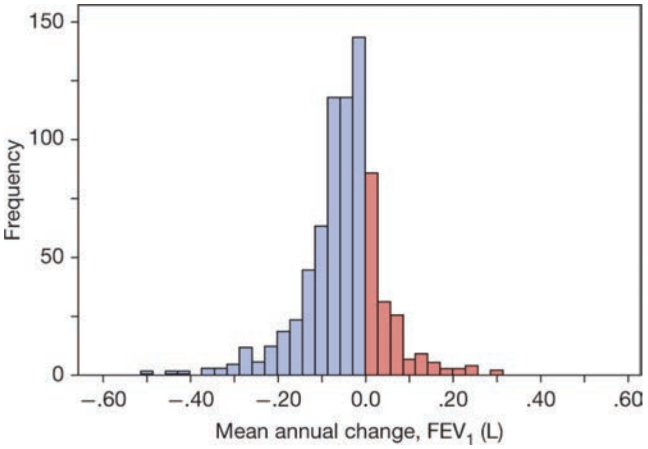

Figure 38-8 Pathologic lesions in small airways in COPD. Multiple abnormalities lead to partial obstruction of the lumen and altered shape and mechanical properties of the airways. *(Reproduced with permission from Casanova C, de Torres JP, Aguirre-Jaíme A, et al. The progression of chronic obstructive pulmonary disease is heterogeneous: the experience of the BODE cohort. Am J Respir Crit Care Med. 2011;184(9):1015–1021.)*

connective tissue–rich adventitial layer. The epithelial layer, the lamina propria, and the smooth muscle–containing layer all demonstrate significant increases in advanced disease, and small airway mucus plugs have been significantly associated with airflow limitation in severe disease.[123] The interplay of small airway pathology, radiologic loss of small airways, emphysema, and their role in causing the airflow obstruction in early COPD are ongoing research areas.

■ Airflow Obstruction

The American Thoracic Society (ATS) and GOLD recommend utilizing post-bronchodilator FEV_1/FVC less than 0.70 as the threshold for the detection of airflow obstruction. Defining and appropriately classifying persons with a reduced FEV_1 with a normal FEV_1/FVC and normal TLC has been controversial. These patients are defined as preserved ratio impaired spirometry (PRISm), an entity that some suggest should not be classified as COPD or interpreted as an obstructive ventilatory defect, while others argue that it should, given the similarity in pathogenesis and similar outcomes such as mortality when compared with COPD.[124,125]

The FEV_1 is an important marker of airflow and it reflects the balance between the elastic recoil of the lungs promoting expiratory flow and the resistance of the airways limiting flow during the performance of an FVC. In normal lungs and lungs affected by COPD, maximal expiratory flow diminishes as the lungs empty because the lung parenchyma provides progressively less elastic recoil, and the cross-sectional area of the airways falls. This leads to an increase in airway resistance. The decrease in flow coincident with the decrease in lung volume is apparent on the expiratory limb of the flow–volume curve (Fig. 38-9). In mild COPD, the abnormality in airflow is evident only at lung volumes at or below functional residual capacity, appearing as a "scooped out" lower part of the descending limb of the flow-volume curve. In many patients with advanced COPD, the entire curve demonstrates decreased expiratory flow. There is wide variability in COPD in the relationships among FEV_1, exercise tolerance, alveolar gas exchange, and quality of life.[126] The correlation between FEV_1 and small airway pathology is strong, and it likely contributes to the reduction independent of the correlation of FEV_1 with emphysema.

■ Airway Hyperresponsiveness

Airway hyperresponsiveness (AHR) is present when there is an acute, temporary decline in maximal expiratory airflow in response to inhaling potential bronchoconstricting agents such as methacholine or histamine. Historically the "Dutch hypothesis" postulated that asthma and COPD are two different manifestations of the same disease due to the similarity in features such as the presence of airway hyperresponsiveness.[127] Distinct from asthma, the type and cause of airway inflammation and consequences of the inflammatory process are different in COPD. Smokers typically do not show AHR until their FEV_1 is reduced, and experimental induction of emphysema often leads to AHR.[128] AHR is of clinical significance as it is associated with an accelerated decline of FEV_1 and is a negative prognostic marker.[129] In the Lung Health Study, AHR was second to smoking as an essential determinant of decline in FEV_1, and it was not related to the initial level of obstruction. AHR was more significant in women smokers than men smokers.[129] Although AHR decreased after smoking cessation and bronchodilator responsiveness improved, bronchodilator responsiveness did not correlate with the rate of FEV_1 decline.[130]

An important component of COPD, AHR in individuals with COPD is underestimated due to the infrequency of bronchoprovocation testing in patients with COPD. It may be a consequence of emphysema, airway wall stiffness, and parenchymal tethering by the extracellular matrix.[128] Distinctions in airway hyperresponsiveness in COPD and asthma are still a significant topic of interest.[128]

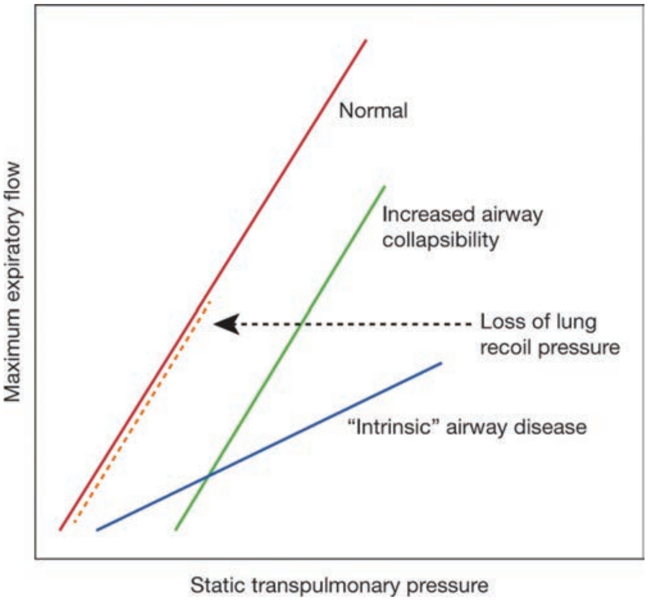

Figure 38-9 Reduced maximum expiratory flow in COPD from maximum expiratory flow versus lung recoil pressure curves. Loss of lung recoil, emphysema (heavy interrupted line)—the flow–pressure curve slope remains normal, but the curve terminates at a lower pressure than normal. Due to airway obstruction, the slope is reduced. Increased airway collapsibility, due to decreased elastic recoil, causes displace the curve to the right. In COPD, the flow–pressure curve has premature termination and a decreased slope and is shifted rightward, indicating decreased elastic recoil, increased airway resistance, and increased airway collapsibility are all involved in the reduced maximum expiratory flow. *(Reproduced with permission from Calverley PMA, Pride NB: Chronic Obstructive Pulmonary Disease. London, Chapman & Hall; 1995.)*

PATHOGENIC MECHANISMS

Numerous well-established pathogenic mechanisms result in the observable COPD phenotypes. These mechanisms include dysregulated inflammatory reactions, excess oxidant stress, mucus hypersecretion, and proteinase imbalance resulting in elastic fiber degradation and increased collagen turnover.

Inflammation

Inflammatory responses can be divided into innate and acquired types.

Innate Immune Responses

Tobacco smoking and other inhaled irritants lead to the recruitment, infiltration, and activation of innate inflammatory cells in the lungs and airways, where an excess of the products of these cells injure lung tissue and disrupt lung repair mechanisms.[118,131,132] Some inflammatory cell types important in COPD include neutrophils, macrophages, and variably eosinophils, but also dendritic cells and lymphocytes. The increased presence of airway inflammation is demonstrated by inflammatory cells in lung biopsy specimens, bronchaoalveolar lavage fluid, and sputum as well as increased volatile products of inflammation in exhaled breath.[133–137] While the presence of inflammatory change can be a normal response to oxidative stress and tissue damage due to irritants such as cigarette smoke, maladaptation of these integral functions to the innate immune dysfunction is key in COPD pathogenesis. Once COPD is established, there can be continued oxidative stress and progression from endogenous sources such as mitochondrial respiration even after the cessation of inhaled toxic exposures.[138]

Activated macrophages and neutrophils are the major participants in lung inflammation in COPD.[139] Monocytes become alveolar macrophages after migrating into the lungs by sensing and following chemoattractant gradients of cytokines and bacterial peptides produced by tissues of infection or inflammation.[140,141] Essential to establishing homeostasis of the inflammatory milieu, alveolar macrophages have both anti-inflammatory (M1) and inflammatory (M2) phenotypes. COPD patients have a dominant M2 phenotype, with several alterations that result in defective phagocytosis and changes in abnormal secretion of cytokines and chemokines.[142–144] Alveolar macrophages in COPD release proteinases that degrade the extracellular matrix of the lung and release chemotactic factors that recruit other inflammatory cells to the lungs.[145] Unlike most circulating cells such as neutrophils that decrease within weeks of limited tobacco smoke exposure, activated alveolar macrophages may be present even years after smoking cessation.[146,147]

Neutrophilic inflammation induced by byproducts of cigarette smoke, viruses, bacteria, and oxidative stress is characteristic of COPD and is the predominant mediator of mucus hypersecretion.[148,149] Neutrophilic inflammation in COPD is unfortunately not responsive to available therapies, with minimal response to steroid therapy.[148,150] Airway epithelial cell exposure to pollutants and inflammatory peptides activates the production of neutrophilic mediators and chemoattractants such as CXCL1, CXCL8, and leukotriene B4, engaging chemoreceptors CXCR2 and BLT1 receptors.[151] All of these are produced in excess in patients with COPD. Investigations into therapeutics such as CXCL8 blockade or the signaling cascade intermediaries such as TNF-α and IL-1β have not shown benefit in lung function or frequency of exacerbations.[148,150,152] Macrophages and neutrophils are commonly seen in patients with COPD; however, the role of eosinophils is now increasingly understood.

The role of eosinophilic inflammation has garnered a lot of attention. About 20% to 40% of patients with COPD have increased airway eosinophilic inflammation.[153] The presence of eosinophilic inflammation is best quantified using the direct examination of lung biopsies, bronchoalveolar lavage fluid, and induced sputum, and airway eosinophilia is associated with increased frequency of exacerbations and hospitalizations for exacerbations.[154,155] Peripheral blood eosinophilia has been advanced as a more practical surrogate marker for eosinophilic airway inflammation due to the expense and challenge and lack of availability of more directed measurements of airway inflammation. The blood eosinophil count is a promising biomarker of response to inhaled corticosteroids in COPD. The lung has tissue-resident eosinophils that are independent of those recruited by chemokine CCL5. While the origin is different, these two populations there are similarities in function.[156] Eosinophils are activated by smoke and infectious byproducts, resulting in the production of the cytokines thymic stromal lymphopoietin (TSLP) and IL-33. TSLP and IL-33 are responsible for recruiting Th2 cells and type 2 innate lymphoid cells (ILC2), which result in eosinophilic inflammation for secreted IL-5.[148] In addition to their effector functions, eosinophils contribute to the immune response through recruitment of dendritic cells (DCs), production of several Th2 chemoattractants, and by performing some functions of antigen presentation.[156–158]

While knowledge of the role of DCs is not as established, they appear to be important in the pathogenesis of COPD. DCs are antigen-presenting cells that impact the activation of adaptive immune cells. It has been shown that once they are primed, DCs in COPD play a role in increasing natural killer (NK) cell cytotoxicity toward epithelial cells.[159] Lung DCs increasing NK cell activity may be significant in COPD pathogenesis. Like alveolar macrophages, DCs are critical to the balance of inflammatory and anti-inflammatory effects.[160] The overall effect of DCs is critical to both the innate immune response and initiating adaptive immune responses.[161]

While not all people with chronic tobacco exposure develop COPD, in those who develop COPD, the inflammatory process initiated by smoking may persist long after smoking has stopped.[147,162,163] The inflammatory processes in COPD are not limited to the lungs and airways. The role of systemic inflammation is evident in stable COPD and to a higher degree in severe COPD and during acute exacerbations of COPD. Systemic inflammation is evident from increased leukocyte counts, cytokines, chemokines, acute phase reactants, or abnormalities in circulating cells.[163–166]

The various contributions from the immune system cells likely contribute to pathogenesis at separate stages and likely impact the different disease phenotypes. The innate immune response mechanisms contribute to COPD progression, and these mechanisms are interlinked with the activity of adaptive immune cells lead to increased COPD severity.

Acquired Immune Responses

Cellular and humoral immunity are also involved in COPD pathogenesis and the continued progression of COPD after smoking cessation. These COPD responses include the proliferation of B and T cells after antigen presentation by macrophages and dendritic cells. Patients with COPD have an increased presence of cytotoxic CD8+ T cells, various CD4+ subsets including Th1 and Th17, and alterations in T regulatory cells (TREGs).[140] In addition to the role of T cells, antigen exposure elicits B cell responses and antibody production. Further, in the past decade, there has been an increase in information about the function of other adaptive immune cells such as natural killer (NK) cells and natural killer T (NKT) cells in COPD. These inflammatory mediators play a different role and are impacted by smoking status and frequency of respiratory infections and exacerbations, as well as the balance of immunoregulatory cell functions.

CD4+ and CD8+ T cells and B cells accumulate in alveolar and airway tissue in COPD. Peribronchial lymphoid follicles are formed through lymphoid neogenesis and the activity of lymphoid chemokines that are important for cell migration such as CCL21, CXCL12, and CXCL13.[167,168] There is an accepted role for autoimmunity, particularly in COPD, as evidenced by an excess of

TABLE 38-2 Proteinases That May Affect the Lung Parenchyma

Proteinase	Cell of Origin
Neutrophil elastase	Neutrophil (monocyte)
Proteinase 3	Neutrophil (monocyte)
Cathepsin G	Neutrophil (monocyte, mast cell)
MMP-1[a]	Macrophage, epithelial cell
MMP-9 (Gelatinase B)	Macrophage, neutrophil, eosinophil, fibroblast, epithelial cell
MMP-12 (Macrophage elastase)	Macrophage
Cathepsin L	Macrophage
Cathepsin S	Macrophage

Parentheses denote minor cellular sources.
[a] *Lacks elastase activity.*

B cell lymphoid follicles and the presence of several autoantibodies in patients with COPD.[167,169] Antigens for immunologically mediated progression of airway disease and emphysema include microbial pathogens, peptides altered by tobacco smoke, and peptides released from damaged lung extracellular matrix.[162,170,171] Difficulties in distinguishing cellular and humoral responses to microbial colonization of advanced airway disease in COPD from pathologic self-directed immune responses will require further study.[167] Due to the complexity and multiplicative nature of the derangements in the immune response in COPD, identifying a therapeutic target, specifically in advanced disease, has been challenging. Targeting therapies in the early stages of disease progression can be a more fruitful endeavor.[172]

■ Proteinase–Antiproteinase Imbalance

The discovery of α1-AT deficiency–associated early-onset emphysema and the advent of experimental animal models producing emphysema with elastolytic enzymes promoted the imbalance of proteinases relative to their inhibitors as a critical factor for emphysema development.[94] Proteinases of several biochemical classes, and various specific inhibitors, are implicated in emphysema pathogenesis. Serine proteinases, especially neutrophil elastase and several matrix metalloproteinases, have been the proteinases for which there are the most data[173] (Table 38-2). It is notable that both neutrophils, which are the source of neutrophil elastase, and MMP-12 from alveolar macrophages are primarily related to continued smoking. Progression after smoking cessation may follow different pathways. Although neutrophil elastase and its main inhibitor α1-AT have predominated the proteinase–antiproteinase imbalance hypothesis, MMPs appear prominent in mouse models and samples from smokers and individuals with COPD. It is likely a combination of many local imbalances involving several proteinases and antiproteinases contributing to progressive lung destruction.

Several aspects of proteinases in COPD should be noted, as solely a straightforward destructive mechanism is likely an oversimplification. In addition to the destruction of lung elastin and other matrix components, proteinases process cytokines and surface receptors involved in the inflammatory and immune responses.[174] Inflammatory cells may not be the exclusive protein source, as structural cells also produce matrix-degrading proteinases.[174,175]

■ Oxidant–Antioxidant Imbalance

Reactive oxygen species in cigarette smoke or released by inflammatory cells and the lungs' structural cells in response to smoke may lead to lung injury.[176] Smoking causes both regional and systemic oxidative stress by altering the balance between oxidants and antioxidants. A puff of cigarette smoke can contain more than 1000 free radicals with more than 4000 oxidant compounds such as superoxides, epoxides, peroxides, nitric oxide (NO; 500 to 1000 ppm), nitrogen dioxide, peroxynitrite (ONOO−), and peroxyacyl nitrates.[177–180] Cigarette smoke–induced oxidative stress initiates a cascade of cellular and molecular reactions that initiate inflammation, cell injury, and apoptosis.[181] The processing of these cigarette smoking sequelae is dependent on the effect of antioxidants. Genetic mutations in antioxidant genes are linked to susceptibility and COPD severity. Genetic polymorphisms in antioxidant genes are associated with the progression of COPD, such as polymorphisms in several genes in the glutathione S-transferase (GST) gene family, including GSTM1, GSTM3, GSTP1 as well as superoxide dismutase 3 (SOD3), and microsomal epoxide hydrolase (EPHX1).[176,182–184] Mutations in transforming growth factor-β1(TGFB1) are protective.[185]

The lung tissue of smokers contains significantly higher iron content, which provides a catalyst for the production of hydroxyl radicals from H_2O_2.[186,187] This is combined with the knowledge that iron-responsive element-binding protein 2 (IREB2) polymorphism is prevalent in smokers with COPD[188,189] (Fig. 38-6). Smokers also demonstrate increased production of neutrophil myeloperoxidase, capable of yielding oxidized halogens such as hypochlorous acid (HOCl).[189,190] The harmful effects of oxidants are numerous and include modification and inactivation of protease inhibitors (α1-AT and secretory leukoprotease inhibitor) and anti-inflammatory proteins like histone deacetylase 2 (HDAC2).[191–193] Oxidants can also affect lipids and DNA, and some specific end products, such as 4-hydroxy-2-nonenal (4-HNE) and 8-hydroxy-2′-deoxyguanosine (8-OHdG), may be biomarkers of COPD.[194,195]

Oxidants can promote inflammation and proteinase expression, facilitate proteinase-mediated extracellular matrix degradation by enhancing matrix molecule susceptibility to proteolytic cleavage, and participate in nonenzymatic degradation of matrix molecules like type I collagen. In experimental animals, the combination of cigarette smoke and elastase leads to more significant emphysema than either insult alone, and antioxidant deficiency results in increased susceptibility.[196–198]

■ Apoptosis and Senescence

Cellular senescence and apoptosis occur more frequently in COPD than in healthy people due to replicative and stress-related factors. In vitro, cigarette smoke induces apoptosis of alveolar epithelial cells, endothelial cells, lung fibroblasts, and granulocytes. Bicaudal D1 (BICD1) has been identified as a susceptibility gene in COPD, with a polymorphism linked to emphysema (Fig. 38-6), and encodes for a protein essential in autophagy and critical to the apoptosis pathway.[199,200]

In addition to apoptosis, cellular senescence is important in COPD pathogenesis. Senescence is a state of stable cell cycle arrest, and usually, due to DNA damage, it makes proliferating cells resistant to growth-promoting stimuli.[201] Senescence is a driving mechanism resulting in the pathogenesis of emphysema. Senescent cells secrete copious inflammatory proteins propagating inflammatory processes and causing more senescence. Changes related to oxidative stress result in the loss of function of silent information regulator (sirtuin) 1. Sirtuin-1 and sirtuin-6 are antiaging molecules whose deacetylation regulates metabolism, increases genomic stability, and reduces cellular stress.[201,202] In animal models, several other proteins with anti-aging effects have been identified such as senescence marker protein 30 (SMP30), DNA-dependent protein kinase (DNA-PK), and Ku86.[202–204] Senescent cells (alveolar, epithelial, and endothelial cells) are prevalent in the lungs of COPD patients.[205–207] Impaired immunity, increased cancer risk, and frequent infections are seen when there is senescence of immune cells (immunosenescence). Early data suggest a potential reversal of these processes, and there are several therapeutic interventions under investigation.[201,208,209]

■ Mucus Hypersecretion

Airway mucus is a complex mixture of mucins, inflammatory cells, water, soluble mediators, and negatively charged ions. It is usually a protective barrier that is continuously replenished and cleared in healthy people. The negative charge of mucus glycoproteins results in sequestration of proteases, volatile hydrocarbons, and possibly preservation of the hydration of the ciliated layer, resulting in protection of the underlying lung and likely improved carcinogen clearance. Pathologic or excess mucus production, known as chronic mucus hypersecretion, is one of the most common respiratory symptoms in most chronic lung diseases. Obstruction of small airways and chronic inflammation are fundamental features of many chronic lung diseases such as cystic fibrosis (CF), asthma, and COPD. Exacerbations of these lung diseases are associated with increased mucus production. Sputum production and cough are associated with COPD progression and increased risk of exacerbations, and may have implications on mortality.[210–213]

Mucus production and regulation is a complex process involving cytokines, chemokines, and several inflammatory mediators as well as toxic agents that induce inflammation and reactive oxygen species (TNF-α, IL-1β, IL-6, IL-9, IL-9, IL-17, prostaglandins, neutrophil elastase, human airway trypsin, metalloproteinases, lipopolysaccharides, cigarette smoke, and airway pollutants).[214–218] In COPD, there is hyperplasia of goblet cells and hypertrophy of glands, with an increase in the ratio of glandular mucus cells to serous cells resulting in pathologic changes to mucus production. Several pathogenic mechanisms are associated with the mucus changes, including altering the mucus proteins (MUCs). Like cystic fibrosis, there is an alteration to favor a predominance of MUC5B over the typical MUC5AC form and an increase in the MUC2 form, which is uncommon in normal lung mucus.[219,220] Additionally, abnormalities in the cystic fibrosis transmembrane conductance regulator (CFTR) have been shown to alter airway mucociliary transport and contribute to COPD disease pathogenesis.[221–223] In COPD, other alterations in the mucus layer include greater acidity, less mucin glycosylation, and decreased antimicrobial peptides.[220] Mediators responsible for mucus hypersecretion include proteinases, cytokines, oxidants, and activation of several signaling pathways such as epidermal growth factor receptor (EGFR).[224–227] The small airway luminal obstruction by mucus is correlated with the degree of airflow obstruction and inversely correlated with survival after lung volume reduction surgery.[228]

■ Lung Elastic Fiber Degradation

Observations linking proteinases to emphysema led to the concept that the destruction of alveolar elastic fibers is key to emphysema development.[229] An imbalance of proteases and antiproteases result in parenchymal destruction. Macrophages, neutrophils, and other effector cells release proteases, including proteinase 3, matrix metalloproteinases (MMPs), and other cytolytic products that activate each other and inhibit other endogenous inhibitors.[230] Structurally, the extracellular matrix of the lung is organized into three interdependent cable systems: (1) an axial system that extends from the central airways through the peripheral airways to the alveolar ducts; (2) a parenchymal system that comprises the matrix of the alveolar septae; and (3) a peripheral system that arises from the visceral pleura and extends into the interlobular septae, forming a fibrous sac around the lung. Distal to the respiratory bronchioles, the axial system forms a helix encircling the alveolar ducts, extending into the interstitium of alveolar walls. Elastic fibers, of which elastin is the main component, loop around alveolar ducts, form rings at the mouths of the alveoli, and penetrate as wisps into the alveolar septae, where they are concentrated at bends and junctions (Fig. 38-10). Elastic fibers, which possess rubberlike reversible extensibility, come under tension and provide elastic recoil throughout the respiratory cycle. Unlike elastic fibers, the interstitial collagen fibers in alveolar septa are not distensible and have high tensile strength.

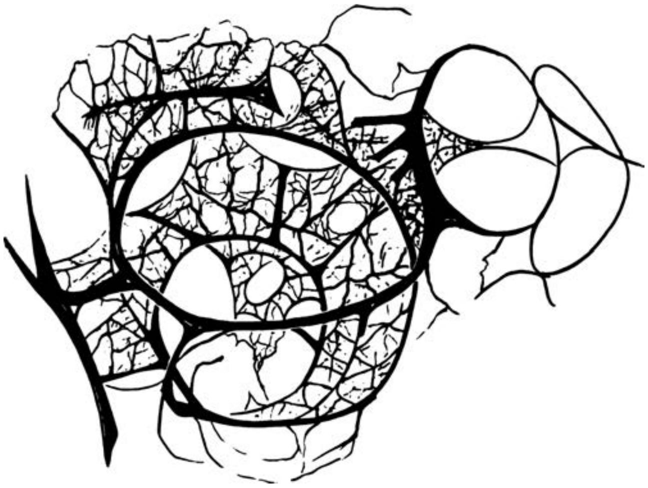

Figure 38-10 Alveolar elastic fiber network. Artist's sketch of the elastic fibers in lung parenchyma showing how elastic fibers form a helix encircling the alveolar ducts and penetrate alveolar septae. *(Reproduced with permission from Pierce JA, Ebert RV. Fibrous network of the lung and its change with age. Thorax. 1965;20(5):469–476.)*

Elastin is present in bronchi and lung parenchyma, and in alveolar regions of the lung, elastin fibers are deployed around alveolar ducts, the openings of alveoli, and extensions into alveolar septa.[231] Distraction of elastic fibers leads to tissue loss, altered alveolar structure, and emphysema. While elastin is resistant to many proteinases, some enzymes can degrade elastin (Table 38-2). Elastic fibers in the lung typically last an entire human life span.[232] Histologic studies of emphysematous lung tissue support the hypothesis that elastic fibers are perturbed in emphysema. There are fragmented elastic fibers in α1-AT deficiency and poorly formed elastic fibers, and elastin clumps in smokers with centriacinar emphysema.[232] The latter changes appear from the aberrant synthesis of new elastin and resemble the findings in emphysematous lungs induced experimentally with elastase.

Animal models employing elastase-induced emphysema have shown acute depletion of elastin following an intratracheal injection of human neutrophil elastase, followed by a burst of synthesis of extracellular matrix including elastin.[233] Over a few weeks, the elastin content of the lungs returns to normal, although the lungs still display emphysema. The elastic fibers, like the elastic fibers in human emphysema, appear disorganized. New elastin gene expression occurs even in severe emphysema in humans (Fig. 38-11). However, there are significant barriers to the effective repair of damaged elastic fibers in the mature lung. When elastic fibers are damaged enough to fail under load, there is no mechanism for cells to recreate a structure with a length many times the size of each cell. The injured adult lung lacks the mechanical and morphogen gradients that initiate alveolar formation during development and may also be unable to coordinate the expression of the many components necessary for functional elastic fiber synthesis.

■ Lung Collagen Turnover

Although elastic fiber destruction dominates the proteolytic basis for emphysema pathogenesis, the degradation of alveolar wall collagen and aberrant collagen deposition in alveolar tissue also may

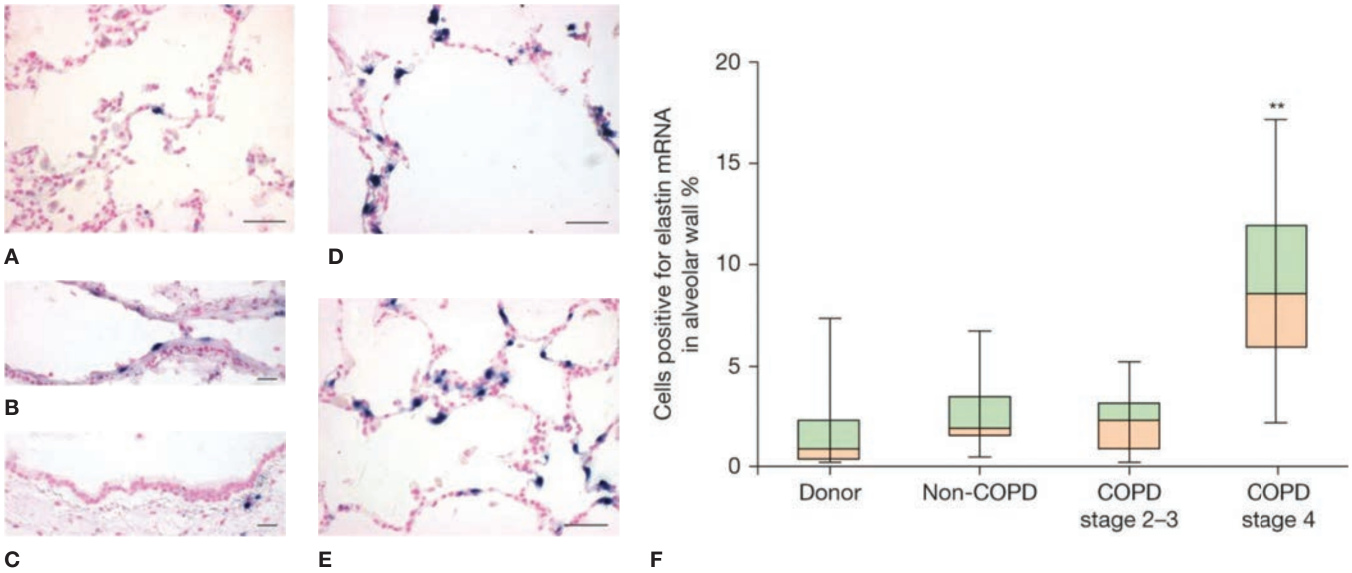

Figure 38-11 Expression of elastin production in severely emphysematous lung removed for lung transplantation. Elastin mRNA *(blue signal)* as detected by in situ hybridization is rarely detected in donor lungs in (**A**) parenchyma, (**B**) intralobal pulmonary arteries, or (**C**) airways but is prevalent in the parenchyma of patients with very severe COPD in regions with moderate (**D**) and severe (**E**) alveolar enlargement. Quantification of cells positive for elastin mRNA (**F**) reveals significantly higher elastin expression in alveolar walls of very severe COPD (GOLD stage 4) lungs compared with donor lungs or less severe COPD lungs. *(Reproduced with permission Deslee G, Woods JC, Moore CM, et al. Elastin expression in very severe human COPD. Eur Respir J. 2009;34(2):324–331.)*

be involved. There is increased collagen deposition in patients with COPD compared with smoker controls.[234] In some forms of experimental emphysema, collagen destruction appears to be a critical event. Human collagenase/matrix metalloproteinase 1 (MMP-1) is important in development of emphysema. Mice genetically engineered to harbor a transgene that leads to the expression of MMP-1 in lung tissue develop structural changes typical of emphysema. These changes occur due to the destruction of alveolar type III collagen.[235,236] In these models, emphysema occurs without obvious disruption and faulty resynthesis of elastic fibers as the elastic fibers in these lungs look normal. Expression of MMP-1 by alveolar epithelial cells in human emphysematous tissue fits with the idea that collagenolytic activity plays a role in emphysema.[175,237]

Cigarette smoke exposure leads to tripeptide proline-glycine-proline (PGP) release from the lung matrix.[238] PGP binds chemokine receptor 2 (CXCR2), a prominent chemokine receptor on neutrophils. PGP functions as a neutrophil chemoattractant, and in an animal model, PGP's repeated instillation into the lung produces emphysema by collagen breakdown.[238,239] Analogous to elastin peptides promoting emphysema in mice, PGP is generated by the sequential breakdown of collagen by MMPs 8 and 9 and prolyl endopeptidase, and blocking PGP reduces emphysema in mice exposed to cigarette smoke.[239,240]

In emphysematous lungs, the pores of Kohn are larger and more numerous than in normal lungs (Fig. 38-12). Because interstitial collagens and basement membrane collagens are prominent in alveolar walls, it is plausible that collagenous structures undergo degradation in the process of generating these interalveolar pores.

CONCLUSION

Despite advances in pathogenesis, the treatment options remain limited, with very few options that significantly impact mortality. Unlike many major causes of death, the disease burden is projected to continue to increase as cigarette smoke exposure continues to increase in low- and middle-income countries. Despite the current efforts at decreasing the burden of the disease, there remains a significant need.

CHAPTER 39

Chronic Obstructive Pulmonary Disease and α1-Antitrypsin Deficiency

Darrell N. Kotton
Andrew A. Wilson

INTRODUCTION

While predisposition to COPD is widely known to have a significant genetic basis,[1] the only known monogenic cause is the genetic mutation that results in α-1 antitrypsin deficiency (AATD). AATD was first identified in 1963 by Laurell and Eriksson, who initially described a cohort of five individuals lacking the α1 globulin fraction, as revealed with serum protein electrophoresis. Three of the five suffered from significant pulmonary disease.[2] Subsequently, AATD was shown to result from the homozygous inheritance of a single base-pair mutation in the *SERPINA1* gene, which encodes α1-antitrypsin protein.

Misfolded AAT proteins are poorly secreted and functionally abnormal—features that collectively predispose affected individuals to developing panlobular emphysema and COPD. While the prevalence in the population is not precisely known, AATD is estimated to afflict approximately 100,000 individuals in the United States and to account for approximately 1% to 4.5% of cases of COPD.[3–7] Coupled with the observation that the cysteine protease inhibitor papain induces emphysema in rats when instilled intratracheally,[8] the discovery of AATD and its association with emphysema led to the formation of the protease/antiprotease hypothesis as a basis for the pathogenesis of COPD (emphysema).

EPIDEMIOLOGY

The Z mutation is believed to have arisen from a single origin approximately 2000 years ago, potentially in the Viking population,[9,10] who then disseminated it in southern Scandinavia. Studies of gene frequency have demonstrated significant variance among European nations, in which a gradient of gene frequency has been found, including high levels in the Northwest that decrease toward the Southeast.[10] In Europe, the highest levels are found in regions of Estonia, Latvia, Sweden, France, Ireland, southern England, and northern Spain.[10] Outside of Europe, the Z mutation is found at high levels in countries where it was introduced by European migration, including the United States, Australia, and New Zealand.[9,11] Z gene frequency varies across African nations, but, on average, is approximately half of that seen in the United States; the frequency is significantly lower in other parts of the world, including China, South Korea, and Japan.[11,12]

The overall prevalence of the Pi*ZZ phenotype has been estimated from population-based studies. A screening study of 200,000 newborns in Sweden in 1972–1974 demonstrated a prevalence of 1 in 1600 newborns.[13] Studies in U.S. populations have estimated a prevalence ranging from 1 in 2857 to 1 in 5097.[14–16] Based on sampling of limited numbers of patients, the Pi*ZZ phenotype is estimated to account for 1% to 4.5% of cases of COPD in the United States.[3,4,6,7]

PATHOPHYSIOLOGY

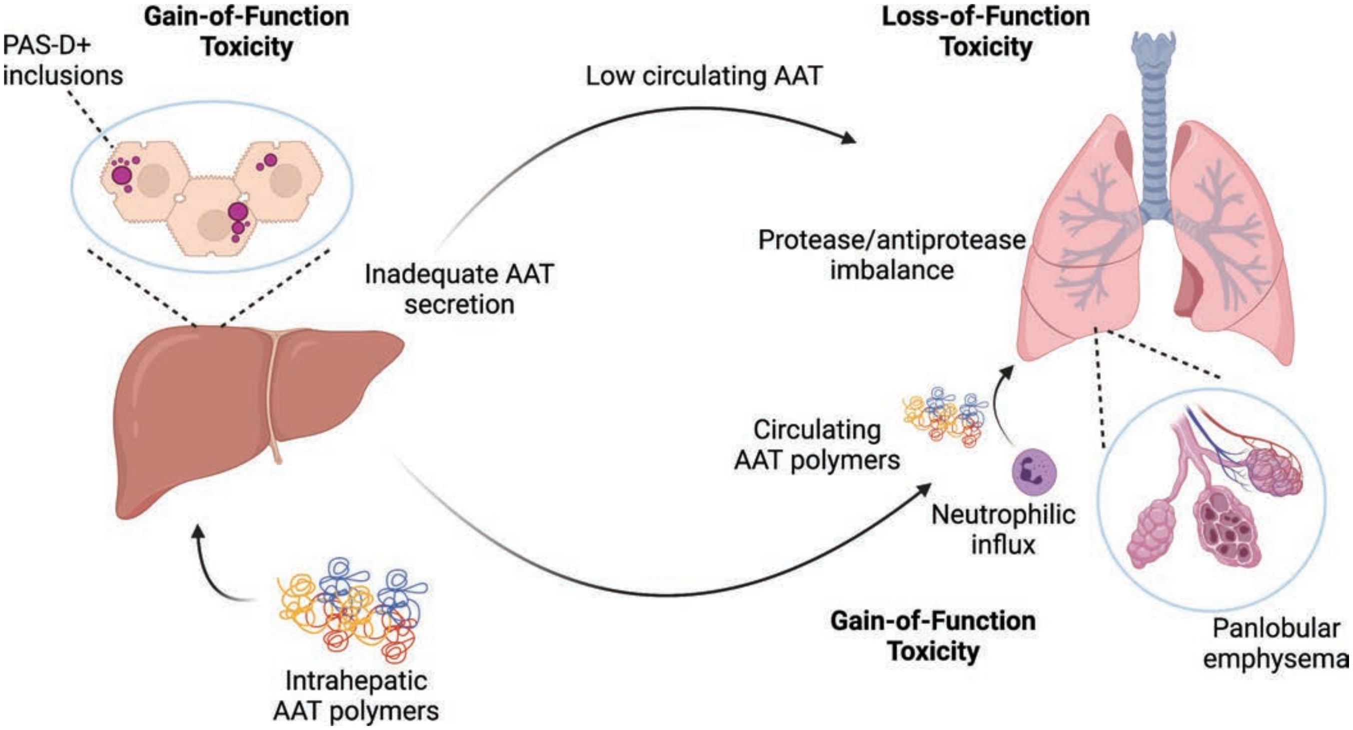
Mechanisms responsible for the development of lung or liver disease resulting from AATD have been extensively studied (Fig. 39-1), and an understanding of these mechanisms continues to evolve as modern molecular methods and animal models of disease improve.[17–19]

Liver hepatocytes express and secrete the highest levels of α1-antitrypsin protein and, consequently, are the predominant source of circulating AAT. As the name of the protein implies, AAT functions as a serine protease inhibitor (serpin) with numerous antiprotease activities, including antitrypsin and antineutrophil elastase functions.[17,20,21] AAT is found in nearly all body fluids, including saliva, tears, breast milk, urine, and semen, with concentrations in bronchoalveolar lavage fluid reaching approximately 10% of those in the circulation.[22–26] Since AAT is found in lung tissue and is considered the major antielastase of the lower respiratory tract, these observations serve as the foundation of the hypothesis that secreted AAT from hepatocytes circulates to lung tissue, where its primary function is to protect lung matrix molecules, such as elastin, from degradation by unrestrained local leukocyte-derived proteases and elastases.[19,20,27] Deficient AAT circulating levels or incomplete antiprotease activity is postulated to result in protease–antiprotease imbalance in the lung and degradation of lung elastin over time due to overexuberant activity of elastase and other serine proteases.[27] In patients with cirrhosis due to AATD who receive liver transplantation from a normal (PiMM) donor, circulating levels of AAT are normalized,[28] consistent with hepatocytes serving as the predominant source of circulating AAT.

Multiple mechanisms in AAT-deficient individuals are responsible for both the abnormally low circulating blood levels of AAT and diminished antiprotease activity; each type of AAT mutation contributes uniquely to one or both perturbations. Mutant Z-AAT protein has been most extensively studied using patient specimens, heterologous cell lines engineered to express a cDNA encoding the human Z mutant protein, or a variety of animal models.[29–34] These studies reveal that in contrast to the normal M-AAT, which is translated and secreted as a protein monomer, Z mutant protein displays posttranslational misfolding, intracellular mistrafficking, delayed protein processing, and polymerization with other Z mutant protein polypeptides, resulting in intracellular accumulation and significantly diminished and delayed extracellular secretion.[19,34–38] The intracellular accumulation of polymerized Z protein in hepatocytes results in activation of a variety of cellular stress pathways, including ER stress, leading to hepatotoxicity and increased risk of neonatal jaundice, juvenile cirrhosis, or adult cirrhosis that is well described in individuals with PiZZ AATD.[37,39] Further exacerbating the diminished antiprotease activity that results from low levels of secreted AAT, the Z mutation also compromises the antiprotease activity of the protein itself.[19]

It is well accepted that two Z alleles result in highly polymeric AAT polypeptides, and recent reports suggest polymerization can also occur extracellularly with detectable polymers, derived from the liver, found circulating in the blood stream, or deposited in nonhepatic tissues of individuals with PiZZ AATD.[40] Less common AATD mutations (such as PiS) do not appear to be polymeric and, thus, are associated with less risk of liver disease. The presence of a single Z allele (e.g., PiMZ or PiSZ) has been shown sufficient to form polymeric AAT protein,[40] and it is well established that all genotypes with a single Z allele exhibit lower circulating serum levels due to diminished hepatic secretion.[18,19,38,41,42]

Accumulating studies in recent years have added complexity to the original and relatively simple hypothesis that COPD pathogenesis in the setting of AATD is due solely to protease–antiprotease imbalance resulting from low and ineffective levels of hepatocyte-derived



Gain-of-Function Toxicity
PAS-D+ inclusions
Low circulating AAT
Loss-of-Function Toxicity
Protease/antiprotease imbalance
Inadequate AAT secretion
Circulating AAT polymers
Neutrophilic influx
Gain-of-Function Toxicity
Panlobular emphysema
Intrahepatic AAT polymers

Figure 39-1 Pathophysiology of liver and lung disease in AATD. Misfolded Z-AAT protein forms polymers in the endoplasmic reticulum of hepatocytes, causing injury through a gain-of-toxic-function mechanism. Intrahepatic inclusions of polymerized Z-AAT protein stain positive with periodic acid–Schiff stain but are resistant to digestion with diastase (PAS-D). Poor hepatic Z-AAT secretion leads to low circulating and tissue AAT levels. Z-AAT polymers in the circulation and lung interstitium are chemoattractant for neutrophils, which are found at increased levels in the lung of PiZZ patients. Together, gain-of-function and loss-of-function mechanisms contribute to an imbalance of protease and antiprotease activity in the lung leading to tissue damage and emphysema.

circulating AAT protein. In addition to its primary role in protease inactivation, numerous investigations demonstrate that AAT exerts both anti-inflammatory and immunomodulatory effects in a variety of conditions and cell types—in some cases, independent of its antiprotease activity.[43–46] Both loss of normal M-AAT anti-inflammatory activity,[43] and gain of pro-inflammatory activities resulting from the presence of Z mutant polymeric protein deposits in tissues, combine to activate potentially destructive lung inflammation.[40,47] Effects on activation and trafficking of multiple immune cell types have been documented, including neutrophils,[48] mast cells,[49] macrophages,[50] and T cells.[51]

Additional studies further support anti-inflammatory and anti-apoptotic effects of normal M-AAT protein. Reports of organ ischemia or cigarette smoke exposure have demonstrated attenuation of neutrophilic infiltration of the kidney, liver, and lung,[52–55] as well as reduction in cell death due to simulated myocardial infarction[56] in the setting of supplementation with exogenous AAT. Collectively, these studies have demonstrated direct antiapoptotic effects of AAT, as well as inhibition of caspases[54,57,58] and anti-inflammatory effects characterized by attenuation of increases in local or systemic TNF-α. Similarly, in animal lung transplant models, treatment with AAT reduced ischemic-reperfusion injury by inhibiting neutrophilic infiltration of the lung, together with reductions in cytokines, including IL-1α, IL-4, IL-12p70, MCP-1, and TNF-α.[44,59]

In contrast to the anti-inflammatory activity of normal M-AAT, the polymeric form of Z mutant AAT is proinflammatory, resulting in cellular toxicity, leukocyte activation, and cytokine release.[60,61] Studies using animals engineered to overexpress human Z protein have found evidence of cellular toxicity or intracellular proteostatic effects in non-hepatic tissues including the lung.[43,62,63] For example, lung epithelial ER stress and dysregulation of autophagy have been found in PiZ transgenic mice.[64] These observations have raised the possibility that misfolded, polymeric AAT protein might also cause toxic gain-of-function effects in lung tissue, as has been established in hepatocytes. In the setting of true null mutations, no AAT protein is produced by the liver or any other lineage. Therefore, elevated COPD risk, without hepatotoxicity, is thought to result solely from low circulating AAT levels and diminished lung antiprotease activity.[65]

Further complicating matters, an increasing number of cell lineages are now recognized as expressing and possibly secreting AAT. While hepatocytes are the main source of circulating AAT, approximately 20% of the total is produced by other AAT-producing cell types—a list that includes monocytes and macrophages, in addition to epithelial cells of the lung, kidney, intestine, pancreas, thymus, adrenal gland, ovary, testis, and corneum.[66–73] The function of normal AAT in these lineages remains poorly understood, but a nascent literature implicates some of these alternate lineages as contributing to disease pathogenesis in AATD settings, for example, through activation of leukocytes.[74,75] Mobilization of bone marrow–derived hematopoietic populations also may be impacted as a result of AATD, since mouse models indicate that local bone marrow AAT functions to precisely regulate proteolytic release of tethered hematopoietic progenitors from their bone marrow niche.[76] It remains unclear, however, whether AAT activity in the bone marrow plays any role in AATD-related lung disease.

In summary, a broad published literature and clinical observations indicate that loss-of-function AAT mutations contribute to COPD pathogenesis in patients with AATD. For example, patients with rare null mutations are at significantly increased risk of developing COPD,[65] and mice engineered through gene editing to have deletions in AAT-encoding genes are significantly more susceptible to spontaneous (age-related) or smoke-induced emphysema.[77] More recent and still evolving literature also suggests that beyond simple loss of function, a subset of mutant AAT proteins, such as Z-AAT, likely also contributes to pathogenesis of COPD through toxic gain-of-function mutations involving protein misfolding, accumulating of polymers, and a variety of potential inflammatory and cytotoxic mechanisms.

CLINICAL MANIFESTATIONS

Patients with AATD-associated COPD present with symptoms that mirror those of the non-AATD population with COPD, including progressive dyspnea, hypoxemia, cough productive of sputum, and wheeze in the context of viral respiratory infection.[78] These similarities can make it challenging to distinguish the two populations. A typical patient with AATD experiences respiratory symptoms for years and seeks evaluation by multiple physicians prior to the diagnosis of AATD.[79,80] Early onset of symptoms in the fourth or fifth decade of life and disease out of proportion to exposure history are common historic characteristics of patients with AATD-associated COPD.[33,81] Features of the family history can be suggestive; a history revealing multiple family members with diagnoses of liver disease or COPD should increase suspicion.

Classically, patients with AATD-associated COPD manifest panlobular, lower-lobe emphysema, distinct from the upper-lobe-predominant, centrilobular emphysema typical of non-AATD COPD.[82,83] However, a variety of other clinical and radiographic presentations are common among patients with AATD-associated COPD. Case series reviewing radiographic patterns of PiZZ AATD-associated disease found that only 20% of plain chest x-rays[82] and 64% of chest CT scans[84] exhibited a basilar distribution of emphysema. Reliance on this classic radiographic presentation as the basis for testing to diagnose AATD is, therefore, insensitive and misses a large proportion of affected individuals.[85]

Aside from emphysema, bronchiectasis is the most common radiographic abnormality observed in PiZZ AATD. Reported frequency of clinically significant bronchiectasis is variable in the literature and ranges from as low as 2% of 1129 participants in the NHLBI registry to as high as 27% of 74 study participants whose lung disease was characterized by CT scan.[86] Although speculative, it seems likely that the increased clinical use of cross-sectional imaging, combined with increasing resolution capabilities of CT scanners, results in increased detection of bronchiectasis in PiZZ AATD.

Patients with PiZZ AATD commonly experience a progressive decline in FEV_1 that can occur at a rate faster than in individuals with non-AATD-associated COPD. Aggregate data from several large longitudinal cohort studies suggest a mean decline in FEV_1 of 41 to 86 mL/year among PiZZ former or never former smokers.[87–89] This decline was higher at 70 to 132 mL/year for current smokers in the same studies, consistent with exquisite sensitivity of PiZZ individuals to cigarette smoke injury. The value of smoking cessation in this population is supported by data from the Danish AAT Deficiency Registry, in which FEV_1 decline among those who quit smoking during the study period was measured at 58 mL/year compared with 132 mL/year among those who continued to smoke.[89] Predictors of accelerated FEV_1 decline among individuals with the PiZZ genotype include male sex, age range 30 to 44 years, active smoking, bronchodilator responsiveness, and mean predicted FEV_1 of 35% to 79%. Occupational or environmental exposure to pollutants also have been identified as risk factors for accelerated lung function decline.[90,91]

Aside from lung disease, the primary organ affected in AATD is the liver, where injury manifests either as jaundice among neonates, or as fibrosis in adults; a subset progress to cirrhotic liver disease. Neutrophilic panniculitis, seen in fewer than 1% of Pi*ZZ patients, can cause erythematous, tender subcutaneous nodules.[92] Other conditions associated with AATD include ANCA-associated vasculitis,[93] glomerulonephritis,[94] and chronic kidney disease.[95]

NATURAL HISTORY AND PROGNOSIS

Data from the Swedish National Registry provide insight into the longevity of individuals with PiZZ. Of 568 PiZZ never-smokers followed in this cohort, 93 had died at the time of analysis, with a median age of death of 76 years,[96] consistent with a relatively normal life expectancy. Within this never-smoking population, a higher mortality rate was observed among individuals in whom AATD was identified on the basis of respiratory symptoms than in those identified through screening, whose mortality rate was similar to that of the general population. Of these 93 participants, the underlying cause of death was identified as emphysema in 42 (45%), despite their status as never-smokers, whereas 26 (28%) died due to complications of liver disease. These findings differ to a degree from those observed in the NHLBI registry, in which 72% of deaths among 204 decedents, of whom only 16 were never-smokers, resulted from emphysema and associated respiratory failure compared to 10% from cirrhosis.[97] A third study of Swedish PiZZ adults identified respiratory failure as the primary cause of death in approximately 60% of 91 deaths, with liver disease accounting for 13%.[98] Mortality rates are not equally distributed among all those with PiZZ and are higher among smokers,[99] those with lower FEV_1,[97,100] and those identified on the basis of respiratory symptoms.[99]

Among patients with Pi*ZZ AATD, the risk of developing emphysema is quite high, although the precise risk is unknown. Of 42 NHLBI registry participants with lung tissue available for review following either autopsy or lung transplant, 100% were found to have emphysema.[101] In another study, 119 consecutive Pi*ZZ patients were evaluated in clinical practice; 17 (14%) did not have significant emphysema based on CT densitometry measurements,[84] consistent with the concept that a subset of Pi*ZZ individuals might not be afflicted. Notably, however, the mean age of these 17 individuals was only 44 years, leaving open the possibility that they eventually might develop disease.

The relative risk of Pi*Z heterozygotes, who represent a considerable percentage of the U.S. Caucasian population, has historically been uncertain. PI* SZ heterozygotes, in particular, were previously thought to be at increased risk of lung damage and were routinely offered augmentation therapy in the United States. Emerging data, however, suggest otherwise. Franciosi et al., in a prospective, observational, family-based study, reported no differences in either spirometry or symptom scores between non-index case, never-smoker individuals with Pi*SZ, and family member controls with Pi*MM or Pi*MS.[102] Zero of 19 Pi*SZ never-smokers in this study were found to have CT-based emphysema, suggesting that a single Z allele does not commonly cause disease in the absence of an environmental insult. Cigarette smoking was associated with worse spirometric outcomes in Pi*SZ ever-smokers relative to controls, although smoking cessation appeared to attenuate the accelerated decline. Intriguingly, emphysema in PI*SZ ever-smokers was noted to occur in an upper-lobe distribution, suggesting a pathophysiology distinct from Pi*ZZ AATD.

Additional data paint a similar picture for Pi*MZ heterozygotes. A family-based, prospective observational study by the investigators who authored the PI*SZ study described above found no differences between never-smoker, non-index Pi*MZs, and Pi*MM controls. Among ever-smokers matched for either high (>20 pack-years) or low (<20 pack-years) levels of smoke exposure, Pi*MZs had worse spirometric outcomes relative to controls.[103] Pi*MZ heterozygosity was associated with an adjusted odds ratio for COPD of 5.18. Additional data derived from 1693 non-Hispanic, white participants of the SPIROMICS cohort (all 40–80 years old with a ≥20-pack-year smoking history) demonstrated that white Pi*MZ heterozygotes had lower lung function, worse spirometric obstruction, and more CT-based emphysema than white Pi*MMs.[104]

In aggregate, the literature suggests that among ever-smokers, Pi*Z heterozygotes as a group are at increased risk of lung disease compared with Pi*MM individuals, consistent with a gene × environment interaction in which ongoing environmental exposure is necessary to induce disease.

DIAGNOSIS

Current clinical guidelines recommend one-time testing of all patients with persistent spirometric airflow obstruction, regardless of age or disease severity.[105–107] In addition to COPD, respiratory presentations that should prompt consideration of testing for AATD include emphysema in the absence of airflow obstruction and a family history of lung or liver disease.

Laboratory testing to diagnose AATD includes evaluation of levels of AAT protein in the serum, identification of AAT protein variants, or testing for variant gene sequences.

Serum AAT levels, most commonly measured by nephelometry, quantify the amount of AAT protein in the serum. A threshold level of 24.4 μM/L (110 mg/dL) distinguishes Pi*MM proteins from protein combinations including at least one S or Z with 73.4% sensitivity and 88.5% specificity.[108] However, because a variety of AAT allele combinations can result in serum AAT ranges with significant overlap, testing for serum AAT levels in isolation frequently does not allow one to infer the patient's phenotype/genotype. Since AAT is a known acute-phase reactant, with serum levels rising in the setting of systemic inflammation, interpretation of testing based solely on serum levels may be limited, particularly if these tests are performed in the setting of active infections or other inflammatory insults.[109,110]

Protein phenotyping to identify specific AAT variant proteins based on their migration pattern by isoelectric focusing can be a useful modality to diagnose or exclude AATD. Phenotyping can be used to identify rare variants that might be missed by PCR-based genotyping. However, the technique can be challenging to interpret in the context of null alleles or alleles that generate similar migration patterns (e.g., M-like alleles may produce a protein pattern similar to M protein).[111]

Detection of gene variants that encode deficient AAT proteins is an increasingly employed testing approach. Most commonly, targeted genotyping using PCR or RFLP analysis is performed to test for the normal M allele, together with a panel of common pathogenic variants. Rare alleles are generally not tested for and, therefore, are not detected using this approach. Gene sequencing, capable of identifying null alleles and other rare variants, can be a useful adjunct modality and is most commonly applied when the clinical presentation, reported AAT level, and genotype or phenotype are incongruent.[111]

Physician practice has lagged behind screening guidelines recommending the testing of all patients with obstructive lung disease[80,112] for AATD. This fact, together with the large size of the screenable population, suggests the need for an approach that maximizes cost effectiveness. A variety of testing algorithms have been evaluated with this goal in mind.[111] Common screening approaches outlined include testing of AAT levels, either alone or in combination with targeted genotyping. Protein phenotyping and DNA sequencing in these reports were subsequently applied if AAT levels were found to be low or if Z or S alleles were identified by genotyping.

MANAGEMENT

Medical management of AATD-related COPD is similar to management of other forms of COPD,[105] including a focus on avoidance of smoke exposure, treatment of hypoxemia, use of inhaled bronchodilators and inhaled glucocorticoids, referral for pulmonary rehabilitation, consideration of lung transplantation in those with severe COPD, and adherence to standard vaccine guidelines (Chapter 40). A significant difference from usual COPD management is consideration of genetic counseling and screening of family members for inherited AATD, as well as specific attention to the deficiency in circulating AAT in those with declining lung function.[19,105] An attempt to correct the hypothesized protease–antiprotease imbalance associated with deficient AAT levels and declining lung function forms the basis of the predominant treatment approach specific for AATD-associated COPD, so-called augmentation therapy. With augmentation therapy, levels of circulating AAT and antiprotease activities are augmented through regular intravenous infusions of normal (M) AAT protein purified from pooled human plasma specimens.[105,113]

Secreted AAT protein circulates with an average concentration of 150 to 300 mg/dL in blood plasma and a half-life of approximately 5 days.[20,37,114] In the most common deficiency state, PiZZ, circulating AAT levels are reduced to 10% to 15% of normal.[37] Several dosing approaches have been pursued in an effort to augment circulating levels in those with progressive loss of lung function due to AATD. Clinical trials have demonstrated variable results.[105,107,113,115–126]

Rather than normalizing circulating levels, the goal of augmentation therapy is to increase deficient levels to a concentration above a protective threshold. Those with treatment criteria, including severely deficient circulating AAT levels (serum levels <11 μmol/L or <57 mg/dL) and evidence of airflow obstruction, qualify for the U.S. Food and Drug Administration (FDA)-approved treatment regimen of weekly intravenous infusions of pooled human plasma-derived AAT at a dose of 60 mg/kg body weight.[105] The global initiative for COPD (GOLD) guidelines suggest patients with AATD with an FEV_1 of 35% to 65% of normal qualify for augmentation therapy,[127] whereas American Thoracic Society guidelines indicate that patients with AATD and an FEV_1 <80% are suitable candidates.[2] Some guidelines suggest evidence of emphysema on CT scan also should prompt consideration for augmentation therapy for AATD.[105]

Data in support of the clinical efficacy of augmentation therapy include randomized clinical trials, as well as longitudinal cohort follow-up studies, registry analyses, and meta-analyses focusing on outcomes such as AAT serum levels, lung function, and lung density on CT; mortality data are more limited.[105,107,113,115–126] For example, a systematic review and meta-analysis performed on data from trials performed prior to 2009 that included a cumulative total of 1509 patients concluded that augmentation therapy slowed FEV_1 decline in COPD; those with moderate airflow obstruction appeared to benefit most.[128]

In a randomized, double-blind, placebo-controlled trial of intravenous augmentation treatment in severe α1-antitrypsin deficiency (RAPID), rates of CT lung density decline were compared between 93 individuals on augmentation therapy versus 87 receiving placebo.[115] There was no statistically significant difference in the co-primary endpoint of CT density assessed at both FRC and TLC combined; however, there was significantly less annual decline in lung density in the treatment group based on CT densitometry measured at TLC, lending support to the conclusion that augmentation therapy slows the progression of emphysema in individuals with severe AATD.

In an open-label extension of the same trial (RAPID-OLE), the long-term efficacy and safety of augmentation therapy for emphysema caused by severe AATD was reported based on continued treatment of 76 participants from the original treatment group (early start group) and 64 participants from the placebo group (late start group with therapy delayed by 2 years compared with the early group).[129] The rate of lung density loss was less in the early-start treatment group. Furthermore, the rate of loss in the delayed treatment group slowed after the initiation of delayed therapy, although previously lost lung density was never recovered.

Support for the clinical efficacy of augmentation therapy is also provided by additional observational studies that suggested beneficial effects on survival and lung function. For example, a retrospective analysis of NHLBI's Alpha-1 Antitrypsin Deficiency Registry found that augmentation therapy improves survival in severely deficient patients with predicted FEV_1 between 10% and 60%.[118] Another study also found a significantly reduced rate of FEV_1 decline in a German cohort of former smokers with AATD receiving augmentation therapy compared with a Danish cohort of former smokers who did not receive therapy over a 3.2-year average follow-up period.[123] Finally, an additional study comparing rates of decline in FEV_1 in individuals followed longitudinally before and after they began augmentation therapy concluded that treatment significantly slowed the loss of FEV_1 in severe AATD.[130]

While the majority of studies finding beneficial efficacy involve the FDA-approved standard weekly intravenous dosing of 60 mg/kg pooled human plasma-derived AAT, alternative regimens, such as increased time intervals or increased dosing regimens, have been reported.[113,117,121] Based on a recent pilot study,[117] doubling the dose of augmentation therapy was found to be safe and to have potentially more anti-inflammatory effects; effects on clinical efficacy were indeterminate.

The optimal timing of initiating augmentation therapy also has been debated, with compelling arguments made for the use of CT scans to detect loss of lung function in patients with AATD earlier than would be discovered by physiologic testing or chest radiographs. Presumably, augmentation therapy would be started prior to significant and irretrievable loss of lung function.[113]

Whether augmentation therapy reduces COPD exacerbation events remains uncertain, based on mixed results from clinical trials, such as the RAPID trial,[115] which found no reduction in exacerbation rates; other studies found augmentation therapy was associated with reduced exacerbations.[131] Acute exacerbations of AATD-related COPD have been reported by some to differ from usual COPD exacerbations, as evidenced by greater frequency and duration of symptoms;[132] however, the extent and consequence of this is not known. Accordingly, conventional COPD treatments are used to treat exacerbations in patients with AATD, despite a paucity of evidence evaluating their efficacy.[132]

As with other forms of severe COPD, referral for lung transplant evaluation should be pursued in those with AATD-related severe and progressive COPD. Posttransplant survival has been studied in recipients with AATD compared to other forms of COPD[133] and was found to be similar, at least in the era since the use of lung allocation scores. In addition, a longitudinal study of patients with COPD following lung transplant[134] found that posttransplant FEV_1 over time, severity of acute rejection, and survival were similar overall in patients with AATD compared with AAT-replete patients. A notable exception were those who received double lung transplants, where FEV_1 declined faster in those with AATD, suggesting that further studies may be needed to compare outcomes in those with AATD receiving single versus double lung transplants.

Some studies have attempted to determine whether there is a beneficial role for augmentation therapy post–lung transplantation in AATD transplant recipients,[135,136] but efficacy of this approach remains uncertain. Since several decades typically elapse before loss of lung function is clinically significant in PiZZ AATD individuals, it remains speculative as to whether prolonged, transient, or episodic augmentation therapy post–lung transplantation is indicated to preserve function of the new graft in AATD transplant recipients. Thus, augmentation therapy is not currently routinely prescribed post–lung transplantation, since it is costly and lacks proven efficacy; furthermore, decisions regarding continuation versus cessation of augmentation therapy post-transplant are individualized and based on expert consultation, given the paucity of available data.

A number of emerging therapeutic options using novel technologies are being actively pursued for potential future use in patients with AATD.[137,138]

Inhaled augmentation therapy has been evaluated in several clinical trials, but clinical efficacy remains uncertain to date.[139–142]

Numerous gene therapy trials have been attempted to correct the loss of function associated with the most frequent mutations responsible for AATD.[143] In mouse models, adeno-associated virus (AAV)-based vectors for episomal overexpression of human cDNA encoding M-AAT have been successfully deployed by in vivo injection or infusion to liver hepatocytes or large muscle beds, resulting in prolonged in vivo secretion into the circulation from cells in the transfected target tissue.[144–148]

Additional proof-of-concept studies using intratracheally delivered local lentiviral overexpression in resident alveolar macrophages in mouse lungs have resulted in secretion of M-AAT into the lung epithelial lining fluid in vivo, ameliorating elastase-induced emphysema in mice.[32]

Despite the promise of gene therapy tests in animal models, in human clinical trials intramuscular injections of AAV vectors have resulted only in low circulating M-AAT levels, far below the therapeutic threshold thought to be needed for efficacy in patients.[144,149,150] Newer AAV-based vectors or RNA interfering molecules have been designed to knock down expression of mutant Z-AAT in liver hepatocytes while either overexpressing M-AAT cDNA from the same hepatocytes or replacing circulating M-AAT with intravenous augmentation therapy.[145] These emerging therapies are being studied in ongoing or planned clinical trials,[151] but to date, gene and RNAi based therapies for AATD remain experimental.

With the recent emergence of gene editing technologies, such as zinc finger nucleases, TALENs, or CRISPR, the possibility of correcting AAT gene mutations to normal in the endogenous AAT gene locus in patient-specific cells has been demonstrated.[137] Induced pluripotent stem cells have been generated from patients with AATD,[152–155] and successful gene editing of these cells from Z to M genotypes has been demonstrated, followed by in vitro differentiation of the corrected stem cells into hepatocytes for transplantation into animal models.[137] More recently, in vivo gene editing of AAT encoding loci in vivo in mouse livers has been successfully demonstrated.[156] These new and emerging proof-of-concept animal studies provide hope that innovative and potentially curative gene editing strategies to correct AATD in humans may be feasible in the future.[138]
